Meconic or Opianylic Stearate, $C^{46}H^{78}O^6 = \left.\begin{matrix}(C^{10}H^8)^{vi} \\ (C^{18}H^{35}O)^2\end{matrix}\right\}O^4$? *Stearate of Meconin. Stearate of Opianyl. Meconine stéarique.*—Formed by heating meconin with stearic acid to 100° for several hours; boiling the product with water, which takes up uncombined meconin; and removing the excess of stearic acid with lime and ether, as in the case of cetylic stearate. It is a neutral, white, solid mass, which melts easily, and solidifies very slowly. (Berthelot, Ann. Ch. Phys. [3] lvi. 75.)

Stearate of Orcin, $C^{25}H^{42}O^3 = \left.\begin{matrix}(C^7H^7)''' \\ C^{18}H^{35}O\end{matrix}\right\}O^2$?—When orcin (iv. 211) is heated with stearic acid to 200° in a sealed tube for some hours, a mixture is obtained from which water extracts the uncombined orcin. On separating the excess of stearic acid from the residue, by means of ether and slaked lime, the stearate of orcin remains dissolved in the ether, and may be purified by evaporation and solution in sulphide of carbon.

It is a slightly coloured, tasteless, neutral wax, which, when heated, evolves an odour of orcin and stearic acid, and volatilises. Combustible. Assumes a red colour with ammonia. Heated to 100° for some days, with moist calcic hydrate, it yields calcic stearate, and a substance soluble in water and alcohol; the latter body becomes coloured with ammonia, like orcin, but does not form crystals.

Stearate of orcin is insoluble in *water*, but easily soluble in *ether* and *bisulphide of carbon.* (Berthelot, Ann. Ch. Phys. [3] lvi. 74.)

STEARIDIC ACID. $C^{18}H^{34}O^2$. (Oudemanns, J. pr. Chem. lxxxix. 193.)—An acid isomeric with oleic acid, obtained by heating bromostearate of silver with water. It is an amorphous mass, resembling the soft animal fats; has a peculiar faint odour, melts at 35°, and distils unchanged. It dissolves in alcohol more easily than elaidic acid, and does not crystallise from the solution. With the alkalis it forms soaps, the alcoholic solutions of which give precipitates with metallic salts.

STEARINS. *Glyceric Stearates. Stearates of Glyceryl.*—Stearic ethers formed from glycerin, $(C^3H^5)'''.H^3.O^3$, by the replacement of $\frac{1}{3}$, $\frac{2}{3}$, or the whole of the typic hydrogen by the monatomic radicle stearyl. They may all be produced artificially, by heating stearic acid with glycerin; tristearin is also a constituent of most of the more solid fats of the animal and vegetable organisms.

MONOSTEARIN, $C^{21}H^{42}O^4 = \left.\begin{matrix}(C^3H^5)''' \\ C^{18}H^{35}O \\ H^2\end{matrix}\right\}O^3$. (Berthelot, Ann. Ch. Phys. [3] xli. 221.)—Prepared by heating a mixture of equal parts of stearic acid and glycerin to 200° in a sealed tube for 36 hours, then leaving it to cool. On opening the tube, there is found floating on the excess of glycerin, a solid layer, containing monostearin and uncombined stearic acid. This layer is melted, mixed with a small quantity of ether, then with slaked lime, and heated to 130° for a quarter of an hour, whereby the stearic acid is made to unite with lime. The monostearin is separated by exhaustion with ether and spontaneous evaporation.

Monostearin forms very small white needles, aggregated in roundish grains, melting at 61°, and solidifying at 60° to a hard, friable, waxy mass. It is neutral in alcoholic solution; volatilises without decomposition in a vacuum. Very slightly soluble in cold ether.

Monostearin decomposes when *heated* in a tube, with formation of acrolein. When it is heated on platinum-foil, a portion evaporates, while the rest turns yellow, and *burns* with a white very luminous flame. Heated with fuming *hydrochloric acid* to 100° in a sealed tube for 110 hours, it is almost wholly resolved into glycerin and stearic acid. A trace of a neutral chlorinated liquid is formed at the same time. Monostearin is decomposed by heating for some hours to 100° with moist *protoxide of lead*, yielding nearly 25 per cent. glycerin (calc. 25·56 p. c. $C^3H^8O^3$). It is not decomposed by heating to 100° for 26 hours with alcoholic *acetic acid.*

DISTEARIN, $C^{39}H^{76}O^5 = \left.\begin{matrix}(C^3H^5)''' \\ (C^{18}H^{35}O)^2 \\ H\end{matrix}\right\}O^3$. (Berthelot, *loc. cit.*)—Obtained: 1. By heating monostearin with 3 pts. of stearic acid to 260° for three hours.—2. By heating stearic acid with an equal quantity of glycerin to 100° for 114 hours; or to 275° for seven hours.—3. By heating the stearin of natural fats with excess of glycerin to 200° for 22 hours. Separated like monostearin. It forms white microscopic laminæ, which melt at 58°, and solidify, like monostearin, at 55°. Obtained in needles by spontaneous evaporation from ether. Neutral; decomposible by moist oxide of lead at 100°.

TRISTEARIN, $C^{57}H^{110}O^6 = \left.\begin{matrix}(C^3H^5)''' \\ (C^{18}H^{35}O)^3\end{matrix}\right\}O^3$. *Stéarine* or *Substance grasse* of Chevreul. *Suif absolu* of Braconnot. *Talgfett.* (Chevreul, *Recherches sur les corps gras.*—Braconnot, Ann. Chim. xciii. 225.—A. Vogel, *ibid.* lviii. 154.—Lecanu, Ann. Ch. Pharm. xii. 25.—Liebig and Pelouze, *ibid.* xix. 264.—Redtenbacher, *ibid.* xxxv. 195.—Francis, *ibid.* xlii. 254.—Arzbächer, *ibid.* lxx. 239.—Heintz, see Memoirs already cited (iii. 1069).—Duffy, Chem. Soc. Qu. J. v. 197, 303.—Berthelot, Ann. Ch. Phys. [3] xli. 216, 432; xlvii. 297; also *Chimie organique*, ii. 52 *et. seq.*—H. Kopp, Ann. Ch. Pharm. xciii. 194.—Bouis, Compt. rend. xlv. 35; Jahresb. 1857, p. 357.—Bouis and Pimentel, Compt. rend. xliv. 1355; Jahresb. 1857, p. 356.—Gm. xvii. 118.)—This compound was first prepared, though in an impure state, by Chevreul; purer by Braconnot. Berthelot's researches have demonstrated the identity of the stearin of natural fats with tristearin. It occurs in many fats, especially in the solid tallows and lards of the animal kingdom (p. 413).—The *stearophanin* of Francis is also resolved by saponification into stearic acid and glycerin, but differs widely from tristearin in its melting-point (p. 426).

Preparation.—Monostearin is heated for three hours with 15 to 20 times its weight of stearic acid to 270° in a sealed tube, and the product is purified in the same manner as monostearin (Berthelot). Heintz (Ann. Ch. Pharm. xcii. 300) heats stearic acid with glycerin to 200° for 24 hours, in a sealed tube filled with carbonic anhydride; the tube is then opened; the glycerin decanted; the free stearic acid removed by treatment with ether and lime; and the mass of glycerides dissolved out by boiling ether. The mixture thus obtained already contains monostearin, and may be converted into tristearin, by heating to 270° for eight hours with a large excess of stearic acid; the uncombined stearic acid may then be removed as before, and the tristearin dissolved out by hot ether.

Chevreul's stearin is obtained by dissolving mutton-suet in boiling alcohol, and recrystallising the fat, which separates out, till the melting-point becomes constant. Purer than this is Braconnot's stearin, obtained by repeatedly melting mutton-suet with oil of turpentine: still purer is that of Lecanu, who melts mutton-suet in the water-bath, adds an equal quantity of ether, stirring all the while; presses the fat when cold, and recrystallises it till the melting-point rises to 62°. Above this temperature the melting-point does not appear to be raised by repeated crystallisation from small quantities of ether; but it may still be raised by repeated crystallisation from 10 to 100 times its volume of ether. After 32 crystallisations thus performed, the melting-point rises to 69·7° (Duffy); but the fat thus treated is still a mixture of tristearin and tripalmitin (Heintz), as shown by its melting-point, and by that of the acids (= 66·5°) separated from it by saponification. The melting-points of the fatty acids obtained by saponifying different varieties of stearin, are as follows:—

Chevreul's stearin,	solidifying at	44°,	yields fatty acids melting at	53°
Braconnot's	,, ,,	61°	,, ,,	62·3°
Lecanu's	,, ,,	62°	,, ,,	66°
Liebig and Pelouze's	,, ,,	60—62°	,, ,,	64—65°
Heintz's	,, ,,	62°	,, ,,	64°

From brindonia-tallow, according to Bouis and Pimentel, pure tristearin may be separated by recrystallisation, yielding by saponification an acid having the melting-point of stearic acid.

Properties.—Tristearin forms white, pearly, shining nodules, together with very fine needles (Bouis and Pimentel); small pearly laminæ, resembling spermaceti or stearic acid (Lecanu). Inodorous; tasteless; neutral. Volatile without decomposition in a vacuum (Chevreul). A non-conductor of electricity. (Rousseau, J. Pharm. ix. 587.)

The stearin of the natural fats, as well as that artificially prepared, exhibits two (or three) different melting-points, since when heated it first becomes fluid and transparent; afterwards, when further heated, again solid and opaque; and, lastly, a second time fluid (Heintz, Duffy, Kopp). It expands when heated, but on first melting undergoes a contraction of about 2¼ per cent.; near its second melting-point it again expands, and at the moment of melting increases about 5 per cent. in volume (Kopp). Tallow-stearin melts first at 51—52°, and the second time at 62°; at 58° it is quite opaque (Heintz). With purer or less pure tallow-stearin somewhat different temperatures are observed.

This phenomenon is not produced by the splitting-up of tristearin into distearin and free acid, inasmuch as alcohol of 56° takes up no stearic acid therefrom (Heintz). According to Duffy, it is to be explained by the hypothesis of three modifications of stearin. (GLYCERIDES, ii. 879.)

α. *First modification.*—Produced when stearin melting at 69·7° is heated to 73·7° or higher, and then cooled, when it solidifies only at 51·7°. It is solid below 52°, but melts at that temperature, passing into the second modification. Shining nodules of specific gravity 0·9867 at 15°, 0·9600 at 51·5° (Duffy), 0·987 at 10°. (H. Kopp.)

β. *Second modification.*—Produced by heating stearin of the first modification to 52°, or a few degrees higher, for some time, until the fused mass has again become solid. Lamellar, melting at 64·2°. Specific gravity = 1·0101 at 15°. (Duffy.)

γ. *Third modification.*—Forms the crystals of stearin which separate from ether. It is also formed when stearin is heated to 65° or 66°, after which it solidifies slowly, at 62—63°, to an opaque, friable, highly crystalline mass, and melts again only at 69·7°. Specific gravity at 15° = 1·0179; at 51·5° = 1·009; at 65·5° = 0·9931; at 68·2° = 0·9746. (Duffy.)

The specific gravity of melted stearin at 65·5° is 0·9245 (Duffy). Duffy's second modification is not obtained from pure stearin, which, however, contains the first and third modifications, even after several recrystallisations; it is, therefore, not to be regarded as pure stearin (Heintz). Tallow-stearin, melting at 60°, possesses at 50°, in the first modification, a volume = 1·031, and after passing into the second modification a volume = 1·008, the volume at 0° being = 1; its volume increases to 1·076 at the melting-point, and on melting to 1·127. (H. Kopp.)

Melted stearin solidifies on cooling to a very indistinctly crystalline mass (Heintz); to a blistered mass, which exhibits transparent and dead-white portions (Bouis and Pimentel). The temperature of melted stearin falls several degrees below the solidifying-point before the mass becomes solid, but rises again during solidification to 44° (Chevreul), 54° (Lecanu); it forms a semitransparent mass, having an even surface, the central part of which ultimately solidifies in radiated crystals. (Chevreul.)

The percentage composition of tristearin is as follows:—

		Calculated.		Chevreul.	Lecanu.	Liebig and Pelouze.
C^{57}	. . .	684	76·85	77·7	76·91	74·52 to 76·09
H^{110}	. . .	110	12·36	11·8	12·39	12·39 „ 12·32
O^6	. . .	96	10·79	10·5	10·70	
$C^{57}H^{110}O^6$		890	100·00	100·00	100·00	

		Arzbächer.	Duffy.			Heintz.		Berthelot.
			a.	*b.*	*c.*	*a.*	*b.*	
C	. . .	76·51	77·12	76·32	76·87	76·74	76·50	75·8
H	. . .	12·28	12·30	12·32	12·20	12·42	12·41	12·4

		100·00	100·00	100·00	100·00	100·00	100·00	100·0

Berthelot analysed artificially-prepared tristearin. The stearin of beef-suet contains, according to Arzbächer, 78·74 per cent. C; but Heintz (*b*) and Duffy (*c*) found it to have the same composition as that from mutton-suet. Duffy examined stearin melting (*a*) at 62·5° and (*b*) at 69·7°. The formula of tristearin was deduced by Berthelot from the combining proportions of glycerin with acids (ETHERS, ii. 519; GLYCERIDES, ii. 877), Duffy having previously shown that in the formation of 1 at. stearic acid from stearin 1 at. carbon is eliminated. Berthelot's formula alone explains how, in the saponification of stearin, the undermentioned amounts of glycerin and acid are produced.

Stearin is not perceptibly soluble in *alcohol* of 30° B., nor even in alcohol of 97 per cent., in the cold; it dissolves abundantly in hot alcohol, and separates in flocks on cooling (Lecanu). 100 pts. of boiling alcohol, of specific gravity 0·795, dissolve 15·04 to 16·07 pts. of Chevreul's tallow-fat from mutton-suet; 15·48 pts, of that from beef-suet; 18·25 from hog's-lard; and 36 from goose-fat. 100 pts. of boiling alcohol of specific gravity 0·805, dissolve 6·63 pts. of tallow-fat; 100 pts. of specific gravity 0·822 dissolve 1·45 of the tallow-fat of butter, which is deposited almost entirely on cooling (Chevreul). Stearin precipitated from an alcoholic solution retains alcohol even after prolonged fusion. (Saussure.)

Stearin dissolves very freely in boiling *ether*, which retains $\frac{1}{225}$th on cooling (Lecanu). It dissolves in hot *acetone* more freely than in cold, and is precipitated on cooling, or by the addition of water (Chenevix). It is easily soluble in *volatile oils*, and mixes with melted *camphor*, and with *drying* and *oil-fat*. A solution of 1 pt. of stearin in 160 pts. almond-oil deposits white flocks of stearin when mixed with 170 pts. of ether; it is therefore not rendered more soluble in ether by admixture with a fatty oil. (Lecanu.)

Decompositions.—1. Stearin yields by dry distillation the products of decomposition of stearic acid and of glycerin—viz., carbonic anhydride, gaseous and liquid hydrocarbons, acrolein, acetic acid, water, and free carbon; part of it, however, passes over unaltered. The hydrocarbons boil between 190° and 245°, and are polymeric with ethylene (Gerhardt).—2. Pure stearin does not alter by exposure to the air, and impure stearin probably turns rancid only when it contains olein or drying oil. (Chevreul.)

3. Tristearin is easily saponified by *alkalis*, *lead-oxide*, and other bases, yielding stearic acid (melting at 70°) and glycerin, 1 at. of pure tristearin yielding 3 at. stearic acid, and 1 at. glycerin:

$$\left.\begin{matrix}(C^3H^5)'''\\(C^{18}H^{35}O)^3\end{matrix}\right\}O^3 + 3H^2O = 3\left(\left.\begin{matrix}C^{18}H^{35}O\\H\end{matrix}\right\}O\right) + \left.\begin{matrix}(C^3H^5)'''\\H^3\end{matrix}\right\}O^3.$$

Pure tristearin from *Brindonia indica* yielded 95·7 per cent. stearic acid; artificial stearin yielded 95·5 per cent. stearic acid, and 10·2 glycerin dried in vacuo (Heintz): the quantities required by calculation are 95·7 stearic acid, and 10·3 glycerin; the purity of the substance and the correctness of the formula are therefore fully proved.

4. A solution of *sodium-ethylate* in absolute alcohol decomposes stearin when heated, yielding sodic and ethylic stearate, together with glycerin: in like manner, with *sodium-amylate*, it yields amylic stearate (p. 421).

5. A solution of dry *ammonia-gas* in absolute alcohol does not act on stearin, even after prolonged boiling.

6. *Bromine* and *chlorine* decompose stearin, forming substitution-products, which are softer and more soluble than stearin itself. The chlorine-compound contains 21·2 per cent. chlorine; the bromine-compound 35·9 bromine. (Lefort, J. Pharm. [3], xxv. 24.)

7. Stearin mixed with *pancreatic juice* yields an emulsion in which the whole of the stearin is resolved into stearic acid and glycerin, on standing for a day or two at a temperature of 30—40°. (Bernard; Berthelot.)

STEAROCHLORHYDRIN. $C^{21}H^{41}ClO^{3} = \left.\begin{matrix}(C^{3}H^{5})'''\\ C^{18}H^{35}O\\ H\end{matrix}\right\}\begin{matrix}Cl\\ O^{2}\end{matrix}$.—Produced by passing hydrochloric acid gas for some time into a mixture of stearic acid and glycerin heated to 100°. After being left to settle, then washed with sodic carbonate, and repeatedly dissolved in ether, it forms a solid mass melting at 28°. (Berthelot.)

STEAROGLUCOSE. *Glucic Stearate* (p. 421). $C^{42}H^{78}O^{7} = 2C^{18}H^{36}O^{2} + C^{6}H^{12}O^{6} - 3H^{2}O$.—A saccharide produced by heating stearin with certain kinds of sugar. To prepare it, a mixture of stearin and anhydrous glucose is heated to 120° for fifty or sixty hours, and the product is purified by ether and lime, like monostearin (p. 422). Cane-sugar and trehalose also yield the same compound; when trehalose is employed, the mixture may be heated to 180°. Small quantities are obtained likewise from stearin and starch at 180°, and from stearin and woody fibre at 200°.

It forms microscopic fine granules, or a white fusible mass resembling stearin. It is neutral. It assumes with oil of vitriol a reddish colour, quickly changing to violet and black. It reduces *potassio-cupric tartrate*; is decomposed by treatment with warm alcoholic *hydrochloric acid*, with formation of glucose, humus-substances, and ethylic stearate. (Berthelot, Ann. Ch. Phys. [3] lx. 95.)

STEAROCONOTE (from στέας, tallow; and κόνις, powder).—The name applied by Couerbe to a fatty substance, which he obtained, together with others, from the brain, by exhaustion with ether and then with boiling alcohol. It is described as a yellow-brown pulverulent fat, insoluble both in alcohol and ether, unless fixed oils are also present, in which case it dissolves in ether; hence it is dissolved out of the brain by ether, and on evaporating the solution to dryness, and exhausting with alcohol, cephalote (i. 822) dissolves, and stearoconote remains behind. According to Couerbe, it contains both sulphur and phosphorus. According to Frémy, however, it is not a definite substance, but a mixture of brain-albumin, oleophosphates, and cerebric acid; and according to the more recent investigations of v. Bibra and W. Müller, all the substances found in the brain by Couerbe and Frémy are chiefly mixtures of different fatty acids. The presence of sulphur and phosphorus in these fats appears very doubtful. (See Nervous Tissue, iii. 32; also Handw. d. Chem. viii. 226).

STEAROLAURETIN. The name applied by Grosourdi (J. Chim. Méd. [3] vii. 257) to a solid fat, which separates, on standing at + 10°, from the oil obtained by warm pressure from the pericarp of bay-berries (the fruit of *Laurus nobilis*). It forms warty masses, but has not been further examined.

STEAROLAURIN. Grosourdi's name for a fat deposited, on standing at + 10° to + 4°, from the oil obtained by warm pressure from the shelled seeds (cotyledons) of the fruit of *Laurus nobilis*. It forms a yellowish-white mass.

STEARONE. $C^{35}H^{70}O = C^{18}H^{35}O.C^{17}H^{35}$. (Bussy, Ann. Ch. Pharm. ix. 269.—Redtenbacher, *ibid.* xxxv. 57.—Varrentrapp, *ibid.* xxxv. 80.—Rowney, Chem. Soc. Qu. J. vi. 97.—Heintz, Pogg. Ann. xciv. 272; xcvi. 65.)—This body, the ketone of stearic acid, is produced by the dry distillation of stearic acid, or more abundantly by that of calcic or plumbic stearate. To purify it, the solid distillate is boiled with water, the finely pulverised residue is heated with ether to the boiling-point, and after cooling, collected on a filter and again treated with ether: pure stearine then remains behind. (Heintz.)

The substance described as margarone by Bussy, Redtenbacher, and Varrentrapp, and obtained by the distillation of impure stearic acid, was a mixture of stearone and palmitone; Rowney's stearone (p. 412) is doubtless also impure stearone.

Pure stearone forms delicate, pearly, microscopic laminæ very strongly electric. It is slightly soluble in boiling *alcohol*, and separates almost entirely on cooling; nearly insoluble in cold and very slightly soluble in boiling *ether*. It melts at 87·8°. (Heintz.)

Bromostearones.—Melted stearone treated with excess of bromine, gives off hydrobromic acid, and is converted into a red oily liquid, which solidifies on agitation with water, and when washed with aqueous ammonia and then with cold alcohol, and repeatedly crystallised from ether, yields dibromostearone, $C^{35}H^{68}Br^{2}O$, in laminar crystals which melt at 72°, and are moderately soluble in cold ether.

By the further action of bromine on stearone, a very fusible substance is formed probably a more highly brominated product.

STEAROPHANIC ACID. Stearic acid from cocculus-grains (p. 413).

STEAROPHANIN. The glyceride obtained from cocculus-grains. It agrees with tristearin in nearly all its properties, but was found by Francis to melt at a much lower temperature, viz. at 35° to 36°, doubtless in consequence of the admixture of fats of lower melting-point.

STEAROPTENES. The more solid constituents of essential oils. (See OILS, iv. 184.)

STEAROYL. Weltzien's name for the hydrocarbon $C^{18}H^{35}$, which may be supposed to exist in stearone, regarding it as $(C^{18}H^{35})^{2}O$.

STEARYL. $C^{18}H^{35}O$.—The radicle of stearic acid, &c.

STEATIN. Syn. with CEREBROTE (i. 830).

STEATITE. A mineralogical term used synonymously, sometimes with SOAPSTONE (p. 324), sometimes with TALC (*q.v.*).

STEATOÏD. A name applied to serpentine occurring in pseudomorphs at Snarum in Norway.

STEEL. *Acier. Stahl.*—The particular kind of metallic iron to which this name is applied possesses characters which render it to some extent intermediate between cast-iron and what is commonly known as malleable iron, while it is distinguished from both by the capability of acquiring very considerable hardness when heated and suddenly cooled, and of becoming soft again when heated and allowed to cool slowly. Steel is generally hardened by plunging it while hot into water, oil, mercury, or some other liquid. The greater the reduction of temperature, and the more rapidly it takes place, the greater is the degree of hardness produced. Steel raised to a white heat and then immersed in cold mercury, acquires a degree of hardness nearly equal to that of the hardest white cast-iron, or even of diamond. It is then also extremely brittle. By heating such hardened steel again, and allowing it to cool gradually, it becomes softer and less brittle. It is in virtue of this capability, which is one of the most distinctive characters of steel, that various degrees of hardness may be communicated to it, by regulating the temperature to which the hardened metal is heated before being allowed to cool gradually, or to which the soft metal is heated before being suddenly cooled. Steel tools and instruments are made and finished while the metal is in the soft state, and the requisite degree of hardness is given to them as above described. This operation is called *tempering* (*tremper*; *anlassen*). The degrees to which the metal requires to be heated, in order to acquire different degrees of hardness, are indicated by the colours which it assumes when heated, and which are due to the formation of an extremely thin film of oxide on the surface. They are as follows:—

Temperature.	*Colour.*	
220°C.	Faint yellow	for surgical instruments.
230	Straw-yellow	for razors, penknives, &c.
255	Brownish-yellow	for scissors, hard chisels.
265	Purple spots	for axes, knives.
277	Purple	for table-knives.
288	Pale-blue	for sword-blades, watch-springs.
293	Dark-blue	for fine saws, boring tools.
316	Blackish-blue	for hand-saws.

The distinction between steel and cast-iron or malleable iron is not by any means absolute, but consists rather in the degree to which considerable hardness, or the capability of acquiring that character, is associated with tenacity and malleability. Accordingly, there are numerous varieties of steel approximating more or less to cast-iron or to malleable iron. Together with such differences in the nature and qualities of steel, it has generally been found that there are corresponding differences in the amount of carbon the metal contains; the closer the approximation to malleable iron, the smaller is the amount of carbon in the metal, and the reverse. When the amount of carbon is less than about 0·65 per cent., the capability of being tempered is either wanting or very slight. When it amounts to 1·75 per cent., the metal is capable of being made very hard, but its tenacity is much reduced. The capability of being hardened and tempered is combined with the maximum tenacity when the carbon amounts to about 1·5 per cent. The opinion that these characters of steel are intimately connected with the amount of carbon it contains has long been entertained; but it is still uncertain in what manner these facts are related.

Among the various substances which are frequently present in metallic iron as impurities, those which appear to be most prejudicial to the quality of steel are *sulphur* and *phosphorus*.

The fact that certain iron-ores containing *manganese* are especially suitable for the production of steel, has given rise to the opinion that this metal was a necessary constituent of good steel; but it is rarely, if ever, the case that steel contains manganese, and whatever beneficial influence the presence of this metal may exercise in the manufacture of steel, would appear to be of a totally different nature.

The presence of *chromium*, *nickel*, or *rhodium* in steel is said to improve its quality, but the data on which the opinion is founded are somewhat insufficient.

The results of observations on the influence of *silver* upon steel are discordant. *Tungsten* and *titanium* have been stated to improve the quality of steel, but further experience is requisite in regard to this question.

The presence in steel of a minute amount of *nitrogen* as a necessary constituent has been alleged by **Frémy**; but **Marchand**, **Rammelsberg**, and **Boussingault** have failed to detect, by their analyses, any greater indications of nitrogen than might be fairly referred to accidental sources. **Caron** infers, from his observations, that if steel contains nitrogen, it is not as an essential constituent. Similar results have been obtained by **Stuart** and **Baker**. (Chem. Soc. J. [2], ii. 390.)

The colour of steel is greyish-white, sometimes almost pure white, and the hardened metal is somewhat whiter than the soft metal. The lustre of steel is not remarkably different from that of malleable iron. The surfaces of fracture present a very fine granular texture, very uniform, and without any of the fibre characteristic of good malleable iron. The fracture of hardened steel presents a remarkably close fine-grained texture. Steel is always harder than malleable iron, but it is never so hard as that kind of white cast-iron known as "Spiegeleisen." The tenacity of steel is greater than of either cast-iron or malleable iron, or indeed of any other metal. According to the experiments of **Musschenbroek** and **Rennie**, it is at least twice as great as that of malleable iron. It is slightly reduced by hardening, but by annealing the metal its tenacity is rendered even greater than that of the unhardened steel.

Tenacity or Tensile Strength of Steel.

Kind of steel.	Lengthwise in pounds.	Crosswise per square inch	Ultimate extension		Authority.
			length	cross.

	75,594	69,082	·198	·196	

See **Kirkaldy**, Trans. Institut. Engineers in Scotland, 1858–9; and *Tensile Strength of Wrought Iron and Steel* (London, 1862); also **Fairbairn**, Brit. Assoc. Report, 1856.

The malleability of soft steel at the ordinary atmospheric temperature is even less than that of hard cast-iron. Hardened steel is very brittle, and will not bear working with the hammer. The malleability of steel is, however, considerably increased when the metal is heated.

The specific gravity of soft steel varies between 7·6224 and 7·8131 (**Karsten**). It is somewhat reduced by hardening the metal; viz. from 7·75 to 7·55 (**Rinman**), 7·79 to 7·67 (**Pearson**).

The specific heat of steel is 0·11848 (**Regnault**). Its linear expansion, when heated from 0° to 100° C., is scarcely greater than that of malleable iron, but less than that of cast-iron (**Davy**). By heating from summer heat to red heat, a steel bar lengthens about $\frac{6}{560}$, malleable iron $\frac{4}{560}$, and cast-iron $\frac{7}{560}$; by heating to whiteness, steel lengthens $\frac{10}{560}$, malleable iron $\frac{7}{560}$, and cast-iron $\frac{12}{560}$. (**Rinman**.)

When steel is heated to whiteness, it becomes soft like malleable iron, under the same condition, and is then capable of being wrought and welded not only to steel, but also to malleable iron. It welds at a lower temperature than iron does.

The melting-point of steel is between that of cast-iron and that of malleable iron, and is probably about 1800° C. The fusibility of steel is, however, influenced by the amount of carbon it contains.

Steel is less susceptible of magnetic induction than pure iron; but it far exceeds iron in the capability of becoming permanently magnetic, for which reason it is generally used for making magnets (iii. 761).

Steel is oxidised much less readily than malleable iron by exposure to the atmosphere at the ordinary temperature, especially when it is polished and clean. When gradually heated in contact with atmospheric air, it acquires, as the temperature rises, a succession of colours at the surface, from faint yellow to blackish-blue. At 360° C. all colour disappears; but if the heat be raised still further, the colours reappear in the same order, more faintly than at first. The coloration is due to an incipient oxidation, and the succession of colours is caused by the increasing thickness of the film of oxide, as in Newton's rings it is caused by the unequal thickness of a layer of air.

Hardened steel is dissolved by acids less readily than soft steel. With dilute hydrochloric or sulphuric acids, soft steel gives a larger amount of the black graphitic substance which is attracted by the magnet, than malleable iron does. By the continued action of the acid, this substance is converted into a carbonaceous mass, which burns without leaving any residue, as in the case of malleable and cast-iron. With dilute nitric acid this substance is not separated from soft steel. Concentrated hydrochloric acid dissolves soft steel completely without residue.

Manufacture of Steel.

By smelting very rich and pure iron-ores with charcoal in a bloomery, much in the same way as that described under the head of IRON (iii. 344), steel, or a kind of steely iron, may be produced direct from the ore; but this method of manufacture, though much practised formerly, and still followed to some extent at a few places, has long been superseded by others. Steel is now generally produced indirectly, either by carbonising bars of malleable iron, or by partially decarburising cast-iron. The steel produced by the former method is called *Cement Steel* (*acier de cémentation; Brennstahl*); that produced by the latter method is called *Natural Steel* (*acier de forge; Rohstahl*), when the decarburation is effected in a finery hearth or forge similar to that used in the manufacture of malleable iron (see iii. 345). But cast-iron is also converted into steel by puddling, and by the direct action of atmospheric air on the melted metal, according to the method lately introduced by Bessemer.

Fig. 777.

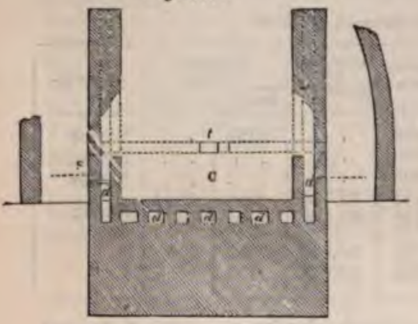

Fig. 778.

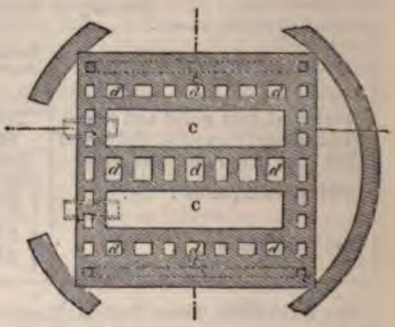

Fig. 779.

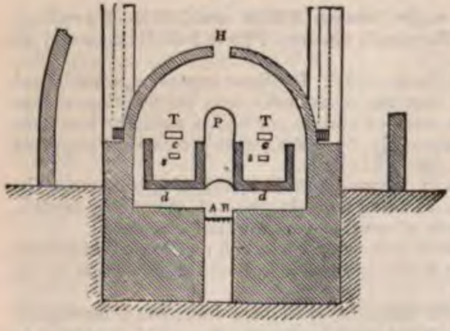

1. CARBURATION METHOD: *Cémentation.*—This method of producing steel is based upon the fact that, when malleable iron is heated in contact with charcoal or other carbonaceous substances, and without access of air, to a temperature somewhat below its melting-point, carbon is absorbed by the metal.

The iron used for producing steel in this way must be of the best quality, and free from the impurities which have already been mentioned as prejudicial to steel (see *ante*, p. 426). The *cement* or carburising material used is coarsely-powdered charcoal, sometimes mixed with horn-shavings, ferrocyanides, and similar substances.

The furnaces in which the operation is conducted, somewhat resemble glass-house furnaces, as shown by *figs.* 777, 778, and 779, and they are arranged so that a uniform temperature may be kept up in them for several days. The bars of iron are placed in the rectangular chambers C C, and imbedded in charcoal-powder. These *pots* (*caisses; Kasten*) are then closed with a layer of loam, and the heat gradually raised, during some three or four days, to the maximum degree, which is maintained two or three days longer, the progress of the operation being ascertained by drawing out a bar and testing it. When the conversion of the iron into steel is completed, the furnace is allowed to cool gradually, and the charge is taken out. The surfaces of the bars of steel are covered with numerous small blisters, for which reason it is called *Blister Steel* (*acier poule; Blasenstahl*).

The mode in which steel is produced by cementation is still but imperfectly understood. For a long time it was supposed that the iron combined directly with carbon in the solid state; but it is more probable that the conversion of the iron into steel is effected indirectly by gaseous carbon-compounds, such as carbonic oxide and hydrocarbons. At a sufficiently high temperature, carbonic oxide yields part of its carbon to iron, and is converted into carbonic acid, while marsh-gas and olefiant gas are decomposed in like manner by iron, yielding carburetted iron and hydrogen. Some years ago, Macintosh proposed to manufacture steel by heating bar-iron in an atmosphere of coal-gas; and, though this method has not come into use, good steel can be made by it, if the gas used for the purpose be free from sulphur. Animal charcoal, horn-shavings, ferrocyanides, &c., are sometimes mixed with the charcoal-powder used in producing steel by cementation, and these substances facilitate the conversion, chiefly by yielding gaseous carbon-compounds.

2. DECARBURATION METHODS.—In all these methods the abstraction of carbon from the cast-iron, and its conversion into steel, is effected by the oxidising action of atmospheric air, either directly or indirectly, through the medium of slags containing ferrous oxide, and the nature of the product depends very much upon the extent to which that action is allowed to continue.

a. Natural Steel is produced by melting white cast-iron (*Spiegeleisen*), or easily fusible grey cast-iron, with charcoal, in a finery-hearth or forge, and under a blast of air. This method of manufacture is restricted to countries where very pure cast-iron is obtained, by smelting spathic and magnetic iron-ores with charcoal. It is practised in Westphalia, Silesia, Styria, Carinthia, Sweden, and some other places, with a variety of modifications, arising chiefly from the nature of the cast-iron to be worked, or from other local circumstances. The process, however, is essentially the same in all cases, and differs from that already described as taking place in the conversion of cast-iron into malleable iron (iii. 345), only in so far that the decarburation is not carried to such an extent as in the manufacture of malleable iron.

β. Puddled Steel is produced, from such kinds of cast-iron as do not contain substances prejudicial to steel, by operating upon it, in reverberatory furnaces, in the same way that cast-iron is converted into malleable iron, but so as to effect only a less advanced decarburation.

γ. Bessemer Steel is produced by forcing atmospheric air into melted cast-iron. The carbon, being oxidised more readily than the iron, is converted into carbonic oxide, which escapes in a sufficiently heated state to take fire on coming in contact with atmospheric air. Considerable heat is generated by the oxidation of the carbon and iron, so that the temperature is kept above the melting-point of steel during the whole of the operation. When the decarburation has been carried far enough, the current of air is stopped, and a small quantity of white pig-iron, containing a large amount of manganese, is dropped into the liquid metal. This serves to facilitate the separation of any gas retained within the melted metal, which, after a few minutes' rest, is run into ingot-moulds.

The bars of blister-steel obtained by cementation are never uniform throughout their entire mass, the exterior portion being more highly carburised than the interior, and this difference is not always the same at all parts of the bars. To render them homogeneous, they are drawn out, while hot, under hammers or rollers, into thin bars, and a number of these bars are laid together in a *faggot* (*trousse; Garbe*), heated to a welding heat, and then hammered or rolled, this operation being repeated several times. The steel is then called *Shear Steel* (*acier raffiné; Gerbstahl*). The same operation has to be performed with the rough bars of natural steel, in order to render their texture uniform.

Steel, produced by either method, may be rendered still more homogeneous by melting it in a crucible, and running it into bars or ingots, *Cast Steel* (*acier fondu; Gussstahl*). Bessemer-steel, from the mode in which it is produced, is always of this kind.

The manufacture of cast-steel for various purposes has long been a very important branch of industry, and it is certain to become still more so, now that the new method of producing steel, introduced by Bessemer, admits of its being dealt with in very much larger masses than heretofore. It is, however, essential to the adoption of this method, to have at command cast-iron of good quality, and free from sulphur and phosphorus, which are so prejudicial to the quality of steel, and are not eliminated in the process of conversion, but are rather relatively increased in amount in the product obtained by the Bessemer method, when they are contained in the pig-iron operated upon. The growing importance of this method, and the rapid application of steel to new purposes, for which iron has hitherto been used, render it extremely desirable that a mode should be devised of smelting iron-ores, so as to prevent these deleterious substances from being retained in the pig-iron, or that some means of effecting their separation should be discovered. B. H. P.

STEINHEILITE. Syn. with DICHROÏTE.

STEINMANNITE. The name applied by Zippe to a mineral from Przibram in Bohemia, containing the sulphides of lead and antimony. It is, however, only galena contaminated with accidental admixtures.

STELLITE. Syn. with PECTOLITE.

STEPHANITE. *Brittle Silver-ore. Brittle Silver-glance. Black Silver. Brittle Sulphuret of Silver. Sprödglaserz. Sprödglanzerz.*—A sulphantimonite of silver occurring in trimetric prisms, homœomorphous with arragonite. Observed combinations: $oP . \infty P . \infty\breve{P}\infty , P . 2\breve{P}\infty$. Angle $\infty P : \infty P = 115° 39'$. Ratio of axes $a : b : c = 1 : 1{\cdot}5844 : 1{\cdot}0897$. Cleavage imperfect, parallel to $2\breve{P}\infty$ and $\infty\breve{P}\infty$. Twins are frequent, with plane of composition ∞P. The mineral also occurs massive, compact, and disseminated. Hardness = 2 to 2·5. Specific gravity = 6·299. Lustre metallic. Colour and streak iron-black. Fracture uneven. Sectile. Heated in an open tube, it melts and yields a sublimate of antimonious oxide, sometimes mixed with arsenious oxide. Before the blowpipe on charcoal it fuses somewhat readily, sometimes emitting an arsenical odour, to a dark-grey bead, which when heated in the reducing flame, either alone or with soda, yields a button of silver. It dissolves easily in warm nitric acid, with separation of sulphur and oxide of antimony.

Analyses: a. From Schemnitz (H. Rose, Pogg. Ann. xv. 474).—*b.* From Andreasberg (Kerl, Berg- u. hüttenm. Zeitung, 1853, No. 2):

	S.	Sb.	Ag.	Fe.	Cu.		
a.	16·42	14·68	68·54	. .	0·64	=	100·28
b.	16·51	15·79	68·38	0·14	. .	=	100·82

These analyses may be represented by the formula $6Ag^2S.Sb^2S^3$, requiring 15·6 per cent. sulphur, 14·0 antimony, and 70·4 silver.

Stephanite is a valuable ore of silver, occurring in veins with other silver-ores at Freiberg, Schneeberg, and Johanngeorgenstadt in Saxony, at Przibram and Ratieborzitz in Bohemia, at Schemnitz and Kremnitz in Hungary, at Andreasberg in the Hartz, at Zacatecas in Mexico, and in Peru. (Dana, ii. 86.)

STERCORITE. Herapath's name for sodio-ammonio-hydric phosphate, $Na(NH^4)HPO^4.4aq.$, found in the guano of Ichaboe (iv. 581).

STERNBERGITE. A sulphide of silver and iron, occurring at Joachimsthal in Bohemia, and at Schneeberg and Johanngeorgenstadt in Saxony, in tabular orthorhombic crystals, commonly implanted, and forming rose-like or fan-like aggregations. Angle $\infty P : \infty P = 119° 30'$; $oP : \bar{P}\infty = 121° 49'$. Axes: $a : b : c = 1 : 1{\cdot}7145 : 1{\cdot}4379$. Crystals sometimes compound, parallel to ∞P. Cleavage perfect, parallel to the base. The mineral is opaque, has a dark pinchbeck-brown colour, occasionally with a bluish-violet tarnish, and a semimetallic lustre; flexible in thin laminæ; very sectile; leaves traces on paper like plumbago. Hardness = 1 to 1·5. Specific gravity = 4·2 to 4·25. Before the blowpipe on charcoal it melts, with evolution of sulphurous anhydride, to a magnetic globule covered with silver; with borax it yields a globule of silver, and a glass coloured by iron. It dissolves in nitromuriatic acid with separation of sulphur. Contains, according to Zippe (Pogg. Ann. xxvii. 690), 33·2 per cent. silver, 36·0 iron, and 30·0 sulphur, agreeing approximately with the formula $(\tfrac{1}{3}Ag^2S.\tfrac{2}{3}Fe''S)^3.\overset{\prime\prime\prime}{Fe}{}^2S^3$, which requires 34·18 per cent. silver, 35·44 iron, and 30·38 sulphur.

STETHAL, or **STETHYLIC ALCOHOL.** $C^{18}H^{38}O = C^{18}H^{37}.H.O.$—The alcohol of the series $C^nH^{2n+2}O$, corresponding to stearic acid. It has not been obtained in the separate state, but occurs in spermaceti, together with ethal or cetylic alcohol ($C^{16}H^{34}O$), methal ($C^{14}H^{30}O$), and lethal ($C^{12}H^{26}O$). All these alcohols are separated together from the fatty acids of spermaceti, when that substance is saponified by alcoholic potash, in the manner described under CETYLIC ALCOHOL (i. 841), the ethal forming by far the largest portion of the alcoholic mixture. The presence of these several alcohols is manifested by their behaviour with potash-lime, by which they are converted into a mixture of palmitic acid (the principal portion), formed from ethol, stearic acid from stethal, myristic acid from methal, and lauric acid from lethal. When the ethal is crystallised several times from alcohol, till its melting-point is brought to 49°, a portion of the ethal, together wth the whole of the methal and lethal, remains in the mother-liquor, while the portion which crystallises out contains the stethal together with ethal. (Heintz.)

STIBETHYL, STIBMETHYL, &c. See ANTIMONY-RADICLES, ORGANIC (i. 339).

STIBILITE. *Stibiolite. Stiblite. Stibiconise.*—An oxide of antimony (formerly referred to antimony-ochre (i. 324), occurring at Losacio in Spain, Felsobanya and Kremnitz in Hungary, Goldkranach in Bavaria, and in the Carmen mine at Zacualpan in Mexico, forming masses of fine-grained to compact texture, sometimes porous and cracked, also pseudomorphs after stibnite (i. 329). Hardness = 5·5. Specific gravity = 5·78. Colour sulphur-, lemon-, or straw-yellow to yellowish-white; lustre waxy to dull; opaque; streak yellowish-white and shining. Reducible to antimony before the blowpipe with soda, but not alone. Contains, according to Delffs (J. pr. Chem. xl. 318), 75·83 per cent. antimony, 19·54 oxygen, and 4·69 water, agreeing approximately with the formula $Sb^2O^4.2H^2O$ (74·58 antimony, 19·83 oxygen, and 5·59 water).

STIBINE. A general name for antimony-bases formed on the type of ammonia, NH^3; thus SbH^3 is stibine; $Sb(C^2H^5)^3$ is ethylstibine, &c.

The same term is used by Beudant as a name of native antimonious sulphide; better called *Stibnite* or *Antimonite.*

STIBIOPHYLLITE. Syn. with Valentinite or native antimonious oxide.

STIBIOZINCYLS. The name given by Cooke to certain alloys of zinc and antimony. [See ZINC.]

STIBITE. A name of native antimonious oxide.

STIBIUM. The Latin name of Antimony.

STIBLITE. Syn. with STIBILITE.

STIBNITE. Native antimonious sulphide, Sb^2S^3.

STIBONIUM. Antimony-radicles formed on the type of ammonium, NH^4; thus $Sb(C^2H^5)^4$ is tetrethyl-stibonium.

STICK-LAC. See LAC (iii. 451).

STICTA PULMONACEA. A lichen formerly used as a remedy in diseases of the lungs. It contains a peculiar bitter principle, which, according to Weppen, is a white powder, slightly soluble in water and in ether, easily soluble in hot alcohol, forming a slightly acid solution which is precipitated by acids, acetate of lead, and silver-salts. Weppen (Pharm. Centr. 1838, p. 177) regarded this bitter substance as identical with cetrarin or cetraric acid (i. 839). According to Knop and Schnedermann (J. pr. Chem. xxxix. 363), the acid of *Sticta pulmonacea,* which they call stictic acid, is distinct from cetraric acid, though very much like it in composition and properties, and may be prepared in a similar manner; but it is less soluble in alcohol; the solution does not turn blue when boiled with hydrochloric or sulphuric acid, and stictate of potassium is less soluble than the cetrarate.

STIGMAPHYLLON. In the expressed juice of the tubers of *Stigmaphyllon jatrophæfolium,* a malpighiaceous tree indigenous in Brazil, De Luca and Ubaldini (Compt. rend. lix. 527) found a considerable quantity of asparagin.

STILBENE. $C^{14}H^{12}$. *Hydride of Stilbyl. Picramyl.* (Laurent, Rev. scient. xvi. 373.)—A hydrocarbon polymeric with benzylene (C^7H^6), obtained by heating sulphide of stilbene (hydride of sulphobenzoyl, i. 571). The compound melts, gives off sulphydric acid and sulphide of carbon; and on increasing the heat, stilbene passes over, first solidifying in scales, and afterwards thionessal:

$$\underset{\substack{\text{Hydride of}\\\text{Sulphobenzoyl.}}}{8C^7H^6S} \quad = \quad 2CS^2 \quad + \quad 3H^2S \quad + \quad \underset{\text{Stilbene.}}{2C^{14}H^{12}} \quad + \quad \underset{\text{Thionessal.}}{C^{26}H^{18}S}$$

To purify the stilbene, the first portions of the distillate are boiled with alcohol; the liquid is filtered to separate the thionessal, which is nearly insoluble in alcohol; and the liquid is left to cool. The stilbene is then deposited in crystals, which may be recrystallised from ether.

Stilbene may also be obtained from the crude product resulting from the action of sulphydrate of ammonium on oil of bitter almonds, the materials being left in contact for two or three weeks.

Stilbene crystallises in colourless nacreous plates belonging to the monoclinic system: observed combination $oP \,.\, \infty P \,.\, \infty P\infty$, the basal face oP predominating. Angle

$\infty P : \infty P = 53^\circ\, 30'$; $oP : \infty P = 100^\circ$; $\infty P : \infty P\infty = 116^\circ\, 45'$; $oP : \infty P\infty = 112^\circ$. The crystals are commonly joined together by the acute angles of the rhombuses. Stilbene is very slightly soluble in cold, but moderately soluble in boiling alcohol, more soluble in ether. It melts at a few degrees above 100°, boils at about 292°, and distils without alteration. Vapour-density = 8·4.

Stilbene dissolves in warm *fuming sulphuric acid*, and the solution saturated with baryta yields a soluble barium-salt of a conjugated acid. Stilbene is not decomposed by dilute *chromic acid*, but the concentrated acid decomposes it with violence when heated with it, converting it into benzoic hydride. With boiling *nitric acid* it yields several products, among which are nitrostilbene, $C^{14}H^{11}NO^2$—which is a yellow resinous substance,—and nitrostilbic acid, a yellowish powder nearly insoluble in water, soluble in alcohol, still more in ether, and apparently consisting of $C^{14}H^9(NO^2)O^4.2aq$.

When chlorine-gas is passed over fused stilbene, two isomeric compounds are formed, viz. chloride of stilbyl and hydrogen, $C^{14}H^{11}Cl.HCl$, and chloride of stilbene, $C^{14}H^{12}Cl^2$ (α and β chloride of stilbyl, according to Laurent). Both these compounds are crystalline; one of them is sparingly insoluble in ether, and nearly soluble in boiling alcohol; the other is easily soluble in alcohol, still more easily in ether. Both are resolved by alcoholic potash into two isomeric chlorides of stilbyl, or chlorostilbenes, $C^{14}H^{11}Cl$ (α and β chlorostilbase, according to Laurent), with simultaneous formation of chloride of potassium.

The *chlorostilbenes* α and β unite directly with 2 at. bromine, forming two isomeric compounds, $C^{14}H^{11}ClBr^2$, or perhaps $C^{14}H^{10}Br^2.HCl$, which dissolve in ether, and crystallise therefrom.

When stilbene is subjected to the prolonged action of chlorine, hydrochloric acid is evolved, and *trichloride of stilbyl*, $C^{14}H^{11}Cl^3$, or *dichloride of chlorostilbene*, $C^{14}H^{11}Cl.Cl^2$, is produced.

When bromine is poured upon stilbene, a white powder insoluble in ether is formed, consisting of *bromide of stilbene*, $C^{14}H^{12}Br^2$, or *bromide of stilbyl and hydrogen*, $C^{14}H^{11}Br.HBr$.

STILBENE, OXIDE OF. Laurent regarded benzoic hydride (bitter-almond oil) as the oxide of stilbene, $C^7H^6.O$.

STILBENE, PEROXIDE OF. Syn. with Stilbous Acid.

STILBENE, SULPHIDE OF. Syn. with Hydride of Sulphobenzoyl (i. 571).

STILBESE, PEROXIDE OF. Syn. with Stilbesic Acid.

STILBESIC ACID. *Acide Stilbeseux. Suroxide de Stilbèse.* (Laurent, J. pr. Chem. xxxv. 430.—Laurent and Gerhardt, Compt. chim. 1850, p. 117.)—A product obtained by treating crude bitter-almond oil (containing prussic acid) with chlorine-gas, assisting the action by heat towards the end. The whole then solidifies, on cooling, to a crystalline mixture of benzoic acid, stilbesic acid, a body crystallising in needles, and chloride of benzoyl; and if the chloride of benzoyl be allowed to drain on a funnel stopped with pounded glass, the mass pressed between paper, and treated with ether-alcohol, stilbesic acid remains behind, and may be crystallised by solution in boiling ether and spontaneous evaporation. It crystallises in monoclinic prisms, very slightly soluble in alcohol and ether, melting at 105°, and containing 71·60 per cent. carbon, and 4·33 per cent. hydrogen. Its solution in alcoholic ammonia yields, with silver-nitrate at the boiling heat, scales containing 48·7 per cent. silver. Hence Laurent deduced for the acid the formula $C^{28}H^{10}O^7$, and for the silver-salt $C^{28}H^8Ag^2O^7$; but its composition is very doubtful.

STILBIC ACID. Syn. with Benzilic Acid (i. 546).

STILBILIC or **STILBILOUS ACID.** Syn. with Stilbous Acid.

STILBIN. Syn. with Stilbene.

STILBITE. *Heulandite. Foliated Zeolite, Euzeolite.* A hydrated calcio-aluminic silicate, occurring in monoclinic crystals, which exhibit the combination $[\infty P\infty]$ $\infty P\infty . + 2P\infty . - 2P\infty . \infty P . oP - P . [P\infty]$; tabular from predominance of $[\infty P\infty]$. Ratio of axes $a : b : c = 2{\cdot}4785 : 1 : 1{\cdot}065$. Angle $b : c = 88^\circ\, 35'$; $\infty P : \infty P = 136^\circ\, 4'$; $oP : [P\infty] = 156^\circ\, 45'$. Cleavage perfect, parallel to the clinodiagonal. The mineral occurs also in globular forms, and granular. Hardness = 3·5 to 4·0. Specific gravity = 2·1 to 2·2. Lustre of $[\infty P\infty]$ pearly, of other faces vitreous. Colour various shades of white, passing into red, grey, and brown. Streak white. Transparent to subtranslucent. Fracture subconchoïdal to uneven. Brittle. Before the blowpipe it intumesces, melts, and becomes phosphorescent. Dissolves in hydrochloric acid, yielding slimy silica, but without gelatinising.

Analyses.—*a.* Faröe Islands (Thomson, *Outlines*, i. 347).—*b.* Iceland (Rammelsberg, *Mineralchemie*, p. 826).—*c.* Iceland (Damour, Ann. Min. iv. x. 207).—*d.* Berufjord, Iceland: crystallised; specific gravity = 2·175 (Waltershausen, Vulk. Gest. p. 252).—*e.* Nerbudda Valley, India: crystallised (Haughton, Jahresb. 1857, p. 676):

	a.	*b.*	*c.*	*d.*	*e.*
Silica . .	59·14	58·2	59·85	58·90	56·59
Alumina . .	17·92	17·6	16·15	16·81	15·35
Lime . .	7·65	7·2	7·55	7·38	5·88
Magnesia . .	. .	. .	. .	0·29	0·82
Soda . .	. .	. .	1·16	0·57	1·45
Potash . .	. .	. .	0·67	1·63	0·89
Water . .	15·40	16·0	14·33	14·32	17·48
Ferric oxide .	. .	. .	. .	0·12	
	100·11	99·0	99·71	100·02	98·46

These analyses are not very accordant, but the third and fourth may be nearly represented by the formula $Ca''O.Al^2O^3.6SiO^2.5$ aq., requiring 59·76 per cent. silica, 16·61 alumina, 9·06 lime, and 14·54 water. According to this formula, stilbite is very nearly related to brewsterite and epistilbite, the three minerals being represented by the formula $RO.Al^2O^3.6SiO^2 + 5$ aq., and the protoxide, RO, consisting, in stilbite, of lime with very little alkali; in epistilbite, of lime with a large proportion of soda; and in brewsterite, of strontia and baryta, with a small quantity of lime.

Stilbite occurs chiefly in amygdaloïdal rocks; also in gneiss, and occasionally in metalliferous veins. The finest specimens come from Iceland and the Faröe Islands, and from the Vendayah Mountains in Hindostan. Red varieties occur at Campsie in Stirlingshire, with desmin of the same colour, and brown in ore-beds at Arendal. It also occurs in the Kilpatrick Hills near Glasgow, in the Isle of Skye, in the Fassa Valley in the Tyrol, in the Hartz, and elsewhere; abundant in the amygdaloid of Abyssinia; occurs also at several localities in North America. (Dana, ii. 331.)

Beaumontite from Jones Falls, Maryland, is regarded by Dana and others as identical with stilbite; but the analysis (i. 524) agrees more nearly with the formula $R''O.Al^2O^3.8SiO^2 + 6$ aq.; moreover, according to Levy, the crystals belong to the dimetric system.

Desmin is a hydrated calcio-aluminic silicate, in which the ratio of the lime, alumina, and silica is the same as in stilbite; but the proportion of water is larger, and the crystals are trimetric. It was formerly called *stilbite* (the mineral just described under that name being then called *heulandite*); also *radiated zeolite*, *foliated zeolite*, *sphærostilbite*, and *hypostilbite*.

The crystals of desmin usually exhibit the combination $P \,.\, \infty\bar{P}\infty \,.\, \infty\breve{P}\infty$, like *fig.* 263 (CRYSTALLOGRAPHY, ii. 46), without $\breve{P}\infty$, but with oP. Axes $a : b : c$ = 0·9284 : 1 : 0·7558. Angle P : P in the brachydiagonal principal section = 119° 15′, in the macrodiagonal = 114° 0′; in the basal = 96°. Cleavage perfect, parallel to $\infty\breve{P}\infty$. It frequently occurs in sheath-like aggregations, and in globular, divergent, and radiated forms.

Hardness = 3·5 to 4. Specific gravity = 2·094 to 2·171. Lustre pearly on the faces $\infty\breve{P}\infty$ and the cleavage-faces, vitreous on the others. Colour white, occasionally yellow, brown, or red. Streak uncoloured. Subtransparent to subtranslucent. Fracture uneven. Brittle. Before the blowpipe it intumesces, and yields a milk-white bead. With acids it yields slimy silica, except Beudant's *sphærostilbite*, which yields a jelly.

Analyses of Desmin (Rammelsberg's *Mineralchemie*, p. 829).—*a.* Rödefjordshamm, in Iceland (Hauy's *stilbite dodecaèdre lamelliforme*), Hisinger.—*b.* Berufjord, Iceland (R. Weber).—*c.* Dalsmypen, Faröe Islands: *prehnitic stilbite* (Retzius).—*d.* Faröe Islands: so-called *sphærostilbite* (Beudant).—*e.* Gustafsberg in Jemtland (Sjögren).—*f.* Ilmen Mountains, near Miask: specific gravity = 2·19 (Hermann).—*g.* Andreasberg, in the Hartz (Karl).—*h.* Rienthal on the Gotthardstrasse, Canton Uri (G. Leonhard).—*i.* Pangelberg, near Nimptsch in Silesia (Zellner):

* Magnesia.

The greater number of these analyses may be represented by the formula $Ca''O.Al^2O^3.6SiO^2 + 6$ aq., requiring 58·09 per cent. silica, 16·14 alumina, 8·80 lime, and 16·97 water.

Of different composition are:—α. The so-called *Hypostilbite* from the Faröe Islands (Beudant); β. White and γ. Red desmin from Dumbarton in Scotland (Thomson):

SiO^2.	Al^2O^3.	CaO.	Na^2O.	H^2O.		
52·43	18·32	8·10	2·41	18·70	=	99·96
54·80	18·20	9·83	. .	19·00	=	101·83
52·50	17·32	11·52	. .	18·45	=	99·79

Desmin occurs mostly in cavities in amygdaloïd or trap. It is found also in some metalliferous veins, and in granite and gneiss. It is abundant in the Faröe Islands, in Iceland, and on the Isle of Skye in trap; at Andreasberg in the Hartz, and at Kongsberg and Arendal in Norway, with iron-ore; in the Vendayah Mountains, Hindostan, in large translucent crystals; in fine crystals, of a brick-red colour, in porphyritic amygdaloïd, near Kilpatrick in Dumbartonshire, &c. (Dana, ii. 833.)

STILBOUS ACID. $C^{15}H^{12}O^{3}$? A compound formed by treating crude bitter-almond oil with fuming sulphuric acid, or with chloride of sulphur (Laurent, Ann. Ch. Phys. [2], lxv. 193). When first prepared, it crystallises from ether or boiling alcohol in monoclinic prisms; but if kept for some time in the fused state, and then dissolved in alcohol, it crystallises in trimetric prisms. It melts at 360°; is insoluble in ammonia; is resolved by boiling caustic potash into benzoic acid and benzoic hydride; but when treated with very strong potash-ley, unites with the potash, forming a compound insoluble in strong, but soluble in dilute aqueous potash.

This compound was originally regarded by Laurent as *hydrate of benzoyl*, $C^{14}H^{5}O.HO$. It is sometimes regarded as identical with benzoate of benzoic hydride (i. 598), formed from crude bitter-almond oil, by the action of moist chlorine; but the identity of the two products is not satisfactorily established. All these compounds formed from crude bitter-almond oil require re-examination: for details respecting them, see *Gmelin's Handbook*, xii. 178.

STILBYL. $C^{14}H^{11}$. Stilbene may be regarded as the hydride of this radicle, $C^{14}H^{11}.H$.

STILLINGIA SEBIFERA. A euphorbiaceous plant, growing abundantly in the valleys of Chusan, the berries of which yield the fat called *Chinese vegetable tallow*. This fat appears to occur in several varieties.

a. Greenish-white; melts at 44·4°; yields, by saponification, an acid, which, after recrystallisation from alcohol, softens at 61·7°, melts at 67·8°, and forms a silver-salt containing 27·95 per cent. silver; probably a mixture of palmitic (margaric, according to Thomson and Wood) and stearic acids. (Thomson and Wood, Phil. Mag. [3] xxiv. 350; J. pr. Chem. xlvii. 239.)

b. The commercial tallow forms a light white mass, of specific gravity 0·818 at 12°, destitute of taste and odour (v. Borck). Has a faint odour, and turns brown on exposure to the air (Maskelyne). Melts at 37° (v. Borck, Maskelyne), solidifies partially at 32° (Maskelyne), 30° (v. Borck); and hardens at 22° (v. Borck), 26° (Maskelyne). The tallow recently melted and cooled again, melts at 44°; by expressing the more fusible portion, the melting-point of the residue may be raised to 49° (Maskelyne). The fat extracted from the husk by boiling alcohol melts at 40°, and after recrystallisation at 48° (v. Borck). It dissolves in oil of turpentine, and in coal-tar oil, in wood-spirit, ether, and alcohol, or in mixtures of these liquids; it dissolves partially at mean temperatures, completely at the boiling heat (Maskelyne). It has an acid reaction, arising from admixture of acetic or propionic acid. It contains olein and palmitin. (Maskelyne, Chem. Soc. Qu. J. viii. 1; v. Borck, J. pr. Chem. xlix. 395.)

STILLISTEARIC ACID. The name applied by v. Borck to the fatty acids obtained by saponification of Chinese tallow, which he supposed to have the composition $C^{15}H^{30}O^{2}$. Maskelyne has, however, shown that it is identical with palmitic acid.

STILLOLITE. Syn. with SILICIOUS SINTER.

STILPNOMELANE. A ferroso-aluminic silicate, occurring at Obergrund in Silesia, and in the Frederike mine, near Weilburg in Nassau, in foliated, radiated, and compact masses, having a specific gravity of 3—3·4; hardness 3—4; a lustre between vitreous and pearly on the cleavage-surface; black or greenish-black colour; and greenish streak. Dissolves imperfectly in acids.

Analyses.—*a*. Obergrund (Rammelsberg, *Mineralchemie*, p. 880).—*b*. Weilburg (Siegert):

	SiO^2.	AlO^3.	FeO.	CaO.	MgO.	KO.	H.	
a.	45·96	5·84	35·60	0·19	1·78	0·75	8·63	= 98·75
b.	45·07	4·92	37·78	1·67	0·94	. .	8·47	= 98·85

Some of the iron appears to be in the state of ferric oxide, but its quantity has not been determined with sufficient accuracy for the deduction of a formula.

STILPNOSIDERITE. A variety of native ferric hydrate, $Fe^2O^3.H^2O$, occurring massive, stalactitic, or incrusting, at Amberg in Westphalia, and two or three other localities. It has a black or blackish-brown colour; hardness = 4 to 5; specific gravity = 3·6 to 3·8.

STINKSTONE. A variety of limestone which emits a fetid odour when struck or rubbed (iii. 697).

STIRIAN. A name applied by Breithaupt to smaltine from Schladming in Styria.

STOÏCHIOMETRY. The law of chemical combination in definite proportions, and its application to chemical calculations.

STOLPENITE. A mineral from Stolpen, resembling bole in appearance, and containing, according to Rammelsberg (Pogg. Ann. xlvii. 180), 45·92 per cent. silica, 22·15 alumina, 24·86 water, and 3·90 per cent. lime, with traces of iron and magnesia.

STOLZITE. Native tungstate of lead. (See TUNGSTATES.)

STORAX. See BALSAMS (i. 497).

STRAKONITZITE. A pseudomorph after augite, occurring in the weathered gneiss of Mutenitz, near Strakonitz in Bohemia. It has a greenish-yellow colour, and specific gravity = 1·41. Contains, according to C. v. Hauer, 53·4 per cent. silica, 19·9 water, 15·4 ferrous oxide, 2·9 magnesia, 1·4 lime, and 7·0 alumina.

STRAMONIUM. See DATURA STRAMONIUM (ii. 307).

STRASS, or *Mentz Flux.* A kind of glass used in the preparation of artificial gems (ii. 841).

STRATIOTES ALOÏDES. *Water-soldier.*—This hydrocharidaceous plant yields, when dried, 17·2 per cent. ash, containing in 100 pts., according to Schulz-Fleeth (Pogg. Ann. lxxxiv. 98):

K^2O.	Na^2O.	CaO.	MgO.	Fe^2O^3.	SiO^2.	P^2O^5.	SO^3.	CO^2.	NaCl.
30·8	1·2	10·7	14·3	0·4	1·8	2·8	3·5	30·4	2·7

STRATOPEITE. A manganic silicate from Philipstad in Sweden. (SILICATES p. 259.)

STREAK OF MINERALS. Coloured mineral substances generally exhibit, when powdered, a lighter or, at all events, a different colour to that which belongs to them in mass: hence similarly coloured minerals may, in some cases, be distinguished one from the other by the colours of their powders. In order to see the colour, however, it is not necessary to pulverise the mineral, as it may be observed by scratching the mineral with a knife, or rubbing its edge on a rough white porcelain plate.

STROGANOWITE. An altered scapolite from the Sludänka river in Dauria (p. 203).

STROMEITE. Syn. with RHODONITE, or SILICIOUS MANGANESE (p. 107).

STROMEYERITE. Native argento-cuprous sulphide, or argentiferous copper-glance (p. 305).

STROMNITE. *Baryto-strontianite.*—A mineral from Stromness in the Orkneys, containing, according to Traill (Edinb. Phil. Trans. ix. 81), 27·5 per cent. sulphate of barium, 62·6 carbonate of strontium, and 2·6 carbonate of calcium, with 0·1 ferric oxide: probably a mechanical mixture.

STRONTIA, STRONTIAN. Oxide of strontium (p. 437).

STRONTIANITE. *Strontite. Strontites.*—Native carbonate of strontium. (See CARBONATES, i. 797.)

STRONTIANOCALCITE. A calcspar containing strontia, from Girgenti in Sicily. The crystals have the form and cleavage of ordinary calcspar, are grouped in spherical masses, colourless and transparent to white and translucent, and have a mother-of-pearl lustre.

STRONTIUM. *Symbol*, Sr. *Atomic weight*, 87·5.

The native carbonate of strontium, discovered, in 1787, at Strontian in Argyleshire, was at first regarded as carbonate of barium. Crawfurd's supposition, published in 1790, that this mineral contained a peculiar earth, was confirmed in 1792 by Hope (Edinb. Phil. Trans. iv. 3), and in 1793 by Klaproth. H. Davy, in 1808, first obtained from it the metal strontium.

Strontium occurs as sulphate in cœlestin, and as carbonate in strontianite; in small quantities in arragonite and brewsterite, and in very minute quantities in the mineral waters of Karlsbad and Kaiser-Franzensbrunnen, the salt-spring at Eger, &c., and in sea-water.

Preparation.—Strontium was first isolated by Davy in the same manner as barium (i. 500). Hare obtained it in a similar manner, and Clarke prepared it, in the same manner as barium, by heating strontia or the nitrate on charcoal in the oxyhydrogen-blowpipe flame. All these methods, however, yielded the metal in an impure state.

The pure metal is easily obtained by electrolysis of the fused chloride, in the manner given by Matthiessen (ELECTRICITY, ii. 438). Caron (Compt. rend. xlviii. 40) obtains it by fusing the chloride with an alloy of sodium and lead, tin, &c.; the reduction is not effected by sodium alone.

Properties.—Strontium has a yellow colour, like that of calcium, only a shade darker. Specific gravity = 2·5418. It oxidises in the air much more quickly than calcium. Its place in the electrolytic series, with water as the exciting liquid, is as follows:

$$\overset{+}{K},\qquad Na,\qquad Li,\qquad Ca,\qquad Sr,\qquad \overset{-}{Mg},\ \&c.$$

It burns like calcium, and acts similarly to it when heated in chlorine, oxygen, bromine, or iodine, or on boiling sulphur, or when thrown on water or acids. (Matthiessen.)

STRONTIUM, BROMIDE OF. $SrBr^2$.—The anhydrous bromide is obtained by evaporating and heating a solution of the carbonate in hydrobromic acid, also by burning strontium in bromine-vapour. It is a white mass, which melts without decomposition at a red heat. From the aqueous solution the bromide separates in long needles, containing $SrBr^2.3H^2O$, which do not effloresce in dry air, or even over oil of vitriol. When heated they melt in their water of crystallisation, and then give it off. The salt is easily soluble in water, somewhat soluble also in alcohol, and the alcoholic solution burns with a purple-red flame.

STRONTIUM, CHLORIDE OF. $SrCl^2$.—Produced when strontium burns in chlorine-gas; also, according to Weber (Pogg. Ann. cxii. 619), by heating anhydrous strontia in a stream of chlorine. It is usually prepared from cœlestin in the same manner as chloride of barium from heavy spar (i. 501). The crystallised chloride, $SrCl^2.3H^2O$, forms long deliquescent needles, which melt when heated, give off their water, and leave the anhydrous chloride in the form of a white enamel-like mass, or, according to Dumas, vitreous and transparent when perfectly pure. The anhydrous chloride absorbs 8 at. ammonia, whereby it is converted into a white powder. It dissolves easily in water; in 116·4 pts. cold and 262 pts. boiling alcohol of 99 per cent. (Fresenius.)

STRONTIUM, DETECTION AND ESTIMATION OF.—1. *Blowpipe Reactions.*—Strontium-compounds heated in the inner flame colour the outer flame carmine-red. An alcoholic solution of a strontium-salt burns with a carmine-red flame. The spectrum of strontium-vapour is characterised by a red line nearly coinciding with the solar line C, and a blue line between F and G (p. 380). All these reactions are distinctly perceptible in presence of a considerable quantity of barium-salt.

2. *Reactions in Solution.*—The reactions of strontium-salts closely resemble those of barium-salts. Sulphate of strontium, however, is somewhat more soluble than sulphate of barium: hence *sulphuric acid* or a *soluble sulphate* does not precipitate a dilute solution of a strontium-salt so quickly as it does that of a barium-salt. A barium-salt gives a precipitate with a solution of *sulphate of strontium*, which a strontium-salt of course does not. Strontium-salts are further distinguished from barium-salts by not forming precipitates with *silicofluoric acid* or *acid chromate of potassium*. A few drops of solution of strontium-chloride, evaporated on a watch-glass, yield needles of the hydrated chloride, whereas a solution of barium-chloride evaporated in like manner yields small cubes.

3. *Estimation and Separation.*—Strontium is best estimated as carbonate by precipitation with ammonium-carbonate and ammonia from a hot solution. The precipitation of strontium by this method is more complete than that of barium. Carbonate of strontium is not decomposed by ignition over an ordinary lamp. Strontium may also be estimated as sulphate; but as this salt is not absolutely insoluble in

water, it is necessary to add alcohol to complete the precipitation, which can only be done when the original strontium-salt is soluble in alcohol.

Strontium is separated from most other metals in the same manner as barium. When a solution previously freed from metals of the first and second groups (i. 217), by treatment with sulphydric acid and sulphide of ammonium, is further treated with carbonate of ammonium, the precipitate may contain the carbonates of barium, strontium, and calcium. From barium, strontium may be separated by dissolving the carbonates in a slight excess of hydrochloric acid; mixing the solution with excess of silicofluoric acid; then adding alcohol; leaving the whole to itself for twelve hours; filtering; washing the precipitate with weak spirit; and precipitating the strontium from the filtrate as sulphate. If the two metals are present as sulphates, it is best to treat the mixture repeatedly with a solution of potassic or ammonic carbonate without applying heat. The residue, when thoroughly washed and treated with dilute hydrochloric acid, leaves pure sulphate of barium, the whole of the strontium dissolving as chloride. (H. Rose, Pogg. Ann. xcv. 286.)

From calcium, strontium may be separated by the insolubility of its nitrate in absolute alcohol.

For the methods of separating strontium from barium and calcium together, see CALCIUM (i. 717).

For detecting small quantities of strontium (and barium) in calcareous minerals, Engelbach (Ann. Ch. Pharm. cxxiii. 255) subjects the pulverised carbonate, obtained by decomposing the natural sulphate or silicate, to strong ignition; then boils it thoroughly with distilled water, and evaporates the rapidly filtered solution with addition of hydrochloric acid—or, if alkali-metals are also present, precipitates with ammonia and carbonate of ammonium—and examines the chlorides or carbonates with the spectroscope.

4. *Atomic Weight of Strontium.*—Stromeyer in 1816 (Schw. J. xix. 228), by decomposing carbonate of strontium with nitric acid, and determining the quantity of carbonic anhydride evolved, estimated the atomic weight of strontium at 88·22. He further reported that, according to H. Rose's determination, 100 pts. chloride of strontium yield by precipitation 181·25 pts. chloride of silver. This gives (for $Ag = 108$, and $Cl = 35·5$) $Sr'' = 87·34$. Pelouze, in 1845 (Ann. Ch. Pharm. lvi. 204), by a similar method, found $Sr'' = 87·70$; and Dumas (*ibid.* cxiii. 34) found $Sr'' = 87·5$, which number may be taken as the correct atomic weight of the metal.

STRONTIUM, FLUORIDE OF, SrF^2, is prepared, like the corresponding barium-compound, by decomposing oxide or carbonate of strontium with hydrofluoric acid, or by precipitating a strontium-salt with fluoride of sodium. It is a white powder, insoluble in water and in aqueous hydrofluoric acid.

STRONTIUM, HYDRATE OF. See STRONTIUM, OXIDE OF.

STRONTIUM, IODIDE OF. SrI^2.—Obtained by saturating hydriodic acid with strontia or sulphide of strontium, and evaporating. It may be fused without decomposition in a closed vessel; but when heated in contact with the air, it gives off iodine, and is converted into strontia. It dissolves easily in water, and may be recrystallised therefrom.

STRONTIUM, OXIDE OF. SrO. *Strontia. Strontian.*—Prepared by heating the nitrate to redness, or by exposing the carbonate, either alone or mixed with charcoal, to the strongest heat of a forge-fire. It is a greyish-white porous mass, of specific gravity 3·0 to 4·0 (Davy), 3·932 (Karsten), infusible, not volatile, and glows in the blowpipe-flame with a dazzling white light. It has an alkaline taste and reaction. When moistened with water, it becomes hot, and falls to powder like lime; if only the exact quantity of water required be added, the strontia hardens to a crystalline hydrate. When heated nearly to redness in a stream of chlorine-gas, it glows brightly throughout its whole mass, and is converted into a sintered mass of chloride of strontium. (R. Weber, Pogg. Ann. cxii. 649.)

Hydrate or Hydrated Oxide of Strontium, $SrH^2O^2 = Sr''O.H^2O$, is produced, as just noticed, by the direct union of water with the anhydrous oxide. On dissolving this hydrate in 5 or 6 pts. of boiling water, filtering hot, and leaving the solution to cool slowly in a closed vessel, it deposits small, needle-shaped, transparent crystals, containing $SrH^2O.8H^2O$, which deliquesce on exposure to the air, and are ultimately converted into carbonate. When heated to 100° or above, they give off 50 per cent. water, and leave the monohydrate SrH^2O^2. By heating the crystals to low redness, the hydrate is obtained in the fused state, and solidifies on cooling to a greyish-white radiated mass. According to Bloxam (Chem. Soc. Qu. J. xiii. 48), hydrate of strontium gives off all its water at a red heat, leaving anhydrous strontia.

The crystals, $Sr''H^2O^2.8H^2O$, dissolve in 50 pts. of cold and 2·4 pts. of boiling water.

The solution, called *strontia-water*, is colourless, strongly alkaline, and absorbs carbonic acid from the air, becoming covered with a crust of carbonate. It may be prepared, like baryta-water, by boiling a solution of the sulphide with oxide of copper (i. 505).

A *peroxide of strontium* is obtained as a hydrate, in shining scales, by mixing strontia-water with peroxide of hydrogen. (Thénard.)

STRONTIUM, OXYSULPHIDE OF. See the next article.

STRONTIUM, SULPHIDES OF. The monosulphide, SrS, is prepared, like the corresponding barium-sulphide (i. 507), by reducing the sulphide with coal or charcoal. It is a white, granular, sintered but friable mass. By solution in a large quantity of boiling water, it is decomposed, the liquid, as it cools, yielding crystals of strontium-hydrate, whilst strontium-sulphydrate remains in solution:

$$2SrS + 2H^2O = SrH^2S^2 + SrH^2O^2.$$

If it be treated with a quantity of water not sufficient for this complete decomposition, a solution is formed containing chiefly sulphydrate of strontium, and on treating the residue with fresh quantities of water, a nearly pure solution of the hydrate is obtained. (H. Rose.)

Polysulphides (Schöne, Pogg. Ann. cxvii. 56).—By digesting 1 at. of the monosulphide and 3 at. sulphur in water, and leaving the solution to evaporate, at a temperature not exceeding 17°, a brownish-red viscid syrup is obtained, which at 8° solidifies to a crystalline mass of the tetrasulphide, SrS^4, with 6 at. water. This compound is very hygroscopic, soluble in water and in alcohol; on exposing the solutions to the air, hyposulphite of strontium is formed and remains dissolved, while sulphur and a small quantity of strontium-carbonate are deposited. On heating the syrup to 100°, or concentrating it under the air-pump at a temperature above 17° (best between 20° and 25°), the tetrasulphide separates with 2 at. water, as a light-yellow solid mass. When heated above 100°, it is decomposed by its water of crystallisation. It is not acted upon by carbonic disulphide.

By exposing the alcoholic solution of the tetrasulphide to the slow action of air, ruby-red, transparent, rhombic crystals are obtained, consisting of a hydrated oxytetrasulphide, $SrO.SrS^4.12H^2O$, which are decomposed by water. They are probably identical with the supposed disulphide, which Gay-Lussac obtained (Ann. Ch. Phys. [2] xiv. 362) by leaving a solution of strontium-sulphide to itself for some time.

Pentasulphide of strontium is formed by digesting the monosulphide in water with 4 at. sulphur, but exists in solution only. On evaporating the solution under the air-pump at about 20°, a residue is obtained consisting of the tetrasulphide mixed with sulphur. (Schöne.)

Sulphydrate of Strontium, $SrH^2S^2 = SrS.H^2S$.—Produced by passing sulphydric acid gas to saturation through strontia-water, or through water in which sulphide of strontium is suspended, or by dissolving sulphide of strontium in a small quantity of boiling water, whereby it is resolved, as above mentioned, into hydrate and sulphydrate. Berzelius, by evaporating in a vacuum the solution prepared by the first method, obtained the sulphydrate in large striated prisms, which when heated melt in their water of crystallisation, then give it off, together with sulphydric acid, and leave a residue of monosulphide of strontium. In other respects the compound exactly resembles sulphydrate of barium (i. 508).

STRUTHIIN. Syn. with Saponin (p. 192).

STRUVITE. Ammonio-magnesic phosphate, $(NH^4)\overset{\prime\prime}{Mg}{}^2(PO^4)^2.12aq.$, occurring in crystals in certain varieties of guano. (Phosphates, iv. 568.)

STRYCHNIC ACID. Syn. with Igasuric Acid (iii. 242).

STRYCHNINE. $C^{21}H^{22}N^2O^2$. (Pelletier and Caventou [1818], Ann. Ch. Phys. x. 142; xxvi. 44.—Pelletier and Dumas, Ann. Ch. Phys. xxiv. 176.—Liebig, *ibid.* xlvii. 171; xlix. 244.—Regnault, Ann. Ch. Phys. lxviii. 113.—Gerhardt, Revue Scientif. x. 192.—Nicholson and Abel, Chem. Soc. Qu. J. ii. 241.—Henry, Pharm. viii. 401.—Corriol, *ibid.* xi. 492.—Robiquet, *ibid.* xi. 580.—Wittstock, *Traité de Chimie de Berzelius.*—Henry, *fils*, J. Pharm. xvi. 752.—Gm. xvii. 479.)

This vegetable alkaloïd exists, together with brucine and igasurine, in nux-vomica, in St. Ignatius-beans, in the wood of *Strychnos Colubrina*, in *Strychnos Tieuté*, *Upas Tieuté*, and probably in several other varieties of *Strychnos* (see Brucine, i. 681). Java arrow-poison, found in a bamboo, contained 62 per cent. of strychnine.

Preparation: 1. *From St. Ignatius-beans.*—The rasped beans are exhausted with ether, and then treated several times with boiling alcohol. The alcoholic solution having been distilled to remove the alcohol, is to be treated with solution of hydrate of potassium to precipitate the strychnine (Pelletier and Caventou). This process is obviously imperfect.

2. *From Nux-vomica.*—*a.* The beans are exhausted with alcohol, and the solution is distilled to recover the alcohol. The residue is dissolved in water, and basic acetate of lead added until no further precipitation takes place. The strychnine remains in solution in the state of acetate; the liquid also contains colouring-matters, and the excess of basic acetate of lead. Sulphide of hydrogen is passed into the solution, which is then filtered, and boiled with magnesia. The precipitated strychnine, after being washed with water, is crystallised from alcohol. The mother-liquors retain the brucine. (Pelletier and Caventou.)

b. The pulverised nux-vomica is exhausted with boiling water, and the decoctions are evaporated until syrupy; powdered chalk is then added by degrees, until in slight excess. The precipitate contains the calcium-salt of an acid existing in nux-vomica, the strychnine, and other substances. After being washed, it is exhausted by treatment with alcohol of specific gravity 0·827, and the liquids are then evaporated in the water-bath to the crystallising-point. The strychnine is purified either by repeated crystallisations, or, better, by conversion into nitrate, and recrystallisation. The alkaloïd may be obtained from the nitrate by precipitation with ammonia. One kilogramme of nux-vomica yields by the above process 5 or 6 grammes of strychnine. (Henry.)

c. The following process is said to be more advantageous than the preceding ones: 1 kilogramme of nux-vomica is to be softened by being steamed, then dried, and pulverised moderately fine. It is then digested in the water-bath, with 4 or 5 litres of alcohol of specific gravity 0·856 acidified by 40 or 50 grammes of sulphuric acid. Quicklime is then added to the alcoholic solution, to remove the acid and precipitate the colouring-matter. The supernatant liquid is decanted, and the deposit is washed with alcohol. All the alcoholic liquors are then mixed, carefully filtered, and distilled. The residue in the still is coloured and alkaline; it is saturated with dilute sulphuric, hydrochloric, or acetic acid; and the solution is to be filtered, concentrated, and precipitated in the cold by a slight excess of ammonia. The precipitate is composed of a mixture of strychnine and brucine. It is to be digested with weak alcohol of specific gravity 0·942, to remove the brucine. The remaining strychnine is to be dissolved in alcohol of specific gravity 0·837, and the boiling solution treated with a small quantity of animal charcoal. The filtered solution, on cooling, deposits the strychnine in crystals. (Henry, *fils.*)

d. Eight pounds of the powdered nux-vomica are mixed with an equal weight of water, so as to form a thick paste, which is then exposed to a temperature of 20° to 25°. In the course of a few days, a violent fermentation sets in, which is generally finished in about eighteen to twenty days. The liquid is now pressed through a hair-sieve; the solid residue pressed, and boiled twice or three times with water; and the united liquids evaporated down to 12 quarts. To this 9 ounces of powdered quicklime are added, the whole left quiet for six or eight hours, and the liquid separated from the precipitate by pressure; it is then mixed with sulphuric acid, the calcic sulphate removed, and the liquid evaporated to 2 quarts. One ounce of lime is now added to it, and the treatment repeated as above described. The precipitate formed is submitted to great pressure, and united to the previous one. The dried precipitate is now digested with 2 quarts of alcohol of specific gravity 0·935, which dissolves out brucine and colouring matters; and from this solution strychnine is likewise obtained by crystallisation. The remaining precipitate is digested repeatedly with 6 quarts of alcohol of specific gravity 0·838, the solution filtered, and four-fifths of the alcohol recovered by distillation. In one or two days the strychnine separates as a white crystalline powder; it is washed several times with alcohol of specific gravity 0·935, to remove any adherent brucine, and is obtained perfectly pure by recrystallisation. (Molyn, J. Chim. méd. iii. 507.)

e. Nux-vomica is to be boiled with alcohol of 94 per cent. The liquid is to be decanted, and the residue dried in an oven; it then becomes easily pulverisable. The powder is to be exhausted with alcohol, and the liquids mixed. After being evaporated to a convenient bulk, acetate of lead is to be added as long as a precipitate is formed. Colouring matters, vegetable acids, and fatty substances are thus removed. The precipitate is thrown on a filter, and well washed; and the filtered liquor is evaporated until reduced to about a half or a third of the weight of the nux-vomica employed. Magnesia is then added to the liquor, and the whole is left at rest for several days, until the brucine has had time to deposit. The precipitate, having been collected on linen, is to be pressed, dried, and treated with alcohol of 83 per cent., to dissolve the alkaloïds. On distilling off the alcoholic liquors, the strychnine is first deposited, while the brucine remains in the mother-liquors. To purify the crude strychnine, it is to be saturated exactly with dilute nitric acid. On concentrating the solution, the nitrate of strychnine is first deposited, in needles, and the nitrate of brucine is afterwards deposited in much larger crystals. The last mother-liquors are gummy, but they still contain some of the alkaloïds, which must be extracted by a fresh treatment with magnesia, &c. as before. When brucine is precipitated, there always remains in solution a considerable quantity, which is deposited after a time in crystalline grains. One kilogramme of nux-vomica yields, on treatment as above, 2 grammes of nitrate of strychnine, and 2 grammes of nitrate of brucine. (Wittstock.)

3. *From Upas Tieutè.*—The filtered aqueous solution of the upas is digested with magnesia; the precipitate is washed, dried, and boiled out three times with alcohol; the alcoholic solutions are evaporated; the residue is dissolved in dilute sulphuric acid and digested with animal charcoal; and the solution is again precipitated by magnesia. The precipitate is then exhausted with alcohol, and the solution evaporated to dryness. (Pelletier and Caventou.)

Detection of Strychnine in cases of Poisoning (i. 127).

Properties.—Small, white, four-sided prisms, terminated by four-sided pyramids (Pelletier and Caventou). — Crystals of the trimetric or rhombic system. Lustre vitreous, pearly on the cleavage-faces. Hardness between 2 and 2·5 (Kengott, Pogg. xcv. 614). Crystals permanent in air, unaltered by light. Rotates polarised light to the left. May be fused without decomposition. Inodorous, taste intensely bitter. Excessively poisonous; one-eighth of a grain will kill a large dog; three-eighths of a grain cause in man violent tetanic, convulsive spasms of the extremities, trismus, opisthotonos, and other formidable symptoms; half a grain, given three times a day for several days, caused death with the usual symptoms. (Pereira, *Materia Medica*, ii. 1310.)

Strychnine in poisonous doses almost invariably produces tetanic convulsions. The smallest dose yet known to prove fatal, was in the case of Dr. Warner, who swallowed half a grain of sulphate of strychnine in mistake for morphia. In a few minutes he was seized with constriction of the throat, tightness of the chest, rigidity of the whole muscular system, and tetanic convulsions. He died in about fourteen minutes (*Taylor on Poisons*, p. 777). The writer has tried the effects of doses of one-twelfth of a grain, repeated every four hours. On the second day the effects were sufficiently unpleasant to render it proper to cease the experiment for a time. Great variation is found in the power of different individuals to resist the poison; doses of even three grains have been endured by patients, where the quantity has been very gradually increased (Gaz. méd., Mars 1845; *Taylor on Poisons*, p. 777). Strychnine has an alkaline reaction. It resists putrefaction, and may consequently be extracted successfully from bodies which have been buried for a long time, even after three years. (Macadam.)

Strychnine dissolves in 6667 parts of cold, and in 2500 parts of boiling water (Pelletier and Caventou.)

Decompositions.—1. Strychnine, when submitted to destructive distillation, yields pyrrol among other products (Grev. Williams). When cautiously heated, it gives off colourless vapours, probably of undecomposed strychnine, then melts to a brown liquid, which when further heated gives off brown vapours, and leaves a carbonaceous residue (Duflos). Strychnine by destructive distillation yields small quantities of chinoline (Gerhardt). Strychnine is very easily oxidised, at a red heat, by oxide of copper or chromate of lead, and therefore, contrary to the statements of many chemists, is very easily analysed by the ordinary processes (Abel and Nicholson). —2. Vapour of *iodine* acts on strychnine, forming a peculiar compound.—3. *Bromine* produces, in solutions of strychnine, a resinous precipitate of bromostrychnine (Laurent). —4. Dry *chlorine* does not act on strychnine or its salts, but chlorostrychnine is formed when the gas is passed into water in which strychnine is suspended. A solution containing 1 pt. of acetate of strychnine in 8,000 pts. of water is rendered turbid by *chlorine* (Marchand).—5. Solution of *chloride of lime* gives a white precipitate in dilute solution of acetate of strychnine (Horsley).—6. Strong *nitric acid*, if hot, converts the alkaloïd into a yellow explosive nitro-compound, which is probably nitrate of nitrostrychnine. The solution, on treatment with alkalis in excess, gives off volatile bases (Anderson). If strychnine turns red with cold strong nitric acid, it indicates the presence of brucine.—7. Cold *oil of vitriol* dissolves strychnine, forming a colourless solution, which yields coloured reactions with most oxidising substances. This solution yields the following reactions with various reagents:—*a. Peroxide of lead* gives a blue coloration, becoming violet, then red, and finally in a few hours yellow.—*b. Acid chromate of potassium* in the solid state, added to the above liquid on a porcelain plate, gives a fine violet coloration; if the quantity of strychnine present is large, the colour is pale-blue.—*c. Ferrocyanide of potassium* yields a somewhat similar reaction to *b*, but more permanent.—*d. Black oxide of manganese* affords a violet coloration, becoming dark-red in the course of an hour. The presence of santonin, or starch, does not prevent the recognition of strychnine by acid chromate of potassium in the above solution; sugar, quinine, or morphine renders it indistinct, but does not affect the reaction with peroxide of manganese. The presence of 30 pts. of tartar-emetic does not prevent the coloration with acid chromate of potassium, but 60 pts. render it indistinct. Very small quantities of animal matters, or vegetable extractive matters, render the above reactions indistinct, when the strychnine is present in minute traces only.—8. Hot solutions of *iodic acid* colour strychnine and its salts violet-red.—9. The iodides of the alcohol-radicles form derivatives which will be described further on.

Combinations.—With Iodine.—a. When a solution of 1 pt. of strychnine in 1 pt. of alcohol and 3 pts. of water is warmed with a little tincture of iodine, and left to cool spontaneously, crystals of an iodine-compound are deposited, having the properties of double absorption. Its formula is probably $C^{21}H^{22}N^2O^2.I^2$ (Herapath).—*b.* When a solution of strychnine in weak alcohol, acidified with hydrochloric or hydriodic acid, is precipitated with tincture of iodine, the precipitate dissolved in boiling alcohol, and the solution left to cool, bright red-brown prisms are formed permanent at 140°, and having the formula $C^{21}H^{22}N^2O^2.HI.I^2$. (Tilden.)

When 2 pts. of strychnine are triturated with 1 pt. of iodine, the resulting mass dissolved in boiling alcohol, and the solution concentrated and allowed to cool, laminæ are deposited having the colour of mosaic gold, and the formula $2C^{21}H^{22}N^2O^2I^3$.

STRYCHNINE SALTS.—Acids easily dissolve strychnine, forming neutral solutions having an intensely bitter taste, and virulently poisonous.

Acetates of Strychnine.—Neutral acetate of strychnine crystallises with difficulty, the acid salt easily. (Pelletier and Caventou.)

Arsenate of Strychnine, $2C^{21}H^{22}N^2O^2.3H^2O.As^2O^5 + H^2O$.—Monoclinic prisms, soluble in 15 pts. of cold, and in 5 pts. of hot water.

Arsenite of Strychnine, $2C^{21}H^{22}N^2O^2.H^2O.As^2O^3$.—Dull white cubes, efflorescing in the air.

Bromomercurate of Strychnine.—Formed in the same manner as the iodine-compound (*infra*), but using bromide instead of iodide of potassium.

Chloro-aurate of Strychnine, $C^{21}H^{22}N^2O^2.HCl.Au'''Cl^3$.—Lemon-yellow precipitate, very slightly soluble in water. Crystallises from alcohol in pale orange-coloured crystals. (Nicholson and Abel.)

Chromate of Strychnine, $2C^{21}H^{22}N^2O^2.H^2O.CrO^3$.—Lemon-yellow needles, neutral, and sparingly soluble in water and alcohol. (Nicholson and Abel.)

Chlorocadmiate of Strychnine, $2(C^{21}H^{22}N^2O^2.HCl).Cd''Cl^2$.—White glittering scales, long needles, or large transparent prisms. Does not lose water at 130°. (Galletly.)

Chloromercurate of Strychnine, $C^{21}H^{22}N^2O^2.HCl.Hg''Cl^2$.—A dense pulverulent precipitate, which soon turns gelatinous, is thrown down on adding solution of mercuric chloride to solution of hydrochlorate of strychnine. Crystallises from alcohol. (Nicholson and Abel.)

Strychnine with Mercuric Chloride, $C^{21}H^{22}N^2O^2.Hg''Cl^2$.—Thrown down by a solution of mercuric chloride from a solution of strychnine in weak alcohol. White crystalline precipitate, insoluble in water, alcohol, and ether. (Nicholson and Abel.)

Sulphate of Strychnine with Mercuric Chloride, $2C^{21}H^{22}N^2O^2.H^2SO^4.2Hg''Cl^2$.—Produced by dissolving the mercurous compound in sulphuric acid.

Strychnine with Mercuric Cyanide, $C^{21}H^{22}N^2O^2.Hg''Cy^2$.—An alcoholic solution of strychnine, precipitated by excess of solution of mercuric cyanide, yields this compound in small prisms, slightly soluble in water and alcohol, insoluble in ether. (Nicholson and Abel.)

Chlorate of Strychnine.—Strychnine dissolved in aqueous chloric acid forms a rose-red solution, which yields thin short prisms, and, when the solution is concentrated, solidifies completely.

Chloroplatinate of Strychnine, $2C^{21}H^{22}N^2O^2.2HCl.Pt^{iv}Cl^4$.—Solution of hydrochlorate of strychnine is precipitated pale-yellow by a solution of tetrachloride of platinum. The precipitate is nearly insoluble in water and ether, and with difficulty in boiling alcohol. From the latter solution it crystallises in scales resembling mosaic gold.

Chloropalladite of Strychnine, $2C^{21}H^{22}N^2O^2.2HCl.Pd''Cl^2$.—When a solution of dichloride of palladium is added to a solution of strychnine in hydrochloric acid, a brown flocculent mass is precipitated. It is soluble in water and alcohol, and from a boiling solution in the latter menstruum, may be obtained, on cooling, in dark-brown needles. It is not decomposed at 100°. (Nicholson and Abel.)

Hydrobromate of Strychnine, $C^{21}H^{22}N^2O^2.HBr$.—Produced by dissolving strychnine in hydrobromic acid, and crystallising from water. (Nicholson and Abel.)

Hydriodate of Strychnine, $C^{21}H^{22}N^2O^2.HI$.—A dense crystalline precipitate is thrown down on adding a solution of iodide of potassium to a solution of strychnine (v. Planta). The alcoholic solution, when evaporated, yields glassy four-sided needles. (Merck.)

Hydrochlorate of Strychnine, $C^{21}H^{22}N^2O^2.HCl$.—100 pts. of strychnine, when exposed to a current of hydrochloric acid gas, and then heated to 150°, retain 10·67 of hydrochloric acid (Regnault). The same salt is easily obtained by dissolving strychnine in hydrochloric acid. It is neutral towards vegetable colours (Nicholson and Abel). It rotates polarised light to the left; $[\alpha]_r = 28 \cdot 18°$. The salt is soluble in about 50 pts. of water at 22° (Bouchardat). (As to water of crystallisation, see Gm. xvii. 494.)

Hydrocyanate of Strychnine.—When strychnine is dissolved in aqueous hydrocyanic acid, and the solution is evaporated, the hydrocyanic acid is entirely expelled. (Pelletier and Caventou.)

Hydroferrocyanate of Strychnine, $4C^{21}H^{22}N^2O^2.H^4Fe''Cy^6.2H^2O$.—Colourless needles, produced by mixing cold saturated solutions of ferrocyanide of potassium and neutral salts of strychnine. (Brandis.)

Hydrofluate of Strychnine, $2C^{21}H^{22}N^2O^2.8HFl.H^2O$.—Colourless right rhombic prisms, having an acid reaction. (Elderhorst.)

Hyposulphite of Strychnine, $2C^{21}H^{22}N^2O^2.H^2S^2O^3.4H^2O$.—Formed in a mixture of strychnine, alcohol, and sulphide of ammonium on standing in the air. (How.)

Iodomercurate of Strychnine, $C^{21}H^{22}N^2O^2.HI.Hg''I^2$.—Obtained by mixing solutions of 2 at. hydrochlorate of strychnine, 6 at. iodide of potassium, and 1 at. mercuric chloride. Shining microscopic crystals, insoluble in cold and in hot water, and but little soluble in boiling alcohol. (Groves.)

Nitrate of Strychnine, $C^{21}H^{22}N^2O^2.HNO^3$.—Strychnine in fine powder is gently heated until dissolved with nitric acid, diluted until it is but feebly acid to the taste; the solution, on cooling, deposits beautiful colourless needles of nitrate of strychnine. If the nitric acid is too concentrated, the solution assumes a yellow colour immediately heat is applied, and a nitro-compound is formed. No acid nitrate is produced.

Mellitate of Strychnine.—When an alcoholic solution of strychnine is mixed with an alcoholic solution of mellitic acid, a dazzling white crystalline precipitate falls. It is soluble in 1500 pts. of cold, and in 650 pts. of boiling water; perfectly insoluble in alcohol. (Karmrodt.)

Oxalate of Strychnine.—*Neutral*, $2C^{21}H^{22}N^2O^2.C^2H^2O^4$. Oxalic acid neutralised with strychnine yields long flat needles, neutral to litmus.—*Acid salt*, $C^{21}H^{22}N^2O^2.C^2H^2O^4$. Obtained by treating the neutral oxalate with oxalic acid.

Perchlorate of Strychnine, $C^{21}H^{22}N^2O^2.HClO^4$.—A solution of sulphate of strychnine decomposed by perchlorate of barium yields small, pale-yellow, glassy, rhombic prisms.

Periodate of Strychnine.—Produced by dissolving strychnine in a warm aqueous solution of periodic acid; it crystallises in six-sided prisms terminated by four-sided pyramids.

Phosphantimonate of Strychnine.—Yellowish-white curdy precipitate, produced by adding a solution of phosphantimonic acid to a solution of a strychnine-salt.

Picrate of Strychnine.—An alcoholic solution of picric acid precipitates an alcoholic solution of strychnine pale-yellow; hot solutions, on cooling, yield fine yellow crystals.

Sulphate of Strychnine.—*Neutral*, $2C^{21}H^{22}N^2O^2.H^2SO^4$. Dilute sulphuric acid saturated with finely powdered strychnine (Nicholson and Abel) yields large four-sided prisms. The salt rotates polarised light to the left; $[\alpha]_r = 25 \cdot 58°$ for the salt dried at 40°.—*Acid*, $C^{21}H^{22}N^2O^2.H^2SO^4$. This salt is formed by adding diluted sulphuric acid to the neutral salt; it crystallises in long thin needles, and is very acid to test-paper. (Nicholson and Abel.)

Sulphocyanate, $C^{21}H^{22}N^2O^2.CyHS$.—Sulphocyanate of potassium throws down, from solutions of strychnine-salts, a dense crystalline precipitate; from hot solutions long silky needles. (Artus; v. Planta.)

Tartrates of Strychnine.—*Neutral dextrotartrate*, $2C^{21}H^{22}N^2O^2.C^4H^6O^6 + 4aq$. Tartaric acid is neutralised with strychnine. Efflorescent needles an inch long.—*Acid dextrotartrate.* Strychnine dissolved in excess of tartaric acid yields slender needles with acid reaction.

Antitartrate of Strychnine.—The *neutral salt* heated to 100° loses 7·8 per cent. water, and nothing more at 200°, but becomes coloured, but to a less extent than the dextrotartrate. The *acid salt* loses all its water of crystallisation (10·3 per cent.) more rapidly than the acid dextrotartrate.

Oxystrychnines, iii. 320.

DERIVATIVES OF STRYCHNINE.

Methylstrychnine, $C^{22}H^{24}N^2O^2 = C^{21}H^{21}N^2(CH^3)O^2$.—Finely-powdered strychnine is heated for some hours with slight excess of methylic iodide in a sealed tube. When the reaction is complete, the excess of methylic iodide is distilled off, and the residue is dissolved in hot water and filtered, to remove any uncombined strychnine. On cooling, the solution yields **crystals** of hydriodate of methylstrychnine, from which the base may be separated by means of oxide or sulphate of silver, as follows:—*a. By oxide of silver.*—The hydriodate, prepared as above, is agitated with 3 or 4 pts. of cold water and some oxide of silver, whereby iodide of silver is formed; the liquid then filtered off, and evaporated to the consistence of a syrup, whereupon it deposits crystals of hydrate of methylstrychnine. As the dark mother-liquor cannot be made to crystallise, the following process may be substituted:—*b.* The solution of hydriodate of methylstrychnine is to be decomposed with an equivalent quantity of sulphate of silver; the solution separated from the iodide of silver is mixed with baryta-water, and evaporated to dryness; and the residue is heated with water, and evaporated: crystals of hydrate of methylstrychnine then separate out. As the salt thus obtained contains excess of water, it is to be dried between 130° and 140°. (For very full details concerning the reactions and decompositions of methylstrychnine, see Gm. xvii. 507.)

It is remarkable that hydrate of methylstrychnine is not poisonous. Rabbits can take 11 grains in the course of a day without being poisoned (Stahlschmidt). Hydrate of methylstrychnine forms easily soluble and crystalline salts with acids. Aqueous methylstrychnine precipitates salts of nickel, cobalt, iron, and copper; it also precipitates alum, but an excess does not redissolve the precipitate.

Phosphate of Methylstrychnine, $C^{21}H^{21}N^2(CH^3)O^2.PH^3O^4$.—Aqueous methylstrychnine neutralised with phosphoric acid yields a crystalline mass, readily soluble in water and alcohol. (Stahlschmidt.)

Sulphate of Methylstrychnine.—a. Neutral, $2C^{21}H^{21}N^2(CH^3)O^2.H^2SO^4$.—*Preparation* (see Methylstrychnine, *b*). May also be obtained by neutralising the aqueous base with dilute sulphuric acid. Thin pearly laminæ, efflorescent, easily soluble in water.—*b. Acid salt,* $C^{21}H^{21}N^2(CH^3)O^2.H^2SO^4$. Crystallises easily in laminæ, which have a strongly acid reaction. (Stahlschmidt.)

Hydriodate of Methylstrychnine, $C^{21}H^{21}N^2(CH^3)O^2.HI$. Pearly laminæ, requiring 212 pts. of cold, but easily soluble in hot water. Difficultly soluble in alcohol. (Stahlschmidt.)

Hydrobromate of Methylstrychnine, $C^{21}H^{21}N^2(CH^3)O^2.HBr$.—Thrown down when bromide of potassium is added to a strong solution of the hydrochlorate. Sparingly soluble in cold, but easily in hot water. (Stahlschmidt.)

Hydrochlorate of Methylstrychnine, $C^{21}H^{21}N^2(CH^3)O^2.HCl$.—Formed by neutralising the base with hydrochloric acid, or decomposing the sulphate with chloride of barium. Fine prisms half an inch long, soluble in water and alcohol.

Chloroplatinate of Methylstrychnine.—Pale-yellow precipitate, difficultly soluble in water and alcohol, insoluble in ether.

Ethylstrychnine, $C^{23}H^{26}N^2O^2 = C^{21}H^{21}N^2(C^2H^5)O^2$.—*Preparation.* Similar to that of methylstrychnine, but substituting ethylic for methylic iodide. The base may be precipitated by ether from the solution filtered from oxide of silver.

Carbonates of Ethylstrychnine.—a. Neutral. When moist carbonate of silver is agitated with hydriodate of ethylstrychnine and water, a colourless solution is obtained, which, evaporated in a vacuum, or at 100°, leaves a crystalline residue. Water dissolves carbonate of ethylstrychnine, leaving flocks of a new base (How).—*b. Acid,* $C^{21}H^{21}N^2(C^2H^5)O^2.H^2CO^3$.—When carbonic acid is passed into the solution of the neutral carbonate, and the filtrate is evaporated *in vacuo*, or at 100°, a white crystalline mass is formed, having an alkaline reaction. It dissolves in absolute alcohol, and is precipitated from the solution by ether in colourless prisms. (How.)

Hydriodate of Ethylstrychnine, $C^{21}H^{21}N^2(C^2H^5)O^2.HI$.—Shining white four-sided prisms. (How.)

Nitrate of Ethylstrychnine, $C^{21}H^{21}N^2(C^2H^5)O^2.HNO^3$.—Prepared by decomposing the hydriodate with nitrate of silver. Colourless, highly refractive prisms, only slightly soluble in cold, easily in boiling water. (How.)

Chloroplatinate of Ethylstrychnine, $2C^{21}H^{21}N^2(C^2H^5)O^2.2HCl.Pt^{iv}Cl^4$.—Yellow precipitate, which becomes crystalline in a few hours. (How.)

Amylstrychnine, $C^{21}H^{21}N^2(C^5H^{11})O^2$.—Prepared, like ethylstrychnine, by acting with moist oxide of silver on the hydrochlorate of amylstrychnine. (How.)

Hydrochlorate of Amylstrychnine, $2[C^{21}H^{21}N^2(C^5H^{11})O^2.HCl]H^2O$.—Prepared by heating, for 100 hours, finely-powdered strychnine with chloride of amyl. Colourless, oblique, rhombic prisms. (How.)

Nitrate of Amylstrychnine, $C^{21}H^{21}N^2(C^5H^{11})O^2.HNO^3$.—Prepared by decomposing hydrochlorate of amylstrychnine with nitrate of silver. Radiated groups of colourless needles.

Compounds produced by the action of Dibromide of Ethylene on Strychnine.

Dihydrobromate of Ethylene-strychnine, $C^{21}H^{20}N^2(C^2H^4)O^2.2HBr$.—When strychnine is heated in a sealed tube for a quarter of an hour, with alcohol and excess of dibromide of ethylene, and the resulting crystals are boiled with water until the alcohol and excess of dibromide of ethylene are expelled, the solution, on standing, deposits crystals of this salt. White crystals, only slightly soluble in cold, but easily in hot water and alcohol. The solution is not precipitated by ammonia, potash, or soda. The crystals, treated with acid chromate of potassium and sulphuric acid, yield the same reaction as strychnine (Ménétriès). Treated with silver-salts, the crystals give up half their bromine, but moist oxide of silver removes the whole; thus two series of compounds are formed.

a. Compounds containing Bromine.—An aqueous solution of the crystals is precipitated by sulphate of silver; the excess of silver, and also of sulphuric acid, is removed by baryta-water; carbonic acid is then passed in, and the solution is filtered: the resulting alkaline liquid, evaporated to dryness, leaves a resin, which Ménétriès calls *Hydrated Oxide of Strychnine-bromethyl-ammonium*, and represents by the formula $C^{21}H^{21}N^2(C^2H^4Br)O^2.H^2O$.

Sulphate of Strychnine-bromethyl, $C^{21}H^{21}N^2(C^2H^4Br)O^2.H^2SO^4$.—Obtained by decomposing dihydrobromate of ethylene-strychnine with sulphate of silver.

Nitrate of Strychnine-bromethyl, $C^{21}H^{21}N^2(C^2H^4Br)O^2.HNO^3$.—Obtained by decomposing dihydrobromate of ethylene-strychnine with nitrate of silver. White needles, sparingly soluble in cold, readily in hot water, not decomposed by alkalis.

Platinum-salt, $2C^{21}H^{21}N^2(C^2H^4Br)O^2.2HCl.Pt^{iv}Cl^4$.—Obtained by precipitating the dihydrochlorate with tetrachloride of platinum.

b. Compounds free from Bromine:—

Hydrate of Ethylene-strychnine, $C^{21}H^{20}N^2(C^2H^4)O^2.H^2O$.—Solution of dihydrobromate of ethylene-strychnine, digested with moist oxide of silver, becomes of a reddish colour, and the hydrate is obtained by evaporating the filtered solution. (Ménétriès.)

Trichlorethylene-strychnine, $C^{21}H^{17}Cl^3N^2(C^2H^4)O^2$. — A white frothy substance, obtained by passing chlorine into an aqueous solution of hydrate of ethylene-strychnine. (Ménétriès.)

Nitrate of Nitro-ethylene-strychnine, $C^{21}H^{19}(NO^2)N^2(C^2H^4)O^2.HNO^3$. — When an aqueous solution of hydrate of ethylene-strychnine is mixed with nitric acid, a white crystalline powder is deposited, insoluble in water, but soluble in strong acids; on evaporation with nitric acid, an orange-red substance is formed, which has probably the above formula.

Chlorostrychnine, $C^{21}H^{21}ClN^2O^2$.—When a hot solution of hydrochlorate of strychnine is treated with chlorine-gas, a resin gradually deposits, the solution retaining hydrochlorate of chlorostrychnine. Ammonia is then added to the solution drop by drop, until a small permanent precipitate is formed, the liquid is filtered, and the filtrate is precipitated with ammonia. (Laurent.)

Sulphate of Chlorostrychnine, $2C^{21}H^{21}ClN^2O^2.H^2SO^4$.—Prepared by neutralising dilute sulphuric acid with chlorostrychnine, and obtained in crystals by evaporating the solution.

STRYCHNOCHROME or **STRYCHNOCHROMIN.**—A resinous yellow colouring matter, from the lichens of false Angustura, also from those found on the bark of *Strychnos Pseudochina*, as well as from *Upas Tieuté*. The lichens are exhausted with ether, and then with alcohol; the alcoholic tincture is evaporated; and the residue is boiled repeatedly with water, which dissolves extractive matters, and leaves the yellow. It is a reddish-yellow, tasteless, non-poisonous powder. It dissolves in strong nitric acid with fine green colour, which disappears on diluting the solution with water; but appears again when the liquid is concentrated, and is turned yellow by sulphuric acid and ferrous sulphate. Strong nitric acid also throws down from alcoholic strychnochrome a green precipitate, which loses its colour when washed. Oil of vitriol turns strychnochrome green; strong caustic potash decomposes it.—It is nearly insoluble in boiling water and dilute alkalis; soluble in acetic acid, from which it is precipitated by alkalis; easily soluble, with reddish-yellow colour, in alcohol; and very slightly soluble in ether and volatile oils. (Pelletier, J. Pharm. v. 546.—Pelletier and Caventou, Ann. Ch. Phys. [2], xxvi. 54.)

The strychnine prepared from *Nux-vomica*, *Faba St. Ignatii*, and *Upas Tieuté* obstinately retains a yellow colouring-matter, which remains in solution when an aqueous extract of the upas is precipitated with magnesia, and is obtained as a yellow extract on evaporation. This body is coloured bright-red by strong nitric acid; it dissolves easily in water and alcohol, and is not precipitated by neutral acetate of lead. (Pelletier and Caventou.)

STRYCHNOS. A genus of apocynaceous plants, including several species which yield strychnine and brucine. *Strychnos colubrina*, a tree growing in the Moluccas, yields snake-wood, which contains a large quantity of fatty matter, and, according to Pelletier and Caventou, a certain quantity of strychnine, but less than nux-vomica; it was formerly used as an antidote to the bites of poisonous serpents. The fruit of *Str. Nux-vomica* yields strychnine and brucine. *Str. St. Ignatii* yields the beans of St. Ignatius, which contain strychnine with a very small quantity of brucine. *Str. Tieuté* yields Upas-tieuté, the Javan arrow-poison, which also contains strychnine with traces of brucine. The bark of *Str. Pseudochina*, a tree growing in Brazil, and used there as a febrifuge, is said by Vauquelin not to contain strychnine.

STUDERITE. A fahl-ore occurring in the dolomite of Ausserberg, in the Valais. It is laminar to massive, of uneven fracture, black, of specific gravity 4·65. According to an analysis by Fellenberg (Jahresb. 1865, p. 872), it contains, in 100 parts:

S.	Sb.	As.	Bi.	Cu.	Zn.	Fe.	Pb.	Ag.
24·47	15·58	11·49	0·58	38·17	5·11	2·76	0·88	0·96

STÜBELITE. A mineral found in the island of Lipari, and analysed by A. Stübel (Jahresb. 1865, p. 892). It is amorphous, botryoïdal, kidney-shaped, or encrusted; very brittle, of conchoïdal fracture, and velvet-black to pitch-black colour. Hardness = 4 to 5. Specific gravity = 2·223 to 2·263. Contains:

SiO^2.	Al^2O^3.	Fe^2O^3.	Mn^2O^3.	MgO.	CuO.	Cl.	H^2O.		
26·99	5·37	10·18	21·89	1·03	15·23	0·77	15·85	=	98·31

STYLOBITE. Syn. with GEHLENITE.

STYLOLITES. Peculiar elongated calcareous formations, occurring in the Muschelkalk at Rüdersdorf, near Berlin.

STYLOTYPE. An antimonial fahl-ore from Copiapo in Chile, occurring in groups of four-sided nearly rectangular prisms, probably belonging to the trimetric system. It has an imperfectly conchoïdal fracture, iron-black colour, and black streak. Hardness = 3. Specific gravity = 4·79. Contains:

S	Sb.	Cu.	Ag.	Fe.	Pb, Zn.		
24·30	30·53	28·00	8·30	7·00	trace	=	98·13

agreeing nearly with the formula $3\left\{\begin{matrix}(Cu^2;\ Ag^2)\frac{2}{3} \\ Fe\frac{1}{3}\end{matrix}\right\}.Sb^2S^3$, which is of the general form $3R''S.Sb^2S^3$.

STYPHNIC ACID. Syn. with OXYPICRIC ACID (iv. 317).

STYPTERITE. Native hydrated sulphate of aluminium. (See SULPHATES.)

STYPTICITE. Native basic ferric sulphate. (See SULPHATES.)

STYRACIN. Styrylic or Cinnylic Cinnamate, $C^{18}H^{16}O^2 = \left.\begin{matrix}C^9H^7O \\ C^9H^9\end{matrix}\right\}O$. (i. 986.)

STYRACOL.
STYRACONE. } Syn. with STYRYLIC ALCOHOL (p. 447).

STYRAX. Syn. with STORAX (i. 497).

STYROL. Syn. with CINNAMENE, C^8H^8 (i. 982).

Distyrol, $C^{16}H^{16}$, is produced by heating cinnamic acid with aqueous hydrobromic acid of specific gravity 1·12, or with a mixture of 1 pt. oil of vitriol and 2 pts. water:

$$2C^9H^8O^2 = 2CO^2 + C^{16}H^{16}.$$

It is an oily hydrocarbon, which forms with bromine the crystalline compound, $C^{16}H^{16}Br^2$. It is not converted into metastyrol (metacinnamene, i. 982) by continued heating to 200°. (Erlenmeyer, Ann. Ch. Pharm. cxxxv. 122.)

STYRONE. Syn. with STYRYLIC ALCOHOL.

STYRYL. Syn. with CINNYL, C^9H^9.

STYRYLAMINE. $C^9H^{11}N = N\left\{\begin{matrix}C^9H^9 \\ H^2\end{matrix}\right.$. *Cinnylamine.* (Ramdohr, Zeitschr. f. Pharm. 1858, p. 113; Jahresb. 1858, p. 448.)—A base, produced by heating styrylic chloride with a solution of ammonia in absolute alcohol in sealed tubes to 100° (the tubes are apt to explode at higher temperatures). The resulting hydrochlorate of styrylamine is purified by recrystallisation from water and pressure between paper; and from the aqueous solution of this salt, the base is separated by potash as a bulky precipitate, which, by solution in ether and spontaneous evaporation, is obtained in small colourless crystals.

Styrylamine melts easily to a yellow oil, which volatilises at 100°. The vapours, as well as the ethereal solution, are alkaline. It has a bitter, caustic, very persistent taste, and dissolves readily in ether. The aqueous solution exhibits the following reactions:—With the *nitrates of barium, calcium*, and *magnesium*, in neutral solution, white precipitates; with *ferric chloride*, a brown-red, rather dense precipitate; with *zinc-sulphate*, white, insoluble in excess of the alkali; with *cupric sulphate* and *nickel-sulphate*, greenish-white, insoluble in excess; with *lead-acetate*, white; with *mercuric chloride*, white, bulky; with *silver-nitrate*, no reaction; with *auric chloride*, immediate yellowish-red precipitate; with *platinic chloride*, egg-yellow; with *potassic permanganate*, copious brown precipitate; with *potassic chromate* and *sulphuric acid*, reduction of the chromic acid to chromic oxide; with *potassic sulphocyanate*, slight crystalline precipitate after some time; with *tannin*, an immediate precipitate.

Hydrochlorate of Styrylamine, $C^9H^{11}N.HCl$, crystallises from water in stellate groups of snow-white crystals, belonging to the regular system. The *chloroplatinate*, $2C^9H^{11}N.H^2Cl^2.Pt^{iv}Cl^4$, is an egg-yellow precipitate, sparingly soluble in cold, more easily in hot water, insoluble in alcohol and ether; when heated it melts, blackens, gives off strong-smelling vapours, and leaves a large quantity of charcoal.

STYRYLIC ALCOHOL. $C^9H^{10}O = \left.\begin{matrix}C^9H^9\\H\end{matrix}\right\}O$.—An alcohol produced by distilling styracin (styrylic cinnamate) with caustic potash or soda;—already partly described as CINNYLIC ALCOHOL (i. 992). According to Ramdohr (Zeitschr. f. Pharm. 1858, p. 113; Jahresb. 1858, p. 446), the distillation should be conducted in copper vessels, because glass vessels are liable to be broken by the percussive ebullition, caused by the separation of the alkaline cinnamate produced. The styrylic alcohol passes over with the aqueous vapour, and separates on the water, in the course of a few days, in fine crystals (or, in warm weather, sometimes as an oil, which may remain liquid for a long time). It is somewhat soluble in cold water, less soluble in a strong solution of common salt.

Styrylic alcohol is converted by oxidation into cinnamic aldehyde, C^9H^8O, and cinnamic acid, $C^9H^8O^2$. When poured in the fused state on *platinum-black*, it is converted, after a few days, almost wholly into cinnamic aldehyde (Strecker).—With *chromic acid*, or a mixture of potassic chromate and sulphuric acid, it becomes hot, and yields cinnamic acid, which separates on the surface, and if the liquid be boiled, is further converted into benzoic aldehyde (bitter-almond oil) (Wolff).—Heated with strong *potash-ley* and *peroxide of lead*, it gives off a large quantity of benzoic aldehyde, and the residue contains cinnamic acid; the peroxide of lead is, at the same time, reduced to protoxide, or sometimes even to metal (Wolff).—With *potash and carbonic disulphide*, it yields a salt analogous to xanthate of potassium (Scharberg).—When heated with *nitric acid*, it dissolves, and is slowly attacked, a large quantity of nitrous acid being evolved, benzoic aldehyde distilling over, and benzoic acid remaining behind. If the formation of nitrous acid be prevented by addition of urea, a smaller quantity of benzoic aldehyde is formed, and the residue contains nitro-cinnamic acid. (For the other reactions see the next article.)

STYRYLIC ETHERS. (Ramdohr, *loc. cit.*)—*Styrylic Acetate*, $C^2H^3(C^9H^9)O^2$, is produced by the action of acetic chloride on the alcohol; it distils without decomposition.—*Styrylic Benzoate*, $C^7H^5(C^9H^9)O^2$, produced in like manner is crystalline, but not volatile without decomposition.

Styrylic Chloride, C^9H^9Cl.—When dry hydrochloric acid gas is passed into crystallised styrylic alcohol, the latter becomes liquid, and separates into two layers; and on heating the product to 100°, washing with dilute soda-ley, and drying with calcic chloride, styrylic chloride is obtained as an oil of light wine-yellow colour, smelling of cinnamon and anise-oils, remaining liquid at −19°, and decomposed by distillation, even in a vacuum.

Heated with cyanide of potassium, either in open vessels or to 100° in sealed tubes, it yields a reddish oil, which quickly decomposes, with formation of a resinous mass, and cannot be purified by distillation.

Styrylic Cinnamate, $C^9H^{16}O^2 = C^9H^7(C^9H^9)O^2$.—Syn. with Cinnylic Cinnamate or Styracin (i. 986).

Styrylic Cyanide, $C^{10}H^9N = C^9H^9.CN$, is produced by heating styrylic iodide with an alcoholic solution of potassic cyanide to 100° in sealed tubes; on opening the tubes, a strong odour of cyanogen becomes perceptible, and an oily layer separates on cooling. Addition of water renders the contents of the tubes milky, and, on further adding common salt, the styrylic cyanide separates as a yellowish oil, easily soluble in ether, sparingly in alcohol, insoluble in water. When heated with potash, it gives off ammonia, and becomes resinised, but does not appear to yield an acid homologous to cinnamic acid.

Styrylic Iodide, C^9H^9I, is produced by the action of iodide of phosphorus on styrylic alcohol. The action takes place without aid of heat; the styrylic alcohol melts, and the mixture, when warmed, separates into two layers, the upper of which consists of styrylic iodide, to be purified like the chloride. It is heavier than water; has an aromatic odour, and burning taste; cannot be distilled, either alone or with water.

Styrylic Oxide, $(C^9H^9)^2O$, is produced by the action of boric anhydride on styrylic alcohol. When the two substances are triturated together, the alcohol first melts, and the mixture solidifies; and on heating it in sealed tubes to 100°, for five or six hours, the formation of the styrylic oxide is completed; the product may be freed from boric acid by means of soda-solution.—Styrylic oxide is a light-yellow viscid oil, having an odour of cinnamon, heavier than water, partially decomposed by distillation.

Styryl-ethylic Oxide, $C^9H^9.C^2H^5.O$, produced by the action of sodic ethylate on styrylic chloride, is a liquid heavier than water, insoluble therein, easily soluble in alcohol and ether, and distilling at a very high temperature.

Styrylic Sulphide, $(C^9H^9)^2S$, obtained by mixing the alcoholic solutions of styrylic chloride and potassic monosulphide, is a yellowish, fetid, non-distillable oil.

STYRYLINE. The name given by Chiozza to a base, C^9H^9N, probably formed by the action of ammonium-sulphide on metastyrol (i. 983).

SUBERAMIC ACID. $C^8H^{15}NO^3 = \left.\begin{matrix} H^2 \\ (C^8H^{12}O^2)'' \\ H \end{matrix}\right\} \begin{matrix} N \\ O \end{matrix}$.—Produced by the dry distillation of ammonium-suberate. It is fusible, soluble in boiling water, and deposited therefrom on cooling. On boiling it with barium-carbonate, and treating the filtrate with silver-nitrate, a gelatinous precipitate is formed, containing 38 per cent. silver, agreeing approximately with the formula $C^8H^{14}AgNO^3$, which requires 38·57 per cent. silver. (Gerhardt, Compt. chim. 1845, p. 178.)*

SUBERAMIDE. $C^8H^{16}N^2O^2 = N^2(C^8H^{12}O^2)^{11}.H^4$.—White crystalline substance, produced by the action of aqueous ammonia on methylic suberate, or by passing ammoniacal gas into an alcoholic solution of ethylic suberate. (Laurent, J. pr. Chem. xxvii. 313.)

SUBERANILIC ACID *Phenyl-suberamic Acid*, $C^{14}H^{19}NO^3 = \left.\begin{matrix} C^6H^5.H \\ (C^8H^{12}O^2)'' \\ H \end{matrix}\right\} \begin{matrix} N \\ O \end{matrix}$. (Laurent and Gerhardt, Ann. Ch. Phys. [3] xxiv. 185.)—Produced, together with suberanilide, by melting suberic acid with an equal volume of dry aniline. When the alcoholic liquid from which suberanilide is precipitated by water, is evaporated till the alcohol is driven off, a brownish oil separates, which solidifies on cooling. This oil is dissolved in boiling ammonia, which leaves a certain quantity of suberanilide, and filtered; from the filtrate hydrochloric acid precipitates colourless suberanilic acid. If during the boiling a slight excess of hydrochloric acid be added, suberanilic acid will separate on cooling, partly crystalline, and partly as a pale-yellowish oil, which afterwards solidifies.

The acid forms microscopic laminæ, irregularly notched, melts at 128°, becoming crystalline on cooling. It is not soluble in cold, and but slightly soluble in hot water. It dissolves readily in ether. The solution in hot water reddens litmus. By dry distillation it yields much charcoal, and a thick oil containing aniline, which partly solidifies on cooling. Fused with potash it yields aniline.

Suberanilate of Ammonium.—The acid dissolves easily in hot ammonia, and the salt is deposited in small granular crystals, whose aqueous solution is not coloured by chloride of lime.

The ammonium-salt precipitates *chloride of barium*; the precipitate dissolves readily in boiling water, and separates on cooling in woolly flakes. With *chloride of calcium* it gives a white precipitate, soluble in hot water; with *lead-salts* a white precipitate, insoluble in water. It precipitates *ferrous salts* yellowish-white, *cupric salts* light-blue, the precipitate being insoluble in water; with *silver-nitrate* a white precipitate, insoluble in water, and turning violet on exposure to light.

SUBERANILIDE. *Phenyl-suberamide.* $C^{20}H^{24}N^2O^2 = \left.\begin{matrix} (C^8H^{12}O^2)'' \\ (C^6H^5)^2 \\ H^2 \end{matrix}\right\} N^2$. (Laurent and Gerhardt, *loc. cit.*)—When equal measures of dry aniline and fused suberic acid are melted together, water is produced. The mixture is kept melted for ten minutes near the boiling heat; and an equal bulk of alcohol is then added, which immediately dissolves the mixture. After a few minutes the solution solidifies to a mass of crystals, which are dissolved in more boiling alcohol, and the solution is left to stand, whereupon most of the suberanilide crystallises out. The rest is precipitated by water, suberanilic acid remaining in solution.

---

* In his *Traité de Chimie organique* (ii. 735), published in 1854, Gerhardt states, however, that suberamic acid has not yet been obtained.

Suberanilide crystallises from alcohol in pearly laminæ. It melts at 183°, and crystallises on cooling. It is but slightly soluble in cold alcohol, but dissolves readily in boiling alcohol and in ether.

When subjected to dry distillation, it leaves a small quantity of charcoal, and yields an oil, which solidifies on cooling, and crystallises from a hot alcoholic solution in pearly laminæ, which however present a different appearance under the microscope, and seem to be somewhat rounded. Gently heated with hydrate of potassium, it immediately gives off aniline. It is not attacked by ammonia, or by boiling solution of potash.

SUBERIC ACID. $C^8H^{14}O^4 = \left.\begin{matrix}(C^8H^{12}O^2)''\\ H^2\end{matrix}\right\}O^2$.—*Korksäure.* (Brugnatelli, Crell. Ann. 1787, i. 145.—Bouillon Lagrange, Ann. Chim. xxiii. 2; J. Pharm. viii. 107.—Chevreul, Ann. Chim. lxii. 323; xcvi. 182.—Brandes, Schw. J. xxxii. 393; xxxiii. 83; xxxvi. 263; Ann. Ch. Pharm. ix. 295.—Bussy, J. Pharm. viii. 107; xix. 425.—Boussingault, J. pr. Chem. vii. 211.—Harff, N. Br. Arch. v. 303.—Laurent, Ann. Ch. Phys. [2], lxvi. 157.—Bromeis, Ann. Ch. Pharm. xxxv. 89.—Tilley, *ibid.* xxxix. 166.—Sacc, *ibid.* li. 222.—Wirtz, *ibid.* civ. 261.—Arppe, *Oxidation of Fats by Nitric Acid*, Ann. Ch. Pharm. cxv. 143; cxx. 288: Jahresb. 1860, p. 246; 1861, p. 357; 1864, p. 377.—Gm. xiii. 204.)

This acid, belonging to the oxalic series, $C^nH^{2n-2}O^4$ (i. 52), was first obtained by the action of nitric acid upon cork (Brugnatelli): hence its name (from the Latin *suber*). It is also produced, together with several other acids of the same series, by the oxidising action of nitric acid on various fatty bodies—*e.g.* oleic acid (Laurent), stearic acid (Bromeis), castor-oil (Tilley), linseed-oil (Sacc), cocoanut-oil (Wirtz); lastly, it is produced by the action of nitric acid on suberone (p. 450).

It is most easily prepared by treating commercial stearic or oleic acid, or castor-oil, with nitric acid, in the manner described under LEPARGYLIC ACID (iii. 571) and PIMELIC ACID (iv. 646). The resulting acid solution, when duly concentrated, yields a white granular mass, which, when freed from oxalic acid by washing with cold and recrystallisation from warm water, and from other more soluble acids by melting the crystals, pulverising the fused mass, and treating the powder with water, yields a mixture of azelaic (lepargylic) and suberic acids; and on treating this residue with cold ether, the azelaic acid is dissolved, while the suberic acid remains behind. Further purification may be effected by repeated treatment with water and ether successively.

Pure suberic acid crystallises, according to Arppe, in needles an inch long, or in tabular crystals (six-sided tables of 120°, apparently belonging to the hexagonal system). It melts at 140°, solidifies in transparent sharp needles, and sublimes between 150° and 160°, with partial decomposition, in slender needles half an inch long. It dissolves sparingly in cold, easily in boiling *water*, more easily in *alcohol* than in water, sparingly in *ether;* sparingly in cold, easily in warm *oil of turpentine*, and mixes with *fixed oils*.

Suberic acid, when heated in a test-tube, gives off suffocating vapours, condensing into drops which become solid and crystalline. It is decomposed by prolonged boiling with *nitric acid*, forming an oily acid, which has the odour of butyric acid (Sacc). Distilled with 4 pts. *manganic peroxide*, 1 pt. oil of vitriol, and 1 pt. water, it yields an acid distillate, smelling of formic acid (Brandes). Distilled with excess of *lime*, it yields suberone (p. 450), together with other products. Distilled with excess of *baryta*, it yields at 80° a liquid distillate, from which by rectification a hydrocarbon is obtained, having the composition C^6H^{14}, and boiling at 76°; $C^8H^{14}O^4 = 2CO^2 + C^6H^{14}$ (Riche, Ann. Ch. Pharm. cxiii. 105). According to R. S. Dale (Chem. Soc. J. [2] ii. 258), the acid distilled with anhydrous or hydrated baryta yields, at a temperature near redness, a yellowish oil, from which, by treatment with a mixture of nitric and sulphuric acids, and subsequent rectification, a hydrocarbon, C^6H^{14}, is obtained, agreeing in properties with hexylic hydride obtained from coal-tar, excepting that the somewhat lower specific gravity (0·6617 at 17·5°) brings it nearer to the β-hexylic hydride discovered by Wanklyn and Erlenmeyer (iii. 153).

Suberic acid fused with *aniline* yields suberanilide and suberanilic acid (p. 448).

Suberates.—Suberic acid is dibasic, the formula of its normal salts being $C^8H^{12}M^2O^4$ or $C^8H^{12}M''O^4$. The suberates of the alkali-metals, earth-metals, zinc, and manganese are more or less soluble in water; and from their solutions, the suberic acid is precipitated by stronger acids as a white powder. They are decomposed by distillation, yielding a white sublimate of the acid.

The aqueous solution of suberic acid does not precipitate any metallic salt except neutral acetate of lead. When saturated with ammonia, it precipitates the solutions of barium-, calcium-, and strontium-chlorides only on addition of alcohol, but forms an immediate white precipitate in solutions of the neutral salts of silver, mercury, zinc, and tin—bluish-green with cupric sulphate, red-brown with ferric sulphate.

The composition and physical characters of the suberates, as determined by Arppe, are as follows:

Neutral suberate of sodium	$2C^8H^{12}Na^2O^4.H^2O$	warty or dendritic aggregates.
Acid „	$C^8H^{13}NaO^4$	tufts of needles.
Suberate of barium	$C^8H^{12}Ba''O^4$	crystalline precipitates.
„ strontium	$C^8H^{12}Sr''O^4$	
„ calcium	$2C^8H^{12}Ca''O^4.H^2O$	
„ magnesium	$C^8H^{12}Mg''O^4.3H^2O$	warty crystalline aggregates.
„ aluminium	. . . .	white amorphous powder.
„ zinc	$C^8H^{12}Zn''O^4$	fine granular precipitate.
„ manganese	$C^8H^{12}Mn''O^4.3H^2O$	light-red crystalline spangles.
„ „	$C^8H^{12}Mn''O^4$	produced on boiling.
„ copper	$C^8H^{12}Ca''O^4.H^2O$	green precipitate.
„ silver	$C^8H^{12}Ag^2O^4$	white precipitate.
„ lead	$C^8H^{12}Pb''O^4$	white precipitate.
„ „ (basic)	$C^8H^{12}Pb''O^4.2Pb''O$	produced on boiling with ammonia.

SUBERIC ETHERS. *Ethylic Suberate*, $C^{12}H^{22}O^4 = \left.\begin{matrix}(C^8H^{12}O^2)''\\(C^2H^5)^2\end{matrix}\right\}O^2$, is obtained by heating suberic acid with alcohol and sulphuric or hydrochloric acid, or by passing hydrochloric acid gas into an alcoholic solution of suberic acid. It is a limpid liquid, having a faint odour and nauseous taste. Specific gravity = 1·003 at 15°. Boils without decomposition at 230° (Bromeis), at 260° (Laurent). It mixes in all proportions with alcohol and ether. It is scarcely attacked by aqueous potash, but alcoholic potash quickly decomposes it. With alcoholic ammonia it yields suberamide (p. 448). By chlorine it is slowly converted into chlorethylic suberate, $C^{12}H^{20}Cl^2O^4$. (Laurent.)

Methylic Suberate, $C^{10}H^{18}O^4 = \left.\begin{matrix}(C^8H^{12}O^2)''\\(CH^3)^2\end{matrix}\right\}O^2$.—Prepared like the ethyl-compound which it resembles. Specific gravity = 1·014 at 18°. Forms suberamide with ammonia. (Laurent.)

SUBERIN. Cellulose from cork.

SUBERONE. *Hydride of Suberyl.*—When suberic acid is distilled with excess of lime, a distillate is obtained, which yields by rectification an aromatic liquid boiling at 176°, and probably consisting of suberone, the ketone of suberic acid, $C^{14}H^{24}O^2 = (C^8H^{12}O^2)''(C^6H^{12})''$—its formation taking place thus:

$$2C^8H^{14}O^4 = 2CO^2 + 2H^2O + C^{14}H^{24}O^2.$$

Its composition has not, however, been ascertained with certainty, and, moreover, it differs from ketones in general in being converted into suberic acid by the action of nitric acid. (Boussingault, Ann. Ch. Pharm. xix. 308.—Tilley, *ibid.* xxxix. 167.)

SUBERYL. $C^8H^{12}O^2$.—The diatomic radicle of suberic acid, &c. Boussingault applied the same term to the radicle $C^8H^{12}O$, which he supposed to exist in the so-called suberone, that compound having, according to his analysis, the composition $C^8H^{14}O = (C^8H^{12}O)''H^2$.

SUBLIMATE. A body obtained in the solid state by the cooling of its vapour—*e. g.* sulphur, iodine, sal-ammoniac, mercuric chloride (corrosive sublimate, &c.)

SUBRUBRIN. The name applied by O'Shaughnessy (Ann. Ch. Pharm. xv. 265) to a faintly reddish body, which he obtained from blood-serum by mixing it with alcohol, filtering, and heating the turbid filtrate; but its separate identity is not established by any satisfactory evidence.

SUBSTITUTION. Under the head of EQUIVALENTS, frequent allusion has been made to the substitution of one element for another. Substitution is, in fact, the great agent of chemical change. The instances in which compounds are formed by direct union of their elements, ultimate or proximate, or decomposed by direct separation of those elements, are comparatively rare; and even these may often be regarded as particular cases of substitution (see CHEMICAL AFFINITY, i. 857): thus the formation of hydrochloric acid, when chlorine and hydrogen come in contact, may be supposed to take place by an interchange of these elements between a molecule of chlorine and a molecule of hydrogen, each consisting of two atoms:

$$\overset{-}{Cl}\overset{+}{Cl} + \overset{-}{H}\overset{+}{H} = HCl + HCl.$$

The following are the most important cases of substitution:—

1. Of *Chlorous* or *Acid Radicles* for *Hydrogen.*—Chlorine and bromine may, in many instances, be introduced into hydrogen-compounds (chiefly organic) by direct substitution, 1 atom of hydrogen being removed and entering into combination with 1 at. chlorine or bromine, while another atom of the haloïd element takes the place of the hydrogen removed. Thus, when chlorine acts upon marsh-gas (methylic hydride), the products are hydrochloric acid and methylic chloride:

$$CH^4 + Cl^2 = HCl + CH^3Cl;$$

and by the continued action of the chlorine, the latter compound may be converted, successively, into CH^2Cl^2 and $CHCl^3$, the last being the compound usually called chloroform. In like manner, acetic and treated with chlorine in sunshine, in different proportions, yields mono- and tri-chloracetic acid:

$$C^2H^4O^2 + Cl^2 = HCl + C^2H^3ClO^2.$$
$$C^2H^4O^2 + 3Cl^2 = 3HCl + C^2HCl^3O^2.$$

Iodine does not act on hydrogen-compounds so easily as chlorine and bromine; but when it is presented in the form of chloride or bromide of iodine, an action takes place exactly similar to that just described, an atom of hydrogen being removed by the chlorine or bromine, and its place supplied by an atom of iodine: *e.g.*—

$$C^5H^4O^3 + ClI = HCl + C^5H^3IO^3.$$

Pyromeconic acid. Iodopyromeconic acid

In some cases an organic compound first unites directly with 2 at. chlorine or bromine, and the product, when treated with alcoholic potash, splits up into hydrochloric or hydrobromic acid (which is removed by the alkali), and a chloro- or bromo-substitution-product: thus ethylene takes up 2 at. chlorine, forming the compound, $C^2H^4Cl^2$ (Dutch liquid), which is resolved by alcoholic potash into HCl and monochlorethylene, C^2H^3Cl. This in like manner takes up 2 at. Cl, forming $C^2H^3Cl^3$, resolvable into HCl and dichlorethylene, $C^2H^2Cl^2$; and by a repetition of these processes, the compounds C^2HCl^3 and C^2Cl^4 are obtained (ii. 573). The chloro- and bromo-naphthalenes are prepared from naphthalene by a similar series of processes (iv. 10).

Oxygen may be substituted for hydrogen (O'' for H^2 or HO for H), by exposing organic compounds to the action of oxidising agents, a familiar example of which is the conversion of alcohol, C^2H^6O, into acetic acid.

Nitro-substitution, or the substitution of nitryl, NO^2, for hydrogen, is effected by subjecting organic compounds to the action of fuming nitric acid, or of a mixture of strong nitric and sulphuric acids, as in the conversion of cellulose into pyroxylin.

Allied to this is the substitution of nitrogen for hydrogen (N for H^3), by the action of nitrous acid on certain organic compounds, as in the formation of the diazo-compounds discovered by Griess (iv. 292, 460): thus aniline, C^6H^7N, is converted by the action of nitrous acid into diazobenzene, $C^6H^4N^2$:

$$C^6H^7N + NHO^2 = C^6H^4N^2 + 2H^2O.$$

2. Of *Hydrogen* and other *Basylous Radicles* for *Chlorous Radicles.*—This reaction, sometimes called inverse substitution, is effected by the action of reducing agents. Chlorinated acids are easily reduced to the primary acids from which they are derived by the action of sodium-amalgam; the first transformation of the kind that was effected was that of trichloracetic into acetic acid. The conversion of nitro-compounds into amidogen-compounds (substitution of NH^2 for NO^2), by the action of sulphydric acid or ferrous acetate, also comes under this head. The well-known preparation of amidobenzene (aniline), $C^6H^5(NH^2)$, from nitrobenzene, $C^6H^5(NO^2)$, may be taken as an example.

An important class of reactions belonging to this head is the substitution of alcohol-radicles for chlorine, oxygen, &c. by the action of the zinc-compounds of the alcohol-radicles: *e.g.*, the preparation of triethylphosphine, $P(C^2H^5)^3$, by the action of zinc-ethyl on trichloride of phosphorus:

$$3Zn''(C^2H^5)^2 + 2PCl^3 = 3ZnCl^2 + 2P(C^2H^5)^3.$$

Another example of this kind of action is the formation of diethoxalic acid and its homologues, by the action of zinc-ethyl, &c. on the oxalic ethers (iv. 272).

3. Of *Basylous* or of *Chlorous Radicles, one for the other.*—To this head belong the innumerable instances of the mutual decomposition of salts, and of double decomposition in general (CHEMICAL AFFINITY, i. 855); also, on the one hand, the precipitation of metals from their solutions, one by the other (as of copper by iron, lead by zinc, &c.), the decomposition of acids by metals, with evolution of hydrogen; and, on the other, the decomposition of bromides and iodides by chlorine, and of iodides by bromine—the

conversion of sulphides into oxides by direct oxidation, &c. Many of these reactions appear to consist in a simple substitution of one element for another, which is eliminated without entering into any new combination. But, on closer examination, they are found to be, at least in some cases, analogous to the chlorine-substitutions already considered. In the oxidation of sulphides, for example, a considerable portion, if not all, of the sulphur eliminated is oxidised to sulphurous anhydride; in the decomposition of bromides and iodides by chlorine, the latter, if in excess, unites with the eliminated bromine or iodine; and even in the precipitation of one metal by another, alloys are frequently formed, as in the precipitation of silver by mercury.

An important class of reactions belonging to this place is the substitution of alcohol-radicles for hydrogen and metals, as in the several processes of etherification by the action of acids on alcohols, of alcoholic chlorides, iodides, &c., on alcohols, and on the silver-salts of acids (see Ethers, ii. 511, 512). The formation of amines, or, in other words, the replacement of the hydrogen in ammonia by alcohol-radicles, may be effected directly, as when an alcoholic iodide is heated with ammonia in sealed tubes (ii. 554, iii. 994); or by indirect methods, as by distilling cyanic or cyanuric ethers with caustic alkali.

Most of the methods of producing organo-metallic bodies, consist in acting on alloys of potassium or sodium with the alcoholic iodides, bromides, &c.: *e.g.*—

$$\underset{\substack{\text{Methylic}\\\text{iodide.}}}{2(CH^3)I} + Na^2Hg'' = \underset{\substack{\text{Mercuric}\\\text{methide.}}}{(CH^3)^2Hg''} + 2NaI;$$

or by acting on a metallic chloride with the zinc-compound of an alcohol-radicle: *e.g.*—

$$Zn''(C^2H^5)^2 + Hg''Cl^2 = Hg''(C^2H^5)^2 + Zn''Cl^2.$$

Substitution-derivatives often exhibit a marked resemblance to their primitives in physical and chemical characters. That this should be the case in bodies formed from one another by the interchange of similar elements or radicles—such as hydrogen and the metals on the one hand, or chlorine, bromine, and iodine on the other—is nothing more than might have been anticipated on any view of the constitution of chemical compounds; but that a radicle of decidedly acid or chlorous character, like chlorine, bromine, or iodine, should be capable of replacing hydrogen atom for atom, and discharging functions similar to that of the hydrogen in the primary compound, is the doctrine of a comparatively recent date, and is, in fact, diametrically opposed to the older views of the constitution of compounds, founded on the electrical relations of their elements. The resemblance of such derivatives to their primitives is, however, strikingly exhibited in numerous instances. Take, for example, acetic and trichloracetic acid. These two acids are both crystallisable, deliquescent, soluble in water and alcohol, have the same capacity for saturation, yield analogous salts and ethers, &c. Dilute trichloracetic acid treated with amalgam of sodium, is reconverted into normal acetic acid; and the two acids, when heated with caustic alkali, are decomposed according to similar equations, yielding the two analogous bodies, marsh-gas and chloroform, thus:

Acetic acid . . . $C^2H^4O^2 = CO^2 + CH^4$ Marsh-gas.
Trichloracetic acid . $C^2HCl^3O^2 = CO^2 + CHCl^3$ Chloroform.

Similar resemblances may be traced between isatin and its derivatives (iii. 406). Thus isatin and chlorisatin are both of an orange-red colour, are isomorphous, partly volatile, slightly soluble in water, more soluble in alcohol and ether; form yellow solutions; and react with hydrate of potassium, by exchanging an atom of hydrogen for one of potassium, to form analogous salts, each of which speedily absorbs an atom of water into its constitution, to form the isatinate and chlorisatinate of potassium respectively. Moreover the two bodies, when acted upon by sulphydrate of ammonium, ammonia, and alkaline bisulphites, yield hosts of analogous compounds, and undergo hosts of analogous reactions. Isatin, chlorisatin, and dichlorisatin treated with hydrate of potassium, yield respectively the bodies, aniline, C^6H^7N, chloraniline, C^6H^6ClN, dichloraniline, $C^6H^5Cl^2N$, each of which, despite the constituent chlorine, has alkaline characters analogous to those of ammonia, and can unite directly with acids to form salts.

The chlorinated derivatives of the natural alkaloïds also resemble the primary alkaloïds in many important respects. Thus dichlorocinchonine, $C^{20}H^{22}Cl^2N^2O$, formed from cinchonine by the direct action of chlorine, resembles the normal base, not only in alkalinity, solubility, crystalline form, &c., but likewise in turning the plane of polarisation of a luminous ray to the left. Chlorostrychnine also, $C^{21}H^{21}ClN^2O^2$, obtained from strychnine or its salts by direct substitution of chlorine, produces poisonous effects, undistinguishable from those of the natural alkaloïd.

From the observation of such resemblances, Dumas and Laurent were led to conclude that elements, even of opposite chemical character, may in many instances replace one another, with but little alteration in the character of the products, and that the properties of a compound are determined by the arrangement and relative position of its atoms more than by their individual character. That this is the case to a considerable extent, is evident from the instances just cited; nevertheless, the question is altogether one of degree. Substitution is always attended with some alteration of properties in the compound, and the alteration goes on increasing with the amount of the substitution. Thus in volatile compounds, such as ethylene, C^2H^4, and its chlorinated derivatives, C^2HCl^3, $C^2H^2Cl^2$, C^2HCl^3, and C^2Cl^4, the vapour-density increases, and the boiling-point rises with each successive replacement of H by Cl. Again, in the chloranilines (iv. 438), the first substitution-product, C^6H^6ClN, is somewhat less basic than aniline itself; while dichloraniline, $C^6H^5Cl^2N$, is still less basic, and in trichloraniline, $C^6H^4Cl^3N$, the basic character has altogether disappeared.

The substitution of alcohol-radicles, such as ethyl and methyl, for the hydrogen of ammonia, gives rise to amines, which are basic like ammonia itself; but in the amides derived from ammonia by substitution of acid-radicles (benzoyl, acetyl, &c.) for hydrogen, the basic character gives place for the most part to an acid character, the amide, if it still retains replaceable hydrogen, exhibiting a tendency to exchange it for a metal. (For the further consideration of this subject, see TYPES.)

SUCCINAMIC ACID, SUCCINAMIDE, SUCCINANIL, SUCCINANILIC ACID, SUCCINANILIDE. See SUCCINIC ACID, AMIDES OF.

SUCCINASPHALT. A resinous substance resembling amber, and apparently related to retinite, obtained from the granular clay iron-ore of Bergen in Bavaria. (Wagner, *Handw. d. Chem.*, viii. 414.)

SUCCINEUPIONE. A name applied by Elsner to a very light oil, obtained by rectifying oil of amber with sulphuric acid.

SUCCINIC ACID. $C^4H^6O^4 = \left.\begin{matrix}(C^4H^4O^2)''\\H^2\end{matrix}\right\}O^2$. *Volatile Salt of Amber. Bernsteinsäure.* (Berzelius, Ann. Chim. xciv. 187.—Lecanu and Serbat, J. Pharm. viii. 541; ix. 89.—Liebig and Wöhler, Pogg. Ann. xviii. 162.—D'Arcet, *ibid.* xxxvi. 80.—Döpping, Ann. Ch. Pharm. xlvii. 253.—Fehling, *ibid.* xlix. 154.—Piria, *ibid.* lxviii. 343.—Dessaignes, *ibid.* lxx. 102.—Pasteur, *ibid.* cv. 264.—Maxwell Simpson, *ibid.* cxviii. 373.—Gm. x. 108.—Gerh., ii. 454.—Kekulé, *Lehrb.* ii. 23.)

This acid, the third of the series of dibasic acids, $C^nH^{2n-2}O^4$, homologous with oxalic acid, was mentioned as *volatile salt of amber* by Agricola, as early as 1657; its acid nature was recognised by Barchhusen, Bouldüc, and Boerhaave; but the first exact investigations of it were made by Berzelius and by D'Arcet.

Succinic acid occurs ready-formed in amber, and in certain lignites, as in those of Muskau, Naumberg, and Altenburg. It has also been found in the turpentine of several species of pine, and in certain plants—viz., in the herb of *Lactuca virosa, Artemisia Absinthium*, &c. According to Walz (N. Jahrb. f. Pharm. xv. 22), the chelidoninic acid found by Zwenger in the mother-liquor of the preparation of chelidonic acid from *Chelidonium majus* (i. 850), is nothing but succinic acid. It is also occasionally found in the animal organism—*e.g.*, in the thymoïd gland of the calf, the spleen of the ox, (Gorup-Besanez), and in certain pathological exudations (Heintz). According to G. Meissner and F. Jolly (Jahresb. 1865, p. 675), it occurs in the urine of dogs fed on flesh and fat, and in that of rabbits fed on carrots.

Formation.—1. Succinic acid is a frequent product of the oxidation of organic substances, especially of fats. All the fatty acids of the series, $C^nH^{2n}O^2$, from butyric acid upwards, when oxidised with nitric acid, yield succinic acid, together with other acids of the same series (p. 449). Its formation from butyric acid is represented by the equation:

$$C^4H^8O^2 + O^3 = H^2O + C^4H^6O^4.$$

According to Pasteur (Bull. Soc. Chim. 1852, p. 52), it is always formed during the conversion of alcohol into acetic acid under the influence of *Mycoderma aceti*, especially when the plant grows on the surface of the alcoholic liquid containing phosphates.

2. By the action of reducing agents on malic acid or its isomer, fumaric acid, which contains 2 at. hydrogen less, or on maleic and tartaric acids, which contain respectively 1 and 2 at. oxygen more than succinic acid.

a. By the action of sodium-amalgam on maleic or fumaric acid:

$$\underset{\substack{\text{Maleic}\\\text{acid.}}}{C^4H^4O^4} + Na^2Hg = Hg + \underset{\substack{\text{Succinate}\\\text{of sodium.}}}{C^4H^4Na^2O^4}.$$

Chloromaleic acid, $C^4H^3ClO^4$ (iii. 788), is also converted into succinic acid by the action of sodium-amalgam:

β. From malic or tartaric acid by the action of hydriodic acid (**R. Schmitt**, Ann. Ch. Pharm. cxiv. 106), or of iodide of phosphorus (**Dessaignes**, *ibid.* cxv. 120; cxvii. 134):

$$\underset{\text{Malic acid.}}{C^4H^6O^5} + 2HI = H^2O + I^2 + \underset{\text{Succinic acid.}}{C^4H^6O^4}.$$

$$\underset{\text{Tartaric acid.}}{C^4H^6O^6} + 4HI = 2H^2O + 2I^2 + \underset{\text{Succinic acid.}}{C^4H^6O^4}.$$

3. In many processes of fermentation, *e.g.*, of asparagin (**Piria**), malic, maleic, fumaric, and aconitic acids (**Dessaignes**), and of sugar, whence it is constantly present, to a small amount, in wine and beer (**Pasteur**). Its formation from malic, maleic, or fumaric acid is probably a simple process of reduction. Its formation from asparagin may be represented by the equation:

$$C^4H^8N^2O^3 + 3H^2O - O^2 = 2NH^3 + C^4H^6O^4.$$

4. By heating cyanide of ethylene to 100° with alcoholic potash (**Maxwell Simpson**, Ann. Ch. Pharm. cxviii. 373):

$$C^2H^4(CN)^2 + 2KHO + 2H^2O = 2NH^3 + C^4H^4K^2O^4.$$

This reaction is precisely analogous to that by which the monobasic acids of the series, $C^nH^{2n}O^2$, are formed from the cyanides of monatomic alcohols (ii. 202). Cyanide of ethylene is also converted into succinic acid by heating with nitric or hydrochloric acid. (**Simpson**, *ibid.* 153.)

Preparation: 1. *From Amber.*—This substance, subjected to dry distillation, yields succinic acid and a volatile oil, together with water and a small quantity of a resinous substance called *Colophonium succini*. On heating the watery distillate to the boiling-point, and filtering hot, a large quantity of oil remains behind; and the solution, on cooling, yields crystallised succinic acid, contaminated however with a considerable quantity of empyreumatic oil, from which it may be freed for the most part, but not perfectly, by repeated crystallisation. Complete purification is, however, easily effected by treating the crude succinic acid with nitric acid.

2. *By fermentation of Malic Acid.*—This is the most advantageous mode of preparing succinic acid, the crude malate of calcium, obtained by neutralising the juice of mountain-ash berries with chalk or slaked lime, being generally used for the purpose. A mixture of 1 pt. of this salt with 6 pts. water and ½ pt. yeast, or 3 pts. water and $\frac{1}{12}$ pt. decayed cheese, is placed in an earthen jar, and left for four to six days at a temperature of 30° to 40°, till the evolution of gas has ceased. The granular precipitate is then collected upon linen, washed several times with water, and mixed with dilute sulphuric acid till it no longer effervesces (from admixed calcic carbonate); another equal quantity of sulphuric acid is then added; the mixture boiled for awhile, till the calcium-salt is no longer granular; the liquid strained through linen; the precipitate on the filter thoroughly washed; the whole of the liquid evaporated till a crystalline crust forms on the surface; oil of vitriol then added in small quantities, as long as gypsum is thereby precipitated; the liquid strained off (after dilution with water, if the gypsum forms a paste); the precipitate washed; and the whole of the liquid again evaporated: it then yields, on cooling, brownish crystals of succinic acid, still contaminated with gypsum. These crystals are purified by recrystallisation from water, sometimes with addition of animal charcoal, and ultimately freed from gypsum by solution in alcohol or by sublimation. By this process, 12 pts. of calcic malate yield from 3·75 to 4 pts. of pure crystallised succinic acid: the mother-liquors do not retain a trace of malic acid. Three pounds of calcic malate thus treated yield about one pound of pure succinic acid. (**Liebig.**)

The formation of succinic acid in this process is accompanied by that of acetic acid and carbonic anhydride: hence the reaction is commonly represented by the equation:

$$\underset{\text{Malic acid.}}{3C^4H^6O^5} = \underset{\text{Succinic acid.}}{2C^4H^6O^4} + \underset{\text{Acetic acid.}}{C^2H^4O^2} + 2CO^2 + H^2O.$$

Probably two reactions go on simultaneously, one part of the malic acid being converted by fermentation into acetic acid, and this fermentation causing the reduction of another portion into succinic acid (**Kekulé**). See MALATE OF CALCIUM (iii. 702).

Properties.—Succinic acid crystallises in prisms belonging to the monoclinic system, generally in rhombic or hexagonal plates, the face ∞P∞ replacing the acute edge of the vertical prism ∞P. The crystals are permanent in the air, have an acid taste, but no smell. Succinic acid is much more soluble in hot than in cold water—viz., in 5 pts. water at 16°, and 2·2 pts. at 100° (**Lecanu** and **Serbat**). It is less soluble in alcohol, and nearly insoluble in ether. It melts at 180°, but begins to emit suffocating vapours even below its melting-point. It boils at 235°, being resolved into water and succinic anhydride.

Decompositions.—1. Succinic acid offers great resistance to the action of oxidising agents, not being affected by nitric acid, chromic acid, chlorine-water, or a mixture of hydrochloric acid and potassic chlorate. When evaporated to dryness with *manganic peroxide* and *sulphuric acid*, it yields acetic acid (Trommsdorff).—2. An aqueous solution of sodic succinate is decomposed by the *electric current*, giving off at the positive pole a mixture of carbonic anhydride and methylic oxide (Kolbe, Ann. Ch. Pharm. cxiii. 244):

$$C^4H^6O^4 + H^2O = (CH^3)^2O + 2CO^2 + H^2.$$

3. When fused with *potassic hydrate*, it yields carbonate and oxalate, together with a gaseous hydrocarbon (Liebig and Wöhler).—4. It is not attacked by strong sulphuric acid (H^2SO^4) even when heated, but *sulphuric anhydride* converts it into succinosulphuric acid.—5. Heated with *bromine*, it forms substitution-products.— 6. By *dehydrating substances*, such as *phosphoric anhydride* and *phosphoric pentachloride*, it is converted into succinic anhydride; in the latter case with formation of hydrochloric acid and phosphoric oxychloride.

Succinates. Succinic acid is dibasic, the general formula of its salts being as follows:

Neutral Succinates	$C^4H^4M^2O^4$ and $C^4H^4M''O^4$
Acid "	$C^4H^5MO^4$ and $C^8H^{10}M''O^8$. $= C^4H^4M''O^4.C^4H^6O^4$.

There are also a few double succinates, several basic lead-salts, and a hyperacid potassium-salt.

Most succinates resist a temperature of 200° without decomposition. When distilled with acid phosphate or sulphate of sodium, they yield a sublimate of succinic anhydride.

The succinates of the alkali-metals and of magnesium are easily soluble in water; those of the alkaline earth-metals, and most other diatomic metals, are sparingly soluble; those of sesqui-atomic metals are insoluble.

Succinic acid and soluble succinates form, with *ferric salts*, a red-brown precipitate resembling that formed by benzoic acid, but much more compact: hence succinate of ammonium is a more convenient reagent for the precipitation of ferric salts than the benzoate. With *acetate of lead*, succinic acid forms a precipitate of succinate of lead, soluble in excess of either reagent. With *chloride of barium*, the acid by itself gives no precipitate; but on addition of ammonia and alcohol, a white precipitate is formed: benzoic acid does not exhibit this reaction. Succinic acid is further distinguished from benzoic acid by not being precipitated from its soluble salts by a mineral acid.

Succinate of Ammonium.—The *neutral salt*, $C^4H^4(NH^4)^2O^4$, is obtained by supersaturating succinic acid with ammonia, and leaving the solution to evaporate over quicklime; it is also formed, according to Piria, in the putrefaction of asparagin. It crystallises in hexagonal prisms, very soluble in water and in alcohol. Gives off ammonia when exposed to the air, and is resolved by heat into ammonia, water, and succinamide. Specific gravity = 1·367 (Bödeker, Jahresb, 1860, p. 17).—The *acid salt*, $C^4H^5(NH^4)O^4$, is produced when the solution of the preceding salt is evaporated by heat. It crystallises easily, is very soluble in water and alcohol, has an acid reaction, and is decomposed by heat, like the neutral salt. The crystals are triclinic, usually exhibiting the combination: $oP \,.\, 'P_,\infty \,.\, {}_,P'\infty \,.\, \infty\bar{P}\infty \,.\, \infty\breve{P}\infty \,.\, \infty P_,'$. Angle $oP : \infty P\infty = 91° 53'$; $oP : \infty\breve{P}\infty = 93° 25'$; $oP : \infty_,P' = 91° 45'$; $oP : 'P_,\infty = 151° 57'$; $oP : {}_,\bar{P}'\infty = 151° 7'$; $\infty\bar{P}\infty : \infty\breve{P} = 100° 15'$; $\infty\breve{P}\infty : '\bar{P}_,\infty = 119° 53'$; $\infty\breve{P}\infty : \bar{P}_,\infty = 117°$; $\infty\breve{P}\infty : \infty P'_, = 135° 46'$. (Brooke, Ann. Phil. xxii. 286.)

Succinate of Barium, $C^4H^4Ba''O^4$ (at 200°).—White crystalline precipitate, slightly soluble in water, moderately soluble in dilute nitric, hydrochloric, and acetic acid, insoluble in ammonia and in alcohol. With chloride of acetyl it yields a mixture of acetic and succinic anhydrides. (Heintz, Jahresb. 1859, p. 279.)

Succinate of Cadmium crystallises in concentric groups of prisms, very soluble in water. According to John, it appears to be resolved by alcohol into two other salts.

Succinates of Calcium.—The *neutral salt* is gradually deposited, on mixing cold concentrated solutions of calcic chloride and sodic succinate, in small needles, containing $C^4H^4Ca''O^4.3H^2O$. If the solutions are mixed hot, a crystalline precipitate is immediately formed, composed of $C^4H^4Ca''O^4.H^2O$. Both precipitates are sparingly soluble in water and acetic acid, insoluble in alcohol. When heated, it gives off a volatile oil, called succinone, still containing oxygen, but having a composition not yet ascertained with certainty (D'Arcet).—The *acid salt*, $C^8H^{10}Ca''O^8$, or $C^4H^4Ca''O^4.C^4H^6O^4$, obtained by treating the neutral salt with excess of acid, is likewise crystallisable, and slightly soluble in water. Alcohol renders the crystals opaque, and converts them into the neutral salt. They are also decomposed by heating to 150°.

Chromous Succinate, $C^4H^4Cr''O^4.H^2O$, is a scarlet precipitate, formed on adding succinate of sodium to chromous chloride.—*Chromic succinate* is not known.

Succinate of Cobalt.—Peach-blossom-coloured, slightly soluble precipitate. According to Handl (Wien. Akad. Ber. xxxii. 254), it forms monoclinic prismatic crystals: ∞P . ∞P*n* . [∞P∞] . oP. Angle ∞P : ∞P (clinod.) = 113°36′, ∞P*n* : ∞P*n* (clinod.) = 136° 38′ ; oP : ∞P = 115°, nearly.

Succinate of Copper, $C^4H^4Cu''O^4$ (at 200°), is obtained on adding recently precipitated cupric carbonate to a boiling aqueous solution of succinic acid, as a bluish-green crystalline powder, slightly soluble in water and succinic acid, less soluble in acetic acid, insoluble in alcohol and ether.

Succinates of Iron.—α. *Ferric salts.* Alkaline succinates form with ferric salts a red-brown or cinnamon-coloured precipitate, consisting of a basic ferric succinate. The addition of sodic acetate before precipitation renders the precipitate more compact. It dissolves in acetic, succinic, and mineral acids. Ammonia appears to convert it into a still more basic salt.—β. *Ferrous succinate* is a greyish-green precipitate, which oxidises in the air, is slightly soluble in water, easily soluble in succinic acid, partially soluble also in ammonia and ammoniacal salts.

Succinates of Lead.—The *neutral salt*, $C^4H^4Pb''O^4$ (at 100°), is obtained by precipitating neutral acetate of lead with neutral sodic succinate, or a hot solution of succinic acid with basic acetate of lead. It is a white powder, which becomes crystalline if precipitated from hot solutions. It is slightly soluble in water, easily soluble in dilute nitric acid and in potash. Specific gravity = 3·800 (Bödeker).—A *basic salt*, $2C^4H^4Pb''O^4.Pb''O$, is obtained on mixing succinate of sodium with basic acetate of lead, as a glutinous precipitate, which sticks to the sides of the vessel while warm, and becomes brittle on cooling. Another basic salt, $C^4H^4Pb''O^4.2Pb''O$ (at 200°), is produced by treating the neutral salt with excess of ammonia. It is a white powder, insoluble in water, easily soluble in potash, and in dilute nitric acid.

Succinates of Magnesium.—The *neutral salt*, $C^4H^4Mg''O^4.6H^2O$, forms prismatic crystals, which give off all their water at 130°. It is very soluble in water, insoluble in alcohol. The aqueous solution appears to yield, by concentration, crystals containing a smaller proportion of water (Fehling).—A *basic salt*, $2C^4H^4Mg''O^4.4Mg''O.H^2O$ (at 100°?), is obtained as a white pulverulent precipitate, on adding ammonia to a solution of the neutral salt.—*Magnesio-potassic succinate*, $C^8H^8Mg''K^2O^8.5H^2O$, crystallises in fine double six-sided pyramids, very soluble in water, permanent in the air, and neutral to test-paper.

Succinate of Manganese, $C^4H^4Mn''O^4.4H^2O$.—Rhomboïdal prisms or quadrangular tables (triclinic, according to Handl), transparent, amethyst-coloured, neutral, permanent in the air, giving off their water at 100°.

Succinates of Mercury.—α. *Mercuric salts.* Mercuric acetate gives a white precipitate with sodic succinate. A mixture of sodic succinate and mercuric chloride yields, by evaporation, slender needles, apparently consisting of a double salt. Recently precipitated mercuric oxide, boiled with aqueous succinic acid, is partly converted into a white powder, which appears to be a basic succinate.—β. *Mercurous salt.* Alkaline succinates form, with mercurous nitrate, a white precipitate of mercurous succinate, mixed with mercurous nitrate.

Succinate of Nickel, $C^4H^4Ni''O^4.4H^2O$.—The solution of nickel-hydrate in hot aqueous succinic acid deposits this salt, by evaporation over oil of vitriol, in green nodules, soluble in water, acetic acid, and ammonia, insoluble in alcohol. It gives off its water at 130°.

Succinates of Potassium.—The *neutral salt*, $C^4H^4K^2O^4.2H^2O$, forms confused deliquescent crystals, soluble in alcohol, insoluble in ether, giving off their water at 100°.—The *acid salt*, $C^4H^5KO^4.2H^2O$, crystallises readily in transparent regular six-sided prisms, which effloresce slightly in contact with the air. It is very soluble in water, reddens litmus, gives off its water of crystallisation at 100°.—A *hyperacid salt*, $2(C^4H^5KO^4.C^4H^6O^4).3H^2O$ (?), obtained by neutralising a hot solution of 1 pt. succinic acid with carbonate of potassium, and then adding 3 pts. more succinic acid, crystallises on cooling, sometimes without water, sometimes with 9·65 per cent. water of crystallisation. (Fehling.)

Succinates of Silver.—*Argentic salt*, $C^4H^4Ag^2O^4$. Succinate of sodium precipitates nitrate, but not sulphate of silver. The precipitate is white, non-crystalline, of specific gravity 3·518 (**Bödeker**), very slightly soluble in water, and in acetic acid, very soluble in dilute nitric acid, and in ammonia. It becomes coloured at 150°. Chlorine decomposes it immediately. When heated to 100° in a current of hydrogen, it assumes a lemon-yellow colour, and yields a sublimate of succinic acid. The residue consists of *argentous succinate.*

Succinates of Sodium.—The *neutral salt,* $C^4H^4Na^2O^4.6H^2O$, crystallises in prisms with rhombic base, very soluble in water and in alcohol, neutral to test-paper, giving off their water at 100°.—The *acid salt,* $C^4H^5NaO^4.3H^2O$, usually crystallises in flattened prisms, having an acid reaction, slightly efflorescent, and giving off all their water at 100°. They belong to the triclinic system, generally exhibiting the combination: $oP\,.\,\infty{,}P\,.\,\infty P'_{,}\,.\,\infty\breve{P}\infty\,.\,m\,\breve{P}\infty$. Angle $oP : \infty{,}\dot{P} = 128°$; $oP : m\breve{P}\infty = 169° 55'$; $oP : \infty\breve{P}\infty = 140° 50'$; $\infty{,}\dot{P} : \infty\breve{P}\infty = 117° 6'$; $\infty{,}\dot{P} : m{,}\breve{P}n = 115° 8'$; $\infty\breve{P}\infty : m{,}\acute{P}n = 108° 7'$. More rarely small, confused, non-efflorescent crystals are obtained, containing only 2 at. water. When redissolved in water, they yield the salt with 3 at. water.

It has not been found possible to prepare double succinates of sodium and ammonium, or of sodium and potassium.

Succinate of Strontium, $C^4H^4Sr''O^4$ (at 200°).—Precipitated as a white powder, slightly soluble in water, whence it is deposited in the crystalline state on evaporation. According to **Handl** (Wien. Akad. Ber. xxxii. 254), it crystallises in monoclinic prisms, $\infty P\,.\,\infty P\infty\,.\,[\infty P\infty]\,.\,oP$. Angle $\infty P : \infty P$ (clinod.) = 30° 12′; $oP : \infty P\infty = 158°$ (nearly). The crystals are always twins, with $\infty P\infty$ as combination-face. The salt dissolves in acetic and in succinic acid, the latter solution yielding it in the crystalline state when evaporated.

Succinates of Uranium.—The *neutral salt,* $C^4H^4(U^2O^2)''O^4.H^2O$, is obtained in the crystalline state by evaporating to dryness a solution of 4 pts. crystallised uranic nitrate and 1 pt. succinic acid, and washing the residue with a small quantity of water; also by mixing a solution of uranic nitrate with acid succinate of sodium, and evaporating. It is a light-yellow salt, very slightly soluble in water, insoluble in alcohol, not giving off its water till heated to between 230° and 240°. Boiling water extracts succinic acid from it.—*Potassio-uranic succinate,* $C^{12}H^{12}(U^2\overset{''}{O}{}^2)^2K^2O^{12}.H^2O$, is obtained by evaporating a solution of uranic nitrate mixed with excess of neutral potassic succinate: it is then deposited as a light-yellow precipitate, which may be purified by washing with alcohol. It may also be prepared by precipitating uranic nitrate with caustic potash, and digesting the washed precipitate with excess of succinic acid, till it contracts and assumes a light-yellow colour, then evaporating to dryness, and washing with hot alcohol. It is insoluble in water, but is decomposed by continued washing into succinate of potassium, and insoluble basic uranic succinate. It gives off its water at 220°.—*Sodio-uranic succinate,* $C^{12}H^{12}(U^2\overset{''}{O}{}^2)^2Na^2O^{12}$, H^2O, is obtained like the potassium-salt.

Succinate of Yttrium, $2C^4H^4Y''O^4.3H^2O$, is precipitated by succinate of ammonium from acetate of yttrium at the boiling heat (not in the cold), as a lamino-crystalline powder, sparingly soluble in hot and in cold water, insoluble in sal-ammoniac, easily soluble in dilute acids; gives off its water at 100°. (**Popp**, Ann. Ch. Pharm. cxxxi. 179.)

Succinate of Zinc, $C^4H^4Zn''O^4$ (at 200°).—White, anhydrous, crystalline powder, very slightly soluble in water and in succinic acid; easily soluble in mineral acids, acetic acid, ammonia, and potash; insoluble in alcohol. Succinate of sodium does not precipitate chloride of zinc.

SUCCINATES OF ORGANIC BASES.—*Acid Succinate of Cinchonine,* $C^{20}H^{24}N^2O.C^4H^6O^4$, crystallises in long oblique-angled needles, containing $\frac{3}{2}$ at. water, or in large thick crystals containing 1 at. water. Both are easily soluble in water, and melt at 110° (**Hesse**, Ann. Ch. Pharm. cxxii. 226.—*Succinate of Cinchonidine,* $2C^{20}H^{24}N^2O.C^4H^6O^4.6H^2O$, crystallises in long asbestiform prisms, which dissolve in 252 pts. water at 10°; the anhydrous salt crystallises in white nodules (**Hesse**, *ibid.* cxxxv. 342).—*Succinate of Quinine,* $2C^{20}H^{24}N^2O^2.C^4H^6O^4.H^2O$, crystallises from alcohol or from water in long white prisms, soluble in 910 pts. water at 10°, easily soluble in hot water and in alcohol. (**Hesse**, *ibid.* cxxxv. 331.)

Succinate of Urea, $2CH^4N^2O.C^4H^6O^4$, crystallises in monoclinic six-sided prisms, $\infty P\infty\,.\,oP\,.\,\infty P\,.\,\infty P2\,.\,+P\infty\,.\,+P2$. Ratio of axes, $a : b : c = 1 : 1·483 : 1·3646$, Angle of axes $b, c = 83° 28'$; $\infty P\infty : oP = 96° 32'$: $\infty P : \infty P$ (clinod.) = 68° 20′; $\infty P\infty : +P\infty = 129° 4'$. The crystals have a vitreous lustre, are unsymmetrical at the two ends, and generally have but imperfectly developed faces; they cleave imperfectly parallel to +P2. [J. Lischmidt, Wien. Akad. Ber. lii. (2 Abth.), 238.]

Derivatives of Succinic Acid.

No chlorinated substitution-products have hitherto been obtained from succinic acid. By the action of chlorine on citric acid, however, Plantamour obtained an oily body (perhaps $C^4Cl^4O^2.Cl^2$.), which when treated with alcoholic potash yielded a potassium-salt having the composition of potassic tetrachlorosuccinate, $C^4Cl^4K^2O^4$; it is not, however, known whether the acid of this salt is really a derivative of succinic acid. (See CITRIC ACID, i. 996.)

Bromosuccinic Acids.—Two of these acids are known, viz. mono- and di-bromosuccinic acid, both of which may be produced by the direct action of bromine on succinic acid.

MONOBROMOSUCCINIC ACID, $C^4H^3BrO^4 = \left.\begin{matrix}(C^4H^3BrO^2)''\\ H^2\end{matrix}\right\}O^2$. (Kekulé, Ann. Ch. Pharm. cxvii. 125.)—The conditions under which this acid is formed are not exactly known. When succinic acid is heated with bromine and water in a sealed tube, dibromosuccinic acid is generally produced, even when the bromine and succinic acid are mixed in the proportions required to form the monobrominated acid. The formation of the latter appears, however, to be promoted by the presence of a quantity of water, larger than that which is most favourable to the production of dibromosuccinic acid. Carius (Ann. Ch. Pharm. cxxix. 6) prepares the monobrominated acid by slowly heating 5 grms. succinic acid with 2½ c.c. bromine and 40 c.c. water, to 120° in sealed tubes, and obtains it pure by one recrystallisation. Even when quite pure succinic acid is used, a small quantity of a heavy brominated oil is likewise produced, having the composition $C^2H^3Br^3$.

Monobromosuccinic acid is very soluble in water, and crystallises in small nodular aggregates. After neutralisation, it throws down from a solution of silver-nitrate a white silver-salt, which quickly decomposes, with formation of silver-bromide. On adding silver-oxide to the aqueous solution, bromide of silver is quickly formed, and the solution contains malic acid.

According to these reactions, monobromosuccinic acid may be regarded, on the one hand, as a substitution-product of succinic acid, on the other as the bromide of malic acid, forming, as it were, the stepping-stone from succinic to malic acid:

$$\underset{\text{Succinic acid.}}{\left.\begin{matrix}(C^4H^4O^2)''\\ H^2\end{matrix}\right\}O^2} \qquad \underset{\text{Monobromosuccinic acid.}}{\left.\begin{matrix}(C^4H^3BrO^2)''\\ H^2\end{matrix}\right\}O^2,\ \text{or}\ \left.\begin{matrix}(C^4H^3O^2)'''\\ H^2\end{matrix}\right\}\begin{matrix}Br\\ O^2\end{matrix}} \qquad \underset{\text{Malic acid.}}{\left.\begin{matrix}(C^4H^3O^2)'''\\ H^3\end{matrix}\right\}O^3}.$$

These relations are analogous to those which exist between acetic acid, $C^2H^4O^2$, monochloracetic acid, $C^2H^3ClO^2$, and glycollic acid, $C^2H^4O^3$.

DIBROMOSUCCINIC ACID, $C^4H^4Br^2O^4 = \left.\begin{matrix}(C^4H^2Br^2O^2)''\\ H^2\end{matrix}\right\}O^2$. (Kekulé, Ann. Ch. Pharm. cxvii. 123; Suppl. i. 131.—Perkin and Duppa, Chem. Soc. Qu. J. xiii. 102.)—Prepared: 1. By heating 12 grms. of succinic acid, 11 c.c. bromine, and 12 grms. water, in sealed tubes, to about 180°, and crystallising the solid portion of the contents of the tube from boiling water, with addition of animal charcoal* (Kekulé). —2. By the action of water on chloride of dibromosuccinyl, $C^4H^2Br^2O^2.Cl^2$ (Perkin and Duppa).—3. From fumaric acid, $C^4H^4O^4$, by direct addition of bromine. (Kekulé.)

Dibromosuccinic acid crystallises in colourless, mostly opaque prisms, sparingly soluble in cold, easily in boiling *water*, also in *alcohol* and *ether*. When heated with *bromine* and water, it is decomposed with formation of bromoform:

$$C^4H^4Br^2O^4 + 2H^2O + 3Br^2 = CH^3Br^3 + 3CO^2 + 5HBr.$$

By *sodium-amalgam* it is reconverted into succinic acid.

---

* The mother-liquor, from which the dibromosuccinic acid has crystallised, contains dibromomaleic acid, $C^4H^2Br^2O^4$, and two isomers of monobromomaleic acid, $C^4H^3BrO^4$ (iii. 788). The dibromomaleic acid volatilises with the vapour of water on distilling the mother-liquor in a retort; the other two acids separate from the mother-liquor on repeated evaporation, and may be purified by fractional crystallisation.—*Metabromomaleic acid*, $C^4H^3BrO^4$, forms large, well-defined, apparently trimetric crystals; melts at 126°—127°, volatilises even below 100°, and dissolves very easily in water, alcohol, and ether. Its *silver-salt*, $C^4HAg^2BrO^4$, separates from a mixture of the acid with silver-nitrate, on addition of ammonia, as a curdy precipitate; the *lead-salt*, $C^4HPb''BrO^4$ (at 100°), is a white precipitate, insoluble in the free acid, but soluble in a large quantity of neutral lead-acetate.—*Parabromomaleic acid*, $C^4H^3BrO^4$, separates in large crystals, apparently triclinic. It is likewise easily soluble in water, alcohol, and ether, and melts at 172°. Its *silver-salt*, $C^4HAg^2BrO^4$, is obtained as a granulo-crystalline precipitate, on mixing the acid with nitrate of silver. It dissolves in boiling water, and more readily in dilute nitric acid.—The *lead-salt*, $C^4HPb''BrO^4.2H^2O$, is soluble both in excess of the acid and in acetate of lead. (Kekulé, Ann. Ch. Pharm. cxxx. 1.)

Dibromosuccinic acid is dibasic. Its salts are easily decomposed by heat, so that, in preparing them, it is necessary to guard against rise of temperature. They are all decomposed by boiling with water, or with excess of base, yielding a metallic bromide, together with another product of decomposition, varying according to the nature of the base. The bromine thus withdrawn (1 or 2 at.) is either replaced by the water-residue, HO, or merely separates in combination with an equivalent quantity of hydrobromic acid, leaving a residue containing 1 at. bromine and 1 at. hydrogen less. Of the decompositions expressed by the following equations, the first three have actually been effected:

$$\begin{array}{llllll}
C^4H^4Br^2O^4 & + \; H^2O & = & HBr & + & C^4H^5BrO^5 \text{ Monobromomalic acid.} \\
C^4H^4Br^2O^4 & & = & HBr & + & C^4H^3BrO^4 \text{ Monobromomaleic acid.} \\
C^4H^4Br^2O^4 & + \; 2H^2O & = & 2HBr & + & C^4H^6O^6 \text{ Tartaric acid.} \\
C^4H^4Br^2O^4 & & = & 2HBr & + & C^4H^2O^4 \text{ (unknown).}
\end{array}$$

Generally, however, several of these reactions take place simultaneously, so that the principal product formed according to one of these four equations, is accompanied by a secondary product formed according to another. Thus *sodic dibromosuccinate*, boiled in aqueous solution, is converted chiefly into acid sodic monobromomalate. On boiling an aqueous solution of *baric dibromosuccinate*, acid baric monobromomaleate is obtained as the chief product of decomposition, together with a small quantity of tartrate.—When *calcic dibromosuccinate* is boiled with water, and lime-water is added till the liquid no longer turns acid after prolonged boiling, the chief product is an insoluble calcium-salt having the composition of the tartrate.—Lastly, *argentic dibromosuccinate* is easily decomposed by boiling with water, yielding (inactive) tartaric acid.

From these reactions, and its mode of formation, dibromosuccinic acid may be regarded either as a substitution-product of succinic acid, or as the bromide of monobromomalic acid, or lastly as a bromide of tartaric acid. It is related to succinic, monobromomalic, and tartaric acids, in the same manner as dibromacetic acid to acetic, monobromoglycollic, and glyoxylic acids (Kekulé's *Lehrbuch*, ii. 33):

$$\begin{array}{lll}
\text{Dibromosuccinic acid, } \left.\begin{array}{r}(C^4H^4Br^2O^2)''\\ H^2\end{array}\right\}O^2 & \left.\begin{array}{r}(C^4H^4O^2)''\\ H^2\end{array}\right\}O^2. & \text{Succinic acid.} \\
\text{”} \quad \left.\begin{array}{r}(C^4H^2BrO^2)'''\\ H^2\end{array}\right\}\begin{array}{l}Br\\ O^2\end{array} & \left.\begin{array}{r}(C^4H^2BrO^2)'''\\ H^3\end{array}\right\}O^3. & \begin{array}{l}\text{Monobromo-}\\ \text{malic acid.}\end{array} \\
\text{”} \quad \left.\begin{array}{r}(C^4H^2O^2)''''\\ H^2\end{array}\right\}\begin{array}{l}Br^2\\ O^2\end{array} & \left.\begin{array}{r}(C^4H^2O^2)''''\\ H^4\end{array}\right\}O^4. & \text{Tartaric acid.}
\end{array}$$

Neutral Dibromosuccinate of Ammonium, $C^4H^2(NH^4)^2Br^2O^4$, crystallises by spontaneous evaporation in large transparent crystals.—The *neutral sodium-salt*, $C^4H^2Na^2Br^2O^4.4H^2O$, is very soluble in water, and remains in small crystals on evaporation; from alcohol it crystallises in shining laminæ.—The *acid potassium-salt* is white, crystalline, and sparingly soluble.—The *calcium-salt*, $C^4H^2Ca''Br^3O^4$, obtained by double decomposition, separates gradually as a crystalline precipitate.—The *silver-salt*, $C^4H^2Ag^2Br^2O^4$, prepared in like manner, is a white powder, insoluble in water.

Ethylic Dibromosuccinate, $C^4H^2(C^2H^5)^2Br^2O^4$, obtained by passing hydrochloric acid gas into an alcoholic solution of the acid and precipitating with water, is very slightly soluble in water, easily soluble in alcohol and ether, and crystallises in long white needles, which melt at 58°, and boil with partial decomposition between 140° and 150°. (Kekulé.)

Dibromosuccinic Anhydride, $(C^4H^2Br^2O^2)''O$, is obtained by heating maleic anhydride, $C^4H^2O^3$, with dry bromine to 100°, for half or three-quarters of an hour. Two atoms of bromine are then taken up, and a yellow liquid is formed, which gradually solidifies to a crystalline mass, to be freed from adhering hydrobromic acid by leaving it, when pulverised, over quicklime. Dibromosuccinic anhydride, thus produced, crystallises from carbonic disulphide in colourless laminæ. It melts at 100°, and is resolved at 180° into hydrobromic acid and bromomaleic anhydride, C^4HBrO^3. With cold water it forms at first a solid mass, which dissolves in a larger quantity of water, and the solution yields, by spontaneous evaporation, a crystallised acid, formed from the anhydride by addition of water, and having the composition, but not the properties, of dibromosuccinic acid, viz.:

Isodibromosuccinic Acid, $C^4H^4Br^2O^4$.—This acid forms large, transparent, well-developed crystals, much more soluble in water than dibromosuccinic acid. It melts at 160°, and is resolved at 180°, or by boiling its aqueous solution, into hydrobromic acid and isobromomaleic acid, $C^4H^3BrO^4$; whereas ordinary dibromosuccinic acid is not decomposed by boiling with water, but when heated by itself is completely decomposed without previous fusion. On boiling the aqueous solution with baryta, *baric isodibromosuccinate* is obtained, which forms warty crystals, and yields isodibromosuccinic acid when decomposed by sulphuric acid.—The *silver-salt* resembles that of ordinary dibromosuccinic acid. (Kekulé, Ann. Ch. Pharm. Suppl. ii. 85.)

SUCCINIC AMIDES. Succinic acid, like other acids of the series $C^nH^{2n-2}O^4$, is capable of forming four normal amides, derivable, but not always directly producible, from the acid and neutral ammonium-salts, by abstraction of water, viz.:

$$\text{Succinamic acid, } C^4H^7NO^3 = \left.\begin{matrix}H^2\\(C^4H^4O^2)''\\H\end{matrix}\right\}\begin{matrix}N\\O\end{matrix} = C^4H^5(NH^4)O^4 - H^2O.$$

$$\text{Succinimide, } C^4H^5NO^2 = \left.\begin{matrix}(C^4H^4O^2)''\\H\end{matrix}\right\}N = C^4H^5(NH^4)O^4 - 2H^2O.$$

$$\text{Succinamide, } C^4H^8N^2O^2 = \left.\begin{matrix}(C^4H^4O^2)''\\H^4\end{matrix}\right\}N^2 = C^4H^4(NH^4)^2O^4 - 2H^2O.$$

$$\left.\begin{matrix}\text{Succinonitrile}\\\text{(Cyanide of Ethylene)}\end{matrix}\right\}C^4H^4N^2 = (C^2H^4)''Cy^2 = C^4H^4(NH^4)^2O^4 - 4H^2O.$$

The first three of these compounds contain hydrogen-atoms replaceable by metals or alcohol-radicles. There is also a trisuccinamide, $(C^4\overset{''}{H}{}^4O^2)^3N^2$, formed by the action of succinic chloride on argentic succinimide.

Succinamic Acid. $C^4H^7NO^3 = \left.\begin{matrix}H^2\\(C^4H^4O^2)''\\H\end{matrix}\right\}\begin{matrix}N\\O\end{matrix}$. (R. Teuchert, Ann. Ch. Pharm. cxxxiv. 136; Bull. Soc. Chim. 1866, i. 286.)—The barium-salt of this acid, $C^8H^{12}Ba''N^2O^6$, is obtained by leaving a slightly warmed solution of succinimide and baric hydrate, in equivalent proportions, to evaporate in a vacuum over oil of vitriol, and repeatedly crystallising the residue from an aqueous solution mixed with alcohol. It forms concentric groups of needle-shaped crystals, easily soluble in water, insoluble in absolute alcohol and in ether, somewhat soluble in aqueous alcohol. The aqueous solution decomposes when kept, and more quickly on boiling, into ammonia and succinate of barium, which is precipitated. With potash, the solution gives off ammonia even in the cold.

By carefully decomposing the barium-salt with somewhat less than the equivalent quantity of sulphuric acid, and evaporating the filtrate, impure succinamic acid (containing baryta) is obtained in rectangular prisms; if the whole of the baryta be precipitated, nothing but succinate of ammonium remains dissolved.

Succinamate of Cadmium, $C^8H^{12}Cd''N^2O^6.H^2O$, remains on precipitating the solution of the barium-salt with sulphate of cadmium, and evaporating the filtrate; it is very soluble in water, insoluble in alcohol, and forms a radiated crystalline mass, or small well-developed rhombic prisms.—The *cupric salt*, $C^8H^{12}Cu''N^2O^6$, prepared in like manner, forms dark-green, microscopic, rhombic laminæ, insoluble in alcohol, slightly soluble in water, and decomposed by boiling with water, with separation of cupric oxide and cupric succinate.—The *lead-salt*, $C^8H^{12}Pb''N^2O^6$, is obtained by heating a solution of succinimide with excess of lead-oxide, and adding alcohol to the filtrate previously treated with carbonic acid, in large, concentrically grouped, easily soluble needles.—The *magnesium-salt*, $C^8H^{12}Mg''N^2O^6.3H^2O$, prepared like the cadmium-salt, is a radiated, nodular, crystalline mass, which by solution and spontaneous evaporation, yields well-developed crystals belonging to the trimetric system.—The *manganous salt*, $C^8H^{12}Mn''N^2O^6.5H^2O$, remains on evaporation as a rose-coloured syrup, which gradually solidifies to a warty or radiate crystalline mass.

The *silver-salt*, $C^4H^6AgNO^3$, is obtained, by mixing the concentrated solutions of argentic nitrate and baric succinamate, as a white crystalline precipitate, and on leaving the filtrate to itself, in prismatic crystals probably belonging to the monoclinic system. It blackens quickly on exposure to light, is easily soluble in ammonia, sparingly in water, and insoluble in alcohol; in boiling water it becomes covered with a black crust.*

Succinamate of Zinc, $C^8H^{12}Zn''N^2O^6$, prepared like the cadmium-salt, forms stellate groups of prisms, easily soluble in water, nearly insoluble in hydrated alcohol, quite insoluble in absolute alcohol.

---

* Laurent and Gerhardt (Ann. Ch. Pharm. lxxii. 291), by boiling argentic succinimide with dilute ammonia, obtained a silver-salt, which they regarded as argentic succinamate. It differed, however, in its properties from that above described, being easily soluble in water, and yielding succinamide when decomposed by hydrochloric acid, whereas succinamate of silver thus treated should yield acid succinate of ammonium. According to Teuchert, the salt obtained by Laurent and Gerhardt was probably a hydrated argentic succinimide isomeric with the succinamate (p. 461).

Phenylsuccinamic or *Succinanilic Acid*, $C^{10}H^{11}NO^3 = \left.\begin{matrix}C^6H^5.H\\(C^4H^4O^2)''\\H\end{matrix}\right\}\begin{matrix}N\\O\end{matrix}.$ (Laurent and Gerhardt, Ann. Ch. Phys. [3], xxiv. 179.)—Obtained by dissolving succinanil in boiling dilute ammonia mixed with a little alcohol, boiling the liquid to expel the latter, and neutralising with nitric acid. The succinanilic acid is then deposited on cooling, in elongated laminæ, which are to be purified by crystallisation from alcohol. It is very slightly soluble in cold, more soluble in hot water: the solution reddens litmus. It melts when heated, and decomposes, at a higher temperature, into water and phenylsuccinimide, which sublimes. It dissolves in ammonia and in potash, and when fused with potash at a gentle heat, gives off aniline.

Succinanilate of Ammonium is very soluble in water, and crystallises in confused masses. The solution does not precipitate *chloride of calcium*, and scarcely produces any turbidity with *chloride of barium*; with *cupric salts* it forms a light-blue, and with *ferrous salts* a yellowish-white precipitate; with *nitrate of silver*, a white precipitate of argentic succinanilate, $C^{10}H^{10}AgNO^3$.

Succinamide, $C^4H^8N^2O^2 = \left.\begin{matrix}(C^4H^4O^2)''\\H^4\end{matrix}\right\}N^2.$ (D'Arcet, Ann. Ch. Pharm. xvi. 215)—This compound separates in small white crystals, on mixing ethylic succinate with strong aqueous ammonia. It dissolves in boiling water, but is nearly insoluble in cold water, also in alcohol and in ether. It melts when heated, and is resolved at about 200° into ammonia and succinimide, $C^4H^5NO^2$. It is easily decomposed by boiling with alkalis. By the action of nitrous acid (*i.e.* by passing nitric oxide into a solution of succinamide in nitric acid), it is resolved, after the manner of amides in general, into succinic acid, water, and nitrogen:

$$C^4H^8N^2O^2 + N^2O^3 = C^4H^6O^4 + H^2O + 2N^2.$$

Phenylsuccinamide or *Succinanilide*, $C^{16}H^{16}N^2O^2 = \left.\begin{matrix}(C^4H^4O^2)''\\(C^6H^5)^2\\H^2\end{matrix}\right\}N^2.$ (Laurent and Gerhardt, Ann. Ch. Phys. [3], xxiv. 179.)—Remains undissolved when the product of the action of succinic acid on anhydrous aniline is exhausted with boiling water; produced also by the action of aniline on succinic chloride. It dissolves easily in boiling alcohol, and is deposited therefrom in tufts of microscopic needles. It is less fusible than succinamide. When melted with potash at a gentle heat, it gives off aniline.

Succinimide, $C^4H^5NO^2 = \left.\begin{matrix}(C^4H^4O^2)''\\H\end{matrix}\right\}N.$ *Bisuccinamide.* (D'Arcet, Ann. Ch. Phys. [2], lviii. 294.—Fehling, Ann. Ch. Pharm. xlix. 198.—Laurent and Gerhardt, Compt. Chim. 1849, p. 108).—Formed: 1. By heating succinamide or succinate of ammonium.—2. By the action of dry ammonia-gas on succinic anhydride:

$$(C^4H^4O^2)''O + NH^3 = H^2O + (C^4H^4O^2)''HN.$$

Succinimide crystallises in large transparent crystals, $C^4H^5NO^2.H^2O$, which give off their water even on exposure to the air. It is easily soluble in water and in alcohol, less soluble in ether; melts at 210°, and sublimes without alteration.

The hot alcoholic solution of succinimide, mixed with a small quantity of ammonia, and then with nitrate of silver, yields on cooling, large crystals of *argentic succinimide*, $C^4H^4O^2AgN$. This compound detonates when heated, and when triturated with sal-ammoniac, is converted, with evolution of ammonia, into argentic chloride and succinimide. By prolonged boiling with water, it yields argentic succinate. When boiled with water containing a few drops of ammonia, it is converted, according to Laurent and Gerhardt, into argentic succinamate. Teuchert, however (p. 460), obtained by this process a hydrated argentic succinimide, $2C^4H^4O^2AgN.H^2O$, and is of opinion that Laurent and Gerhardt's compound was also a hydrated argentic succinimide, containing $C^4H^4O^2AgN.H^2O$, isomeric therefore with argentic succinamate.

A solution of argentic succinimide in a small quantity of ammonia, leaves, on spontaneous evaporation, an alkaline syrupy liquid, which solidifies after some time to a mass of hard brittle crystals, consisting of *argentammonium-succinimide*, $C^4H^4O^2(NH^3Ag)N$, which is distinguished from argentic succinimide by its property of giving off ammonia when treated with potash at ordinary temperatures.

Chlorosuccinimide.—Ethylic perchlorosuccinate (p. 463) is converted by ammonia into a crystallisable and sublimable body, probably consisting of tetrachlorosuccinimide, $C^4Cl^4O^2HN$. The analysis of this body does not agree very well with this formula, but the formation of trichloracetamide, at the same time, seems to show that it is produced in the manner shown by the equation:

$$\underset{\substack{\text{Ethylic per-}\\\text{chlorosuccinate.}}}{C^8Cl^{14}O^4} + 3NH^3 = 4HCl + \underset{\text{Trichloracetamide.}}{2C^2H^2Cl^3NO} + \underset{\substack{\text{Tetrachlorosuc-}\\\text{cinimide.}}}{C^4Cl^4O^2HN}.$$

On treating the product with ether, the tetrachlorosuccinimide and trichloracetamide dissolve, while sal-ammoniac remains behind; and the ethereal solution leaves on evaporation, a residue, from which cold water extracts an ammoniacal compound of tetrachlorosuccinimide (chlorazosuccate of ammonium), leaving the trichloracetamide. The aqueous solution, mixed with hydrochloric or nitric acid, deposits the tetrachlorosuccinimide in four-sided prisms. It is nearly insoluble in water, very soluble in alcohol and ether; melts in water between 83° and 85°, in the air at 200°; sublimes at 125°, and turns yellow at 250°. It decomposes carbonates, and its ammoniacal solution precipitates the salts of calcium and copper. Its ammoniacal solution evaporates over the water-bath, decomposes with brisk effervescence, and yields, among other products, a crystalline substance, regarded by Gerhardt as **chlorosuccilamide**, $C^3H^2Cl^3NO^2$, the amide of chlorosuccic acid (p. 463), possibly thus:

$$\underset{\substack{\text{Chlorosuccini-}\\\text{mide.}}}{C^4Cl^4O^2HN} + H^2O = CO^2 + HCl + \underset{\substack{\text{Chlorosuccila-}\\\text{mide.}}}{C^3H^2Cl^3NO}.$$

Phenylsuccinimide, or *Succinanil*, $C^{10}H^9NO^2 = \left.\begin{matrix}(C^4H^4O^2)''\\ C^6H^5\end{matrix}\right\}N$. (Laurent and Gerhardt, Ann. Ch. Phys. [3], xxxiv. 179.)—Obtained by heating pulverised succinic acid with dry aniline, and treating the crystalline mass with boiling water, which dissolves the greater part of it, consisting of succinanil, and leaves a residue of succinanilide. The succinanil crystallises on cooling in colourless laminæ, and by recrystallisation from alcohol it may be obtained quite puro, in fine long interlaced needles. It appears to be sublimable without decomposition. It is insoluble in cold water. Aqueous potash has no action upon it, but when heated with solid potash it gives off aniline. Boiling aqueous ammonia converts it into succinanilic acid (p. 460).

Trisuccinamide, $(C^4\overset{\prime}{H}{}^4O^2)^3N^2$. (Chiozza and Gerhardt, Ann. Ch. Pharm. xc. 108.)—Produced, together with argentic chloride, by treating argentic succinimide with an ethereal solution of succinic chloride:

$$2(C^4H^4O^2)''AgN + (C^4H^4O^2)''Cl^2 = 2AgCl + (C^4\overset{\prime\prime}{H}{}^4O^2)^3N^2.$$

It is slightly soluble in ether, easily soluble in absolute alcohol, and crystallises in small triangular plates which melt at 83°. By aqueous alcohol it is quickly decomposed, yielding succinic acid, ethylic succinate, and succinimide.

SUCCINIC ANHYDRIDE. $C^4H^4O^3 = (C^4H^4O^2)''O$. *Anhydrous Succinic Acid*. (D'Arcet, Ann. Ch. Phys. [2], lviii. 282.—Gorhardt and Chiozza, Compt. rend. xxxvi. 1050.—Kraut, Ann. Ch. Pharm. cxxxvii. 254.)—Obtained: 1. By boiling succinic acid very rapidly in a retort, and absorbing the water as fast as it condenses.—2. By distilling succinic acid once or twice with phosphoric anhydride (D'Arcet).—3. By heating the acid with phosphoric pentachloride:

$$C^4H^6O^4 + PCl^5 = 2HCl + POCl^3 + C^4H^4O^3.$$

—4. By heating ethylic succinate with chlorobenzene. (Kraut, p. 463.)

Succinic anhydride is a white mass, less soluble in *water*, but more soluble in *alcohol*, than succinic acid. It dissolves in boiling absolute alcohol, apparently without formation of ethylic succinate, and is deposited from the solution in long needles. It is very little soluble in *ether*, either cold or boiling. Melts at 119·6° (Kraut). By solution in boiling water, it is reconverted into succinic acid. With dry *ammonia-gas* it becomes hot, and forms succinimide, together with water:

$$C^4H^4O^2.O + NH^3 = H^2O + C^4H^4O^2.HN.$$

With *phosphoric pentachloride*, it yields succinic chloride and phosphoric oxychloride:

$$C^4H^4O^2.O + PCl^5 = POCl^3 + C^4H^4O^2Cl^2.$$

SUCCINIC CHLORIDE, or *Chloride of Succinyl*, $(C^4H^4O^2)''Cl^2$. (Gerhardt and Chiozza, *loc. cit.*)—Produced as above, by distilling succinic anhydride with phosphoric pentachloride, and purified by rectification. It is a fuming, strongly refracting liquid, boiling at about 190°. With water it easily yields succinic acid; with alcohol, ethylic succinate.

Dibromosuccinic Chloride, $C^4H^2Br^2O^2.Cl^2$, is obtained by heating succinic chloride with bromine to 120°—130°, for three or four hours (Perkin and Duppa, Chem. Soc. Qu. J. xiii. 102); also by direct addition of bromine to fumaric chloride, $C^4H^2O^2Cl^2$ (Kekulé). It is a liquid, which boils at 220° (Kekulé), and is converted by water into dibromosuccinic acid. (Perkin and Duppa.)

SUCCINIC ETHERS. *a.* Of succinic ethers containing monatomic alcohol-radicles, only the neutral methylic, ethylic, cetylic, and benzhydrolic ethers have hitherto been obtained.

Methylic Succinate, $C^6H^{10}O^4 = \left.\begin{matrix}(C^4H^4O^2)''\\(CH^3)^2\end{matrix}\right\}O^2$, is produced by passing hydrochloric acid gas into a solution of succinic acid in methylic alcohol. When purified in the usual way, it forms a crystalline mass, melting at 20°, and solidifying again at 16°. It is nearly insoluble in water, but dissolves in alcohol and ether; boils at 198°. Specific gravity of liquid = 1·179 at 20°; of vapour 5·29. (Fehling, Ann. Ch. Pharm. xlix. 195.)

Ethylic Succinate, $C^8H^{14}O^4 = \left.\begin{matrix}(C^4H^4O^2)''\\(C^2H^5)^2\end{matrix}\right\}O^2$.—Prepared like the methylic ether, or by distilling 10 pts. succinic acid, 20 pts. alcohol, and 5 pts. strong hydrochloric acid, and purifying the oily product by distillation over massicot (D'Arcet, Ann. Ch. Phys. [2], lviii. 291); also by dropping alcohol into a retort in which succinic acid is heated to a temperature near its boiling-point (Gaulthier de Clanbry). It is an oil, slightly soluble in water, boiling at 214°, and burning with a yellow flame. Specific gravity of liquid = 1·036; of vapour = 6·22. (D'Arcet.)

When potassium is introduced into ethylic succinate, the liquid becomes hot, gives off hydrogen, and forms a pasty mass, from which, after treatment with water and crystallisation of the undissolved portion, yellowish laminæ are obtained, having the composition $C^6H^8O^3$ [therefore, perhaps, *ethylsuccinic anhydride*, $C^4H^3(C^2H^5)O^3$]. The crystals melt at 133°; sublime at 206°; and are decomposed by alkalis into alcohol and an alkaline succinate. With ammonia they form a light-yellow substance, crystallising in needles (Fehling, Ann. Ch. Pharm. xlix. 192). Respecting the rational formula, see Geuther. (Zeitschr. Ch. Pharm. 1866, p. 5.)

Ethylic succinate heated with chlorobenzene (chloride of phenyl) in a sealed tube to 250°, for several hours, yields ethylic chloride, ethylic benzoate, and succinic anhydride (Kraut, Ann. Ch. Pharm. cxxxvii. 254):

$$\left.\begin{matrix}(C^4H^4O^2)''\\(C^2H^5)^2\end{matrix}\right\}O^2 + C^7H^5OCl = C^2H^5Cl + \left.\begin{matrix}C^7H^5O\\C^2H^5\end{matrix}\right\}O + (C^4H^4O^2)''.O.$$

Substitution-products of Ethylic Succinate (Cahours, Ann. Ch. Pharm. xlvii. 29; Malaguti, *ibid.* lvi. 291).—When ethylic succinate is saturated with chlorine, and then exposed to sunshine in a bottle filled with chlorine-gas, a crystallisable substance is formed, which melts at 115°—120°, has the composition $C^8HCl^{13}O^4$, and may therefore be regarded as ethylic succinate in which all the hydrogen, except one atom, is replaced by chlorine. By distillation it is resolved, at about 290°, into carbonic anhydride, chloride of trichloracetyl, trichloride of carbon, and probably chlorosuccide, C^3HCl^3O:

$$C^8HCl^{13}O^4 = CO^2 + C^2Cl^3O.Cl + C^2Cl^6 + C^3HCl^3O.$$

With alcohol it yields neutral ethylic carbonate (i. 800), ethylic trichloracetate (i. 879), hydrochloric acid, and the ethylic ether of chlorosuccic acid.—The chlorinated ether, or the product formed from it by the action of alcohol, yields, when treated with potash, carbonate, chloride, formate, and chlorosuccate of potassium. (Malaguti.)

Laurent and Gerhardt suppose that Malaguti's chlorinated ether contains no hydrogen, but consists of perchlorinated ethylic succinate, $C^8Cl^{14}O^4$. Gerhardt regards chlorosuccic acid as $C^4HCl^3O^2 = \left.\begin{matrix}C^3Cl^3O\\H\end{matrix}\right\}O$ (trichloracrylic acid), and chlorosuccide as the corresponding chloride, $C^3Cl^3O.Cl$. These formulæ afford simple explanations of all the reactions, but they do not agree well with the analytical numbers obtained by Cahours and Malaguti.—Chlorinated ethylic succinate, treated with ammonia, yields, among other products, a compound designated by Malaguti as chlorazosuccic acid (C^3HCl^3ON), but regarded by Laurent as tetrachlorosuccinimide, $C^4Cl^4O^2.HN$ (p. 461). For further details respecting these chlorinated compounds, see Gerhardt's *Traité*, ii. 466, 477.

Cetylic Succinate, $C^{36}H^{70}O^4 = \left.\begin{matrix}(C^4H^4O^2)''\\(C^{16}H^{33})^2\end{matrix}\right\}O^2$. (Tüttscheff, Rep. Chim. pure, ii. 463.)—Produced by heating 1 at. succinic acid and 2 at. ethal for 15 hours (to what temperature?). Crystallises from hot ether-alcohol in white laminæ, melting at 58°, slightly soluble in alcohol, more soluble in ether.

Benzhydrolic Succinate, $C^{30}H^{26}O^4 = \left.\begin{matrix}(C^4H^4O^2)''\\(C^{13}H^{11})^2\end{matrix}\right\}O^2$.—Produced by heating succinic acid with benzhydrol; described under Phenylbenzoyl (iv. 479).

β. *Succinic Ethers containing Diatomic Alcohol-radicles.*

Only two of these ethers have yet been obtained, viz., the acid and neutral succinates of ethylene, both discovered by Lourenzo. (Ann. Ch. Pharm. cxv. 358.)

Ethylene-succinic, or *Glycolsuccinic Acid*, $C^6H^{10}O^5 = \left.\begin{matrix}(C^4H^4O^2)''\\(C^2H^4)''\\H^2\end{matrix}\right\}O^3$.—Produced by heating succinic acid with glycol to 150°: $C^4H^6O^4 + C^2H^6O^2 = C^6H^{10}O^5 + H^2O$.

It forms small crystals, melting below 100°, soluble in water and alcohol, insoluble in ether.

Neutral Ethylenic Succinate, or *Succinate of Glycol*, $C^6H^8O^4 = \left.\begin{matrix}(C^4H^4O^2)''\\(C^2H^4)''\end{matrix}\right\}O^2$, remains when ethylene-succinic acid is heated to 300°, as a crystalline mass, which melts at about 90°, is insoluble in water and in ether, but may be crystallised from boiling alcohol.

SUCCINITE. An amber-coloured variety of lime-garnet. The name is applied also by Breithaupt to amber.

SUCCINONE. This name has been applied to a volatile oil obtained by the distillation of neutral calcic succinate (p. 455).

SUCCINO-SULPHURIC ACID. Syn. with SULPHOSUCCINIC ACID.

SUCCINUM. Syn. with AMBER.

SUCCINYL. $C^4H^4O^2$. The diatomic radicle of succinic acid, &c.

SUCCINYLIC ACID. Syn. with SUCCINIC ACID.

SUCCISTERENE (from *succinum* and *stearin*).—The name applied by Pelletier and Walter to the portion of *Colophonium succini* which is insoluble in alcohol and ether. (See AMBER, i. 163.)

SUCROSE. Syn. with CANE-SUGAR.

SUET. The solid fat of the ox or sheep. Mutton-suet is more solid than beef-suet, and consists mainly of stearin, together with palmitin, and small quantities of olein and hircin; melts at 50° (Arzbächer). Beef-suet contains more stearin than human fat, more palmitin than mutton-suet, and about the same quantity of olein; melts at 47°. (Arzbächer.)

SUGARS. Under this name are included a number of organic compounds, mostly of vegetable origin, which are soluble in water, mostly crystallisable, have a sweet taste, and neutral reaction to vegetable colours, and in the state of solution rotate the plane of vibration of a ray of polarised light. They may be divided into fermentable or true sugars, and non-fermentable sugars or saccharoïds.

A. *Fermentable Sugars.*—These sugars are carbohydrates, represented[*] by the general formula $C^nH^{2p}O^p$, and may be subdivided into the two following groups, the first including those sugars which are directly susceptible of vinous fermentation, the second those which undergo this transformation only after conversion into sugars of the first group:

a. $C^{12}H^{12}O^6$ (Glucoses).

	Molecular rotatory power.
Dextrose or Dextroglucose (ii. 855)	+ 56°
Lævulose or Lævoglucose (ii. 863)	− 106° at 14° − 53° at 90°
Galactose (iii. 1023).	+ 83°

To this group belong also a number of sugars differing more or less in properties from the three preceding, viz. Maltose (iii. 999), Mannitose (iii. 826); the sugar found by Meissner (Jahresb. 1861, p. 800) as a normal constituent of muscular flesh; Dulcitose, a product of the oxidation of dulcite by nitric acid (Carlet, Ann. Ch. Pharm. cxvii. 143); the sugar which Berthelot obtained (ii. 856) from mannite and glycerin by the action of a peculiar ferment; and many of the sugars resulting from the decomposition of natural glucosides under the influence of acids (ii. 865).

b. $C^{12}H^{22}O^{11}$ (Cane-sugar and its isomers).

	Molecular rotatory power.
Saccharose or Cane-sugar	+ 73·8°
Parasaccharose	+ 108°
Lactose or Milk-sugar	+ 59·3
Melezitose (iii. 868)	+ 94
Melitose (iii. 869)	+ 102
Mycose (iii. 1068)	+ 192·5
Trehalose ,,	+ 199

The sugars of this group may be regarded as ethers of the glucoses, being related to them in the same manner as diethylenic alcohol to glycol, or as diglycerin to glycerin (iii. 576, 884):

$$\begin{array}{ccc} \text{Glucose.} & \qquad\qquad & \text{Saccharose.} \\ \left.\begin{array}{c}(C^6H^6)^{vi} \\ H^6\end{array}\right\}O^6 & & \left.\begin{array}{c}(\overset{vi}{C^6H^6})^2 \\ H^{10}\end{array}\right\}O^{11} \end{array}$$

B. *Non-fermentable Sugars* or *Saccharoids.*—Of these bodies, the first four in the following list have the composition of the glucoses; the rest are not carbohydrates, but contain a quantity of hydrogen larger than is sufficient to convert the whole of the oxygen into water:

	Molecular rotatory power.
Eucalyn, $C^6H^{12}O^6$ (ii. 601)	+ 55° (nearly)
Sorbite, $C^6H^{12}O^6$ (v. 352)	− 46·9°
Quercitose,* $C^6H^{12}O^6$? (v. 37)	0°
Inosite, $C^6H^{12}O^6$ (iii. 274)	0°
Mannite, $C^6H^{14}O^6$ (iii. 825)	0°
Dulcite, $C^6H^{14}O^6$ (ii. 348)	0°
Isodulcite,† $C^6H^{14}O^6$ (v. 7)	+ 7·6°
Quercite, $C^6H^{12}O^5$ (v. 6)	+ 33·5° (nearly)
Pinite, $C^6H^{12}O^5$ (iv. 652)	+ 58·6°
Erythromannite, $C^{12}H^{30}O^{12}$ (ii. 504)	0°

In these tables the value of the molecular rotatory power is given for the transition-tint (iii. 672), which is the same as that for the medium yellow ray, and is commonly expressed by the symbol $[\alpha]_j$. The value for the red ray is related to this by the equation:

$$[\alpha]_r = \frac{23}{30}[\alpha]_j$$

The molecular or specific rotatory power $[\alpha]$ is given by one of the following equations:

$$\text{I.}\quad [\alpha] = \frac{\alpha}{\epsilon\,.\,\delta\,.\,\lambda} \quad . \quad . \quad \text{(iii. 673.)}$$

$$\text{II.}\quad [\alpha] = \frac{a\,V}{l\,p} \text{ or } [\alpha] = \frac{a}{v\,l}$$

In these equations, α or a is the observed angle of rotation; ϵ, the concentration of the solution (1 grm. of solution containing ϵ grms. of substance); δ, the specific gravity of the solution; λ or l, the length of the column of liquid in decimetres.‡

Further: p, the weight of the substance in grammes; V, the volume of the solution containing it.

Also: v, the concentration of the solution according to volume, *i.e.* the quantity of grammes of the substance contained in 1 cub. cent. of solution, so that $v = \frac{p}{V} = \epsilon\,.\,\delta$.

The equation I. is used when the concentration and specific gravity of the solution are known; the equation II. when, as is generally the case, the solution is prepared by weighing out the substance, and filling up the liquid with water to a given bulk.

The molecular rotatory power of most sugars is but little affected by temperature; that of lævulose, however, diminishes rapidly as the temperature rises. A recently prepared mixture of crystallised dextrose (grape-sugar) exhibits, when recently prepared, a rotatory power of about 112°; but it decreases gradually at ordinary temperatures, and quickly when the liquid is heated, and ultimately remains constant at + 56°.

Mixtures of dextrose and lævulose exhibit dextro- or lævo-rotation, according to the proportions in which the two are mixed; this is seen in different samples of honey, and in fruits. Inverted sugar (ii. 863), produced by the action of acids on cane-sugar, is a mixture of dextrose and lævulose in equal quantities. Its specific rotatory power varies greatly according to temperature: at 15° it is $[\alpha] = -\frac{106}{2} + \frac{56}{2} =$

---

* The sugar obtained by decomposing quercitrin with dilute sulphuric acid is, according to Rigaud (Ann. Ch. Pharm. xc. 195), identical with dextrose in every respect, excepting that it is optically inactive.

† According to Hlasiwetz and Pfaundler, on the other hand (Jahresb. 1864, p. 564), quercitrin thus treated yields a saccharine substance, which they call isodulcite, crystallising in the same form as cane-sugar, but differing therefrom in properties and composition. The crystals contain $C^6H^{12}O^5.H^2O$, and melt, with loss of their crystallisation-water, between 105° and 110°. Isodulcite dissolves in 2·09 pts. water at 15°, and is also readily dissolved by hot absolute alcohol. It reduces an alkaline cupric solution, and forms with nitric acid, a nitro-compound containing $C^6H^9(NO^2)^3O^5$.—Hydrated isodulcite is isomeric with mannite and dulcite; the anhydrous compound with pinite and quercite.

‡ In the equation given under LIGHT (iii. 673), the unit of length for l, is 1 centimetre: and the specific rotatory power of cane-sugar there calculated from the formula is 7·3°, whereas in the table on p. 464, where the unit of length is supposed to be a decimetre, it is ten times as much, namely 73·8°.

$-25°$; at $25°$ it is $-12·5°$; at $90°$ it is nearly $= 0$, and at higher temperatures the mixture becomes dextrorotatory.

Chemical Reactions of Sugars: 1. *Decomposition by heat.*—All sugars are decomposed by heat. Those which contain water of crystallisation give it off at 100° or a little above—viz., grape-sugar, melitose, trehalose, eucalyn, and inosite at 100°, melezitose at 110°, mycose at 130°. At somewhat higher temperatures the glucoses give off more water, and yield anhydrides analogous to mannitan (iii. 823): thus

$$\left.\begin{matrix}\text{Dextrose}\\ \text{Lævulose}\end{matrix}\right\} C^6H^{12}O^6 = \left\{\begin{matrix}H^2O + C^6H^{10}O^5 \text{ Glucosan}\\ H^2O + C^6H^{10}O^5 \text{ Lævolusan.}\end{matrix}\right.$$

When further heated, they yield a number of somewhat indefinite compounds, designated by the general name caramel; and at still higher temperatures, they undergo complete decomposition, giving off carbonic oxide, carbonic anhydride, marsh-gas, acetic acid, aldehyde, acetone, furfurol, liquid hydrocarbons, and other products. The sugars, $C^{12}H^{22}O^{11}$, appear to be first converted by heat into a mixture of glucoses and glucosanhydrides (*e. g.*, cane-sugar into dextrose and lævolusan), which are resolved by further heating into the products above mentioned.

2. *Oxidation.*—Sugars are easily oxidable. With strong oxidising agents they mostly yield products of comparatively simple constitution, such as carbonic, formic, and oxalic acids. Glucose and cane-sugar, &c., distilled with a mixture of *manganic peroxide* or *potassic chromate* and sulphuric acid, or with *peroxide of lead* and water, yield chiefly formic and carbonic acids; milk-sugar distilled with *potassic chromate* and sulphuric acid yields the same products, together with aldehyde.

By prolonged boiling with *strong nitric acid*, sugars yield chiefly oxalic acid. With *more dilute acid*, and at lower temperatures, acids are formed nearer in composition to the sugars—chiefly mucic, saccharic, and tartaric acids, sometimes also racemic acid. The formation of the isomeric compounds, mucic and saccharic acids, is represented by the equation:

$$C^6H^{12}O^6 + O^3 = H^2O + C^6H^{10}O^8.$$

Tartaric acid is probably formed by further oxidation of saccharic acid; and racemic acid by oxidation of mucic acid (p. 35).

Cane-sugar, glucose, and indeed most other sugars, yield by this gradual oxidation, only saccharic acid; milk-sugar yields mucic with a small quantity of saccharic acid; melitose yields saccharic with a small quantity of mucic acid.

Sugars are oxidised by many metallic oxides and salts, and therefore act as reducing agents: thus from *silver-salts*, especially in presence of ammonia, they throw down metallic silver; from *cupric salts*, especially in alkaline solution, they precipitate cuprous oxide (ii. 860). The glucoses in general exert a stronger reducing action than cane-sugar and its isomers; of the latter, milk-sugar reduces more quickly than cane-sugar. The products formed in these reactions have not been very closely investigated. (See Gallactic and Pectolactic Acids, iii. 1024.)

3. *Very strong nitric acid* (specific gravity, 1·525), or a mixture of strong *nitric* and *sulphuric acids*, converts sugars into nitro-compounds: cane-sugar thus treated yields nitro-saccharose, probably $C^{12}H^{18}(NO^2)^4O^{11}$; inosite yields crystallisable nitro-inosite, $C^6H^6(NO^2)^6O^6$; isodulcite, $C^6H^{12}O^5.H^2O$, yields $C^6H^9(NO^2)^3O^5$; dextrose, milk-sugar, and trehalose yield nitro-compounds whose composition has not been exactly ascertained.

4. Reactions with other *acids.*—By boiling with dilute *sulphuric* or *hydrochloric acid*, cane-sugar and its isomers are converted into glucoses:

$$C^{12}H^{22}O^{11} + H^2O = C^6H^{12}O^6 + C^6H^{11}O^6.$$

In this manner melezitose yields 2 at. of dextrose; lactose yields 2 at. of galactose; cane-sugar yields 1 at. dextrose + 1 at. lævulose; and melitose yields 1 at. dextrose + 1 at. eucalyn.

The glucoses offer considerable resistance to further transformation by dilute mineral acids; but ultimately they turn brown and decompose, the more quickly as the acid is less dilute, yielding brown humus-like products of indeterminate composition; this transformation is most quickly effected by strong hydrochloric acid.

Concentrated sulphuric acid acts on the sugars, $C^{12}H^{22}O^{11}$, much more strongly than on the glucoses. A strong syrup of cane- or milk-sugar mixed with concentrated sulphuric acid, is immediately decomposed with great intumescence, evolution of sulphurous anhydride and various volatile products, and separation of a black carbonaceous mass.—Dextrose, on the other hand, mixed with strong sulphuric acid, forms, without blackening, a sulpho-acid, $C^{24}H^{48}SO^{27} = 4C^6H^{12}O^6.SO^3$, the action being exactly similar to that of the organic acids on the glucoses (p. 467):

$$4C^6H^{12}O^6 + H^2SO^4 = H^2O + C^{24}H^{48}SO^{27}.$$

Phosphoric acid appears also to form a similar compound with dextrose.

The glucoses heated with solutions of *organic acids* act like polyatomic alcohols yielding ethereal compounds called saccharides, which resemble the mannitic ethers (ii. 521), inasmuch as they are derivatives, not directly of glucose, $C^6H^{12}O^6$, but of glucosan, $C^6H^{10}O^5$: thus—

$$\underset{\text{Dextrose.}}{C^6H^{12}O^6} + \underset{\text{Butyric acid.}}{2C^4H^8O^2} - 3H^2O = \underset{\text{Dibutyryl-glucosan.}}{C^6H^8(C^4H^7O)^2O^5}$$

$$\underset{\text{Dextrose.}}{C^6H^{12}O^6} + \underset{\text{Stearic acid.}}{2C^{18}H^{36}O^2} - 3H^2O = \underset{\text{Distearyl-glucosan.}}{C^6H^8(C^{18}H^{35}O)^2O^5}$$

$$\underset{\text{Dextrose.}}{C^6H^{12}O^6} + \underset{\text{Acetic acid.}}{6C^2H^4O^2} - 7H^2O = \underset{\text{Hexacetyl-glucosan.}}{C^6H^4(C^2H^3O)^6O^5}$$

$$\underset{\text{Dextrose.}}{C^6H^{12}O^6} + \underset{\text{Alcohol.}}{2C^2H^6O} - 2H^2O = \underset{\text{Diethyl-glucosan.}}{C^6H^8(C^2H^5)^2O^5}{}^*$$

Cane-sugar and its isomers, heated with organic acids, are first converted into glucoses, and then into saccharides as above.

With *tartaric acid*, the sugars appear to form several different compounds. The following are described by Berthelot (*Chim. org.* ii. 294):

1. From Dextrose, $C^6H^{12}O^6 + 4C^4H^6O^6 - 5H^2O = C^{22}H^{26}O^{25}$
2. „ Cane-sugar, $C^6H^{12}O^6 + 2C^4H^6O^6 - 3H^2O = C^{14}H^{18}O^{15}$
3. „ Milk-sugar, $C^6H^{12}O^6 + 4C^4H^6O^6 - 3H^2O = C^{22}H^{30}O^{27}$
4. „ „ $3C^6H^{12}O^6 + 4C^4H^6O^6 - 7H^2O = C^{34}H^{46}O^{35}$

5. *Reactions with Alkalis.*—Sugars act like weak acids, inasmuch as they are capable of forming saline compounds with certain bases, or, in other words, of exchanging part of their hydrogen for metals. Thus dextrose, $C^6H^{12}O^6$, forms with baryta the compound $C^{12}H^{22}Ba''O^{12}$; and cane-sugar forms with the same base, a compound which may be formulated as $C^{12}H^{20}Ba''O^{11}.H^2O$, or as $C^{12}H^{22}O^{11}.Ba''O$. Dextrose and cane-sugar also form saline compounds with potash and soda; these compounds are obtained by agitating the alcoholic solution of the sugar with alcoholic potash.

In aqueous solution, on the other hand, the glucoses are very easily decomposed by alkalis, even when very dilute. The decomposition takes place slowly in the cold, more quickly on heating, the liquid first turning yellow, then brown, and yielding a quantity of indeterminate brown humous substance. Dextrose thus treated yields glucic acid (ii. 848), as the first product of the reaction.

The sugars, $C^{12}H^{22}O^{11}$, are for the most part much less readily attacked by alkalis than the glucoses; they are not attacked by dilute alkaline solutions in the cold, and but slowly even when heated; but they are decomposed by boiling with concentrated alkaline liquids. When fused with caustic alkalis they yield oxalic acid.

In general those sugars (and other carbohydrates), which are most easily attacked by acids, offer the greatest resistance to the action of alkalis.

The sugars and other carbohydrates, when treated with *ammonia* in the form of gas, or of aqueous solution, are capable of forming compounds somewhat resembling gelatin, and containing in some cases as much as 14—19 per cent. nitrogen. Dusart (Compt. rend. lii. 974), by heating glucose, milk-sugar, or starch with aqueous ammonia to 150°, obtained nitrogenised substances, which were precipitated by alcohol in tenacious threads, and formed with tannic acid an insoluble, non-putrefying compound. Similar results were obtained by Schützenberger (Jahresb. 1861, p. 910). P. Thénard (*ibid.* p. 908), by operating in a similar manner, but at a temperature of 280°, obtained yellow or brown nitrogenised products—some soluble, others insoluble in water, and containing as much as 19 per cent. nitrogen. These results are especially interesting in connection with the observation made by Hunt (Jahresb. 1847-48, p. 845), that bone-gelatin has, approximately, the composition of an amide of the carbohydrates:

$$C^6H^{12}O^6 + 2NH^3 = C^6H^{10}N^2O^2 + 4H^2O;$$

and that, on the other hand, gelatin and similar substances, when boiled for some time with sulphuric acid, yield, among other products, sugars resembling glucose.

Action of Ferments.—The glucoses, viz. dextrose, lævulose, and galactose, are directly susceptible of vinous fermentation; that is to say, when their aqueous solutions are placed in contact with yeast at a certain temperature, they are immediately resolved into alcohol and carbonic anhydride: $C^6H^{12}O^6 = 2C^2H^6O + 2CO^2$. Cane-sugar and its homologues, on the other hand, do not undergo this change until they have first been converted into glucoses, this action being due to a peculiar soluble ferment, analogous to diastase, contained in the yeast (p. 471). Respecting the various circumstances attending vinous fermentation, and the action of other ferments on sugars, see FERMENTATION (ii. 623).

---

* Produced by heating cane-sugar with ethylbromide and potash.

Most of the sugars enumerated in the preceding tables (pp. 464, 465), have already been described in their alphabetical places. We have here to consider in detail the one to which the name sugar is especially applied, viz.:

CANE-SUGAR OR SACCHAROSE.*

This kind of sugar is very widely diffused in the vegetable kingdom, and has been lately shown to exist in many plants, from which, in consequence of the modes of extraction formerly adopted, only grape-sugar (dextrose), or uncrystallisable fruit-sugar (a mixture of dextrose and lævulose), had been obtained. It is very abundant in the stems of certain grasses, especially in the sugar-cane (*Saccharum officinarum*), which contains more than 20 per cent. of it, unmixed with any other kind of sugar, and the sorgho or Chinese sugar-cane (*Sorghum saccharatum*, p. 354), which contains it to the amount of 9 to 9½ per cent. The juice of maize-stems, cut shortly after flowering, contains a quantity of sugar amounting to between 7·4 and 7·9 per cent. of the juice, and about half consisting of cane-sugar (Lüdersdorff).—Cane-sugar is abundant in many fleshy roots, as those of the carrot and parsnip, and especially in that of beet (*Beta vulgaris*), which contains on the average from 7 to 11 per cent. of it, sometimes as much as 14 per cent.; and in the stems of certain species of birch and maple, especially of the sugar-maple (*Acer saccharinum*), and of many kinds of palm. (See PALM-SUGAR, iv. 336.)

Most sweet fruits contain cane-sugar together with inverted sugar (ii. 863); some, as walnuts, hazelnuts, almonds, coffee-beans, and St. John's-bread (the fruit of *Ceratonia siliqua*), contain only cane-sugar. Honey and the nectars of flowers contain cane-sugar together with inverted sugar; the sugar in the nectars of cactuses is almost wholly cane-sugar.

Manna from Sinai (the produce of *Tamarix mannifera*) contains 55 per cent. cane-sugar, 25 inverted sugar, and 20 dextrin, &c. Manna from Kurdistan contains 61 per cent. cane-sugar, 16·5 inverted sugar, and 22·5 dextrin, &c. (Berthelot, Compt. rend. liii. 583.)

Cane-sugar has been known in India and China from very early times, and in Europe since the time of Alexander the Great. The culture of the sugar-cane was imported, in the fourteenth and fifteenth centuries, from Nubia, Arabia, and Egypt, into Spain, Portugal, and the Canary Islands, and afterwards to America: it was only after this last importation that it came into general use. The presence of cane-sugar in beet and other plants indigenous in Europe was first demonstrated, in 1747, by Marggraf, and its preparation on the large scale from beet was introduced by Achard. The chemical composition of cane-sugar was established by Gay-Lussac and Thénard.

Preparation.—Cane-sugar has not yet been formed artificially. It is prepared almost exclusively from the juice of the sugar-cane, and of field-beet or mangold-wurzel; smaller quantities are obtained from the sorgho and the sugar-maple.

1. From the Sugar-cane.—The ripe canes cut close to the ground and stripped of their leaves are crushed between rollers, and the expressed juice, which is apt to run quickly into fermentation by the action of the albuminous matters which it contains, is *defecated* by heating it in a copper boiler to about 60° C. (140° F.), with a small quantity of lime. The impurities then form a scum, which is removed as fast as it collects. The juice, when sufficiently clarified, is rapidly concentrated to about 23° of the hydrometer, then passed through cloth filters and evaporated to a very thick syrup, which is run into shallow vessels to accelerate cooling, then poured into vessels having their bottoms pierced with holes which are kept plugged. The syrup, after being left at rest for some hours, is agitated to promote the crystallisation of the sugar; and as soon as it has set into a solid mass, the plugs are removed, to allow the still remaining liquid to run off, and the syrup is again boiled till it no longer yields any crystals. The last mother-liquors, which are thick, brown, and refuse to crystallise, are called molasses or treacle, and are used chiefly for the preparation of rum.

The solid sugar, obtained as above, is sent to Europe under the name of raw sugar, or Muscovado sugar. It is a yellowish granular powder, still impregnated with treacle, and often contaminated with foreign substances, which impart to it a more or less disagreeable taste: hence it requires refining.

The formation of molasses is entirely due to the conversion of the cane-sugar into uncrystallisable sugar by the heat to which the juice is subjected; the fresh juice of sound canes contains nothing but crystallisable sugar. Great improvements have recently been effected in the methods of boiling down syrups, especially by the use of vacuum-pans, whereby a beautiful crystallised product is obtained from the juice at the first evaporation, and the formation of molasses is greatly diminished.

---

* For Literature see *Gmelin's Handbook*, xv. 237.

On the manufacture of sugar from the cane, see *Ure's Dict. of Arts*, &c., iii. 802—816.—Manufacture of Maple-sugar, *ibid.* p. 826.

2. From **Beetroot.**—The roots of mangold-wurzel are reduced to a fine pulp, from which the juice is separated, either by pressure, after adding a quantity of water equal to 20 per cent. of the weight of the root; or by lixiviating it with cold water; or, finally, by subjecting it in perforated cylinders to the rotatory action of a centrifugal machine.—The juice is heated to 68° by hot steam, every 1000 quarts being mixed with a quantity of milk of lime prepared from 12 lbs. of lime, and the mixture is further heated to the boiling-point, whereby phosphate of calcium, albumin, albuminate of calcium, and other matters are separated, in the form of a dense white crust. The heating is interrupted as soon as the boiling juice begins to break through the crust, the clear liquid below is run off, and the muddy residue is submitted to pressure. The calcareous *thin syrup* thus obtained is treated with carbonic acid (from 0·6 to 0·8 per cent. lime, however, remains dissolved as sugar-lime); separated by subsidence and decantation from precipitated carbonate of calcium; filtered through bone-black, which removes a small quantity of sugar-lime; and evaporated to 20—22° Bm., either in open pans or in a vacuum-apparatus. The *thick syrup*, again filtered through bone-black, and evaporated in vacuo at about 22" barometric pressure, till it becomes thick enough to draw out into threads, yields, after cooling and standing, crystals of cane-sugar; and the mother-liquor, when further evaporated, yields a second and third crop, till nothing remains but uncrystallisable molasses. The last very dark-coloured crop of crystals is moistened with water, and freed from adhering molasses by means of the centrifugal machine. The mixture of all the successive crops of crystals thus obtained constitutes raw beet-sugar. (For details, see *Handw. d. Chem.* ix. 1101.)

Refining.—To obtain pure, colourless, crystallised sugar from raw sugar, the latter, dissolved in about a third of its weight of water, is mixed with a small quantity of milk of lime, and heated to the boiling-point; and the juice is decanted from the impurities, which separate in the form of a crust, then filtered through bone-charcoal, and evaporated in a vacuum pan. The strongly concentrated juice is made to crystallise by moderating the heat and running in small quantities of unthickened juice, whereupon a magma of sugar-crystals immediately forms. To give them the requisite hardness, heat is again applied, the crystalline magma is left to drain in the sugarloaf moulds, and the formation of small uniform crystals is promoted by stirring and breaking up the crust which forms on the surface. When the crystallisation is complete, the apex of the mould, which has previously been closed, is opened, to allow the syrup to drain off, and that which remains adhering to the crystals is displaced by pouring in pure sugar-syrup. By due desiccation, the *loaf-sugar* or *refined sugar* of commerce is obtained. (*Ure's Dict. of Arts*, &c. iii. 802.)

Formerly the clarification of the syrup was effected by adding a certain quantity of the serum of bullock's blood; on heating the syrup, the albumin of the serum became coagulated and rose to the surface, carrying with it the greater part of the impurities.

Preparation on the small scale.—The sacchariferous portion of a plant, after being dried and pulverised, is boiled with 2 pts. of strong alcohol, and the filtrate is left to cool; it then, after some time, deposits crystals of sugar. (**Marggraf.**)

From **fruits**, likewise containing uncrystallisable (inverted) sugar, cane-sugar may be extracted by filtering the expressed juice (after adding an equal volume of alcohol, if necessary, to prevent alteration), then saturating it with slaked lime, and filtering. The filtrate heated to the boiling-point, and again filtered at that temperature, leaves on the filter insoluble sugar-lime, which, after thorough washing with water, is to be decomposed by carbonic acid. The sugar-solution is then evaporated to a syrup, decolorised with animal charcoal, mixed with alcohol till it becomes turbid, and left to crystallise. The insoluble sugar-lime produced at the boiling heat does not contain more than $\frac{2}{3}$ of the total quantity of sugar present: hence the treatment with lime must be repeated. If the decomposition of the sugar-lime by carbonic acid yields very turbid liquids, they must be precipitated with basic acetate of lead, and the filtrate treated with sulphydric acid. (**Buignet.**)

Properties.—Cane-sugar separates from its solutions by slow evaporation in large crystals (sugar-candy), having the form of monoclinic prisms, generally with hemihedral faces. Axes $a : b : c = 0·7952 : 1 : 0·7$. Angle of axes b, $c = 76° 44'$; $\infty P : \infty P$ (orthod.) $= 101° 30'$; $+ P\infty : + P\infty$ (clinod.) $= 98° 50'$; $+ P\infty : c = 64° 12'$.—Ordinary combinations, $\infty P . oP . \infty P\infty$ (*fig.* 780), and $\infty P . oP . \infty P\infty . + P\infty . [P\infty]$ (*fig.* 781). By the cooling of hot saturated solutions, the sugar is obtained or masses of smaller crystals having the same form (loaf-sugar). The crystals exhibit phosphorescence when broken, also when a strong electric discharge is passed through them. Specific gravity = 1·606.

Fig. 780.

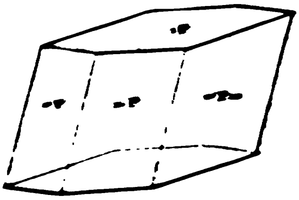

Fig. 781.

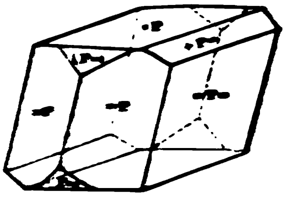


Cane-sugar is very soluble in water, dissolving in a third of its weight of cold, and still more easily in hot water: concentrated solutions are syrupy. It is insoluble in ether and in cold absolute alcohol; boiling alcohol dissolves about 1¼ per cent. of it; aqueous alcohol dissolves it much more readily.

Percentage of Cane-sugar in Aqueous Solutions of different Densities.

(Extracted from the Tables of Balling and Brix.)

Cane-sugar per cent.	Specific gravity at 17·5°.	Cane-sugar per cent.	Specific gravity at 17·5°.
1	1·0040	55	1·2610
5	1·0200	60	1·2900
10	1·0404	65	1·3190
15	1·0614	70	1·3507
20	1·0832	75	1·3824
25	1·1059	80	1·4159
30	1·1295	85	1·4499
35	1·1540	90	1·4849
40	1·1794	95	1·5209
45	1·2057	99	1·5594
50	1·2165		

The aqueous solution of cane-sugar turns the plane of a polarised ray to the right, for the transition-tint, $[\alpha]_j = +73·8°$. The rotatory power varies but little with changes of temperature.

Cane-sugar melts at 160° to a clear liquid, and solidifies on cooling to a transparent amorphous mass, commonly called barley-sugar, which gradually becomes opaque and crystalline.

Decompositions.—1. Cane-sugar heated a little above 160°, is converted, without loss of weight, into a mixture of *dextrose* and *levulosan* (ii. 864):

$$C^{12}H^{22}O^{11} = C^6H^{12}O^6 + C^6H^{10}O^5.$$

At a higher temperature, water is given off, the dextrose being probably converted into glucosan (ii. 854), afterwards at about 210°, more water is given off and caramel remains (1). At a still higher temperature, an inflammable gaseous mixture is given off, consisting of carbonic oxide, marsh-gas, and carbonic anhydride; a distillate is obtained, consisting of brown oils, acetic acid, acetone, and aldehyde; and a considerable quantity of charcoal remains behind. The brown oils contain a small quantity of furfurol (ii. 750), and a bitter substance called assamar (i. 418). (For further details respecting these products, see Gm. xv. 248.)

2. By prolonged boiling with *water*, cane-sugar is converted into a mixture of dextrose and lævulose, called inverted sugar (ii. 863), because the rotatory power of the lævulose is greater than that of the dextrose:

$$\underset{\text{Saccharose.}}{C^{12}H^{22}O^{11}} + H^2O = \underset{\text{Dextrose.}}{C^6H^{12}O^6} + \underset{\text{Lævulose.}}{C^6H^{12}O^6}.$$

This transformation is accelerated by the presence of acids, and apparently also of certain salts. Very dilute acids convert the cane-sugar into inverted sugar, slowly in the cold, very quickly when heated. Different acids act with various degrees of rapidity—mineral more quickly than organic acids, sulphuric acid most quickly of all. When sugar is boiled even with very dilute acids, especially if the boiling be long-continued, a number of brown amorphous products are formed, called ulmin, ulmic acid, &c. (Gm. xv. 254); if the air has access to the liquid, formic acid is likewise produced.—Concentrated hydrochloric acid decomposes sugar very quickly.

Strong sulphuric acid decomposes dry sugar when heated, and a concentrated solution, even at ordinary temperatures, with copious evolution of sulphurous anhydride and formation of a large quantity of black carbonaceous matter. By this reaction cane-sugar may be distinguished from glucose (ii. 859, 864).

3. Cane-sugar is very easily oxidised. It reduces *silver-* and *mercury-salts* when heated with them, and precipitates *gold* from the chloride. Pure *cupric hydrate* is but slowly reduced by it, even at the boiling heat; in presence of alkali, however, a blue solution is formed, and on boiling the liquid cuprous oxide is precipitated. An alkaline solution of *cupric tartrate* is very slowly reduced by cane-sugar.—Cane-sugar takes fire when triturated with 8 pts. *peroxide of lead*, and forms with *chlorate of potassium* a mixture which detonates on percussion, and burns vividly when a drop of oil of vitriol is let fall upon it. Cane-sugar, distilled with a mixture of *sulphuric acid* and *manganic peroxide*, yields formic acid. Heated with *dilute nitric acid*, it yields saccharic and oxalic acids. 1 pt. sugar mixed with 3 pts. nitric acid of specific gravity 1·25 to 1·30, and heated to 50°, is wholly converted into saccharic acid:

$$C^{12}H^{22}O^{11} + O^6 = 2C^6H^{10}O^8 + H^2O.$$

At the boiling heat, the product consists chiefly of oxalic acid. Very strong nitric acid, or a mixture of strong nitric and sulphuric acids, converts sugar into nitrosaccharose, probably $C^{12}H^{18}(NO^2)^4O^{11}$. Sugar is likewise oxidised by *chloride of lime*, but the products have not been examined.

4. Cane-sugar does not turn brown when triturated with *alkalis*, a character by which it is distinguished from glucose: it combines with them, however, forming compounds called sucrates. By boiling with *potash-ley* it is decomposed, but much more slowly than the glucoses. When fused with *potassium-hydrate* containing water, it yields chiefly formic, acetic, and propionic acids; with dry potassium-hydrate it yields oxalic acid (Gottlieb, Ann. Ch. Pharm. lii. 122). Distilled with *soda-lime*, it yields small quantities of ethylene, tritylene, and amylene (Berthelot, Jahresb. 1857, p. 426); and, when distilled with *quicklime*, it gives off acetone, metacetone, &c. (Gottlieb.)

5. Dry *chlorine* does not attack sugar at ordinary temperatures; but at 100°, a brown substance is formed, partly soluble in water. On passing chlorine into sugar-water, hydrochloric acid is slowly formed, together with carbonic acid, a brown substance, and an uncrystallisable organic acid.—*Perchlorides* act upon sugar (and other carbohydrates) in the same manner as free chlorine, producing dark-coloured products. This reaction is applied by Maumené (Compt. rend. xxx. 314) to the detection of sugar and analogous substances in liquids. For this purpose a drop of the liquid is placed on a strip of white merino, previously steeped in a solution of stannic chloride and dried; and the strip is warmed over a hot coal or the flame of a lamp: the presence of any saccharine substance will then be indicated by the production of a black spot.

6. Sugar does not absorb *fluoride of boron* in the cold, but on applying heat, the gas is absorbed, and the sugar is blackened.

7. Cane-sugar is not directly *fermentable*, but when its dilute aqueous solution is mixed with yeast, and exposed to a warm atmosphere, it is first resolved into a mixture of dextrose and lævulose (p. 470), which then enter into fermentation, yielding alcohol and carbonic anhydride:

$$C^6H^{12}O^6 = 2C^2O^2 + 2C^2H^6O.$$

When equal weights of cane-sugar and glucose are dissolved in equal quantities of distilled water, and a very small quantity of yeast added to each, the glucose immediately begins to ferment, even at the mean temperature of summer (about 20°); but the cane-sugar remains unaltered for months, even at 30°—40°. To bring it to the fermenting state, it is necessary to add seven or eight times the original quantity of yeast (H. Rose, J. pr. Chem. xxiii. 393). The conversion of cane-sugar into inverted sugar is effected by the soluble ferment in yeast (analogous to diastase), and by the ferment contained in most fruits.

Estimation of Cane-sugar: Saccharimetry.—If the solution contains nothing but cane-sugar, the specific gravity is observed, and the percentage of sugar determined therefrom (*vid. inf.*). If other substances which affect the density are likewise present, the quantity of cane-sugar may be determined:

1. From the weight of carbonic anhydride formed in the vinous fermentation of the sugar, or from the quantity of alcohol thereby produced. According to older statements, 100 pts. cane-sugar yield (after deduction of 5·26 pts. water), 51·44 pts. carbonic anhydride and 53·80 absolute alcohol; according to Pasteur's direct determination, 49·12 pts. carbonic anhydride and 51·01 absolute alcohol, the remaining portion of the sugar being consumed in the formation of glycerin and succinic acid. See

ii. 628; also **Buignet's** description of the process. (Ann. Ch. Phys. [3], lxi. 239.)

2. From the weight of cuprous oxide which the sugar can reduce from potassio-cupric tartrate, or from the volume of a standard solution of that salt decomposed by the sugar. For this reaction, the cane-sugar must be previously heated with acids, to convert it into inverted sugar, which reduces the same quantity of cupric oxide as grape-sugar. (See GLUCOSE, ii. 863.)

3. *From the Rotatory Power of the Solution.*—If the solution contains only cane-sugar, or, at least, no other optically active substance, the amount of sugar may be calculated from the rotatory power in the manner described under LIGHT (iii. 673). Turbid or gummy solutions are mixed with $\frac{1}{10}$ their volume of isinglass-solution; then, after agitation, with 1½ vol. alcohol, whereupon the mixture, without being heated, coagulates, and yields a filtrate adapted for observation. Coloured solutions are decolorised by animal charcoal; but as this substance (according to some statements) takes up sugar, the first fourth of the liquid that runs through is rejected, and only the remainder used for the observation. If, in addition to cane-sugar, the solution contains grape-sugar, inverted sugar, or any other optically active substance, whose rotatary power is not altered by heating with acids, the amount of cane-sugar may be determined by observing the rotatory power of the solution, both before and after inversion, the temperature being likewise observed in the latter case. The first observation having been made, 100 c.c. of the solution are mixed with 10 c.c. fuming hydrochloric acid, the mixture heated to 68°, and kept at that temperature for a quarter of an hour. Since the rotatory power of the solution cooled to the original temperature (supposing the observation to have been made in a tube longer by one-tenth than the former), remains unaltered in so far as it was due to the glucose, whereas the cane-sugar has been replaced by inverted sugar, the amount of cane-sugar may be calculated from the rotatory power peculiar to this inverted sugar, as follows:—The rotatory power (a) observed before inversion was made up of the molecular rotatory power (c) of the cane-sugar (C), and that of the grape-sugar ($g\,G$): therefore

$$a = c\,C + g\,G.$$

The rotatory power (a') observed after inversion is, in like manner, made up of the unaltered rotatory power of the grape-sugar ($g\,G$), and that of the inverted sugar ($i\,C$); therefore:

$$a' = i\,C + g\,G.$$

Consequently the difference, $a - a'$, of the rotations observed before and after inversion, is equal to $c\,C - i\,C$:

$$a - a' = C(c - i).$$

or, finally:

$$C = \frac{a - a'}{c - i}$$

Suppose, for example, a sugar-solution before inversion turns the plane of polarisation 25·96° to the right, and after inversion, 5·80° to the right, at a temperature of 14°; then $a = 25{\cdot}96$ and $a' = 5{\cdot}80$. Now, the molecular rotatory power of cane-sugar (c) is 73·8°, and that of inverted sugar is 25° at the temperature of 15°: consequently,

$$C = \frac{25{\cdot}96 - 5{\cdot}80}{73{\cdot}8 + 27} \quad \text{or} \quad C = \frac{20{\cdot}16}{98{\cdot}8} = 0{\cdot}204\,;$$

which quantity, therefore, gives the number of parts by weight of cane-sugar contained in a unit of weight of the solution employed, or, when multiplied by 100, the percentage of cane-sugar in the solution.

Suppose another sugar-solution, before inversion, to turn the plane of polarisation 9·36° to the right, and after inversion 10·80° to the left (= −10·80° to the right): in this case, $a = 9{\cdot}36$; $a' = -10{\cdot}80$, $a - a' = 9{\cdot}36 + 10{\cdot}80 = 20{\cdot}16$, which number divided by 98·8 again gives 0·2, or 20 per cent. of cane-sugar in the solution.

If, in both cases, the nature of the second optically active substance present in addition to the cane-sugar is known, its quantity may be determined from the observations just described; if, on the other hand, its quantity is previously known, its nature may be determined. Thus, it might be inferred that grape-sugar was present, in the first case, besides the cane-sugar in the original solution, and inverted sugar in the second. This mode of proceeding, however, is admissible only when the deflection after inversion has been observed at a temperature for which the molecular rotatory power of the inverted sugar (which varies with the temperature) has been previously determined. (**Biot**, Compt. rend. xv. 523, 619, and 694 [3], xvii. 755.—**Clerget**, Ann. Ch. Phys. [3], xxvi. 175; Jahresb. 1849, p. 126.)

Compounds and Derivatives of Cane-sugar.

I. **With Acids.**—The compounds formed by the action of acids on cane-sugar may be divided into two groups:

a. Ethereal Compounds of Cane-sugar itself.—The only known compound belonging to this group is:

Nitrosaccharose, $C^{12}H^{18}(NO^2)^4O^{11}$?, produced by adding cane-sugar to a mixture of strong sulphuric and nitric acids. It is an amorphous mass, which detonates when struck. (Gm. xv.)

β. Ethereal compounds of the glucoses, produced from cane-sugar by the action of acids. To this class belong the saccharides obtained by heating cane-sugar with acetic, butyric, and stearic acid (ii. 855; v. 144).

II. **With Bases.** (Péligot, Ann. Ch. Pharm. xxx. 69, 92; lxxx. 342.—Stein, *ibid.* xxx. 82.—Soubeiran, *ibid.* xliii. 125, 227.—Berthelot, Jahresb. 1856, p. 635):

Potassium- and *Sodium-compounds* of cane-sugar, $C^{12}H^{21}KO^{11}$ and $C^{12}H^{21}NaO^{11}$, are formed, as gelatinous precipitates, on mixing an alcoholic solution of cane-sugar with potash- or soda-ley.

A *barium-compound*, $C^{12}H^{20}Ba''O^{11}.H^2O$ or $C^{12}H^{22}O^{11}.Ba''O$, is obtained, as a crystalline precipitate, on adding hydrate or sulphide of barium to an aqueous solution of sugar. It may be crystallised from boiling water, but is insoluble in alcohol.

Calcium-compounds.—Lime dissolves in sugar-water much more readily than in pure water. The solution has a bitter taste, and is completely but slowly precipitated by carbonic acid. There are three or four of these compounds, which may be approximately represented by the following formulæ:

(1.) $C^{12}H^{22}O^{11}.Ca''O$.
(2.) $2C^{12}H^{22}O^{11}.3Ca''O$ (?).
(3.) $C^{12}H^{22}O^{11}.2Ca''O.2H^2O$.
(4.) $C^{12}H^{22}O^{11}.3Ca''O$.

The constitution of these compounds is not exactly known; but a part, at least, of the calcium probably replaces hydrogen in the sugar.

The first compound, **monocalcic sucrate**, is soluble in water, and is obtained as a white precipitate on adding alcohol to a solution of calcic hydrate in sugar-water, not containing too much lime.—The compound (2) is formed when sugar-water is boiled with excess of calcic hydrate, and the filtrate is evaporated: it is probably a mixture of (1) and (3).—The compound (3) is precipitated by alcohol, from the liquid obtained by digesting sugar-water with excess of calcic hydrate.—The compound (4) is slightly soluble in water, and separates, on heating a cold-digested solution of calcic hydrate in sugar-water, as an amorphous mass: hence solutions of lime in sugar-water usually solidify to a pasty mass when boiled.

Magnesia and *lead-oxide* are likewise dissolved by sugar-water. A crystalline **lead-compound**, $C^{12}H^{18}Pb^2O^{11}$, is obtained by boiling sugar-water with litharge, and leaving the filtrate to cool; by mixing sugar-water with neutral lead-acetate and ammonia; or by precipitating neutral lead-acetate with a solution of sugar-lime.

III. **With Salts.**—*a.* With *Chloride of Sodium*, $C^{12}H^{22}O^{11}.NaCl$.—This compound separates, in small deliquescent crystals, from a mixed solution of common salt and sugar. (Péligot, Ann. Ch. Pharm. xxx. 71.)

β. With *Borax*, $3C^{12}H^{22}O^{11}.(Na^2O.2B^2O^3).5H^2O$.—Borax dissolves in sugar-water more freely than in pure water, and the solution, when evaporated or precipitated with alcohol, yields this compound.

Parasaccharose. This is an isomer of cane-sugar, produced, according to Jodin (Compt. rend. liii. 1252; lv. 720: Jahresb. 1861, p. 722; 1862, p. 473), by spontaneous fermentation. An aqueous solution of cane-sugar containing phosphate of ammonium left to itself in summer (between June 15 and September 15, 1861), yielded, under circumstances not further specified, a crystallisable sugar isomeric with saccharose, together with an amorphous sugar having the composition of a glucose, both dextrorotatory. Parasaccharose, $C^{12}H^{22}O^{11}$, is very soluble in water, nearly insoluble in alcohol of 90 per cent. Specific rotatory power at 10° = + 108°, appearing to increase a little with rise of temperature. It does not melt at 100°, but becomes coloured, and appears to decompose. It reduces an alkaline cupric solution, but only half as strongly as dextrose (1 at. parasaccharose = 5 at. CuO; 1 at. dextrose = 10 at. CuO). It is not perceptibly altered by dilute sulphuric acid, even at 100°; hydrochloric acid weakens its rotatory power, turns the solution brown, and heightens its reducing power for cupric oxide.

Paraglucose. This is the amorphous dextrorotatory sugar produced, together with parasaccharose, as above described. When dried at 15°, it has the composition $C^6H^{12}O^6.H^2O$. It is hygroscopic, gives off half its water of crystallisation at 50° and the whole at 100°, melting, and turning brown at the same time. Its specific rotatory power is about + 40°. It reduces alkaline cupric solutions less strongly than glucose, and about as strongly as milk-sugar (1 at. paraglucose = 7 at. CuO). It is not perceptibly altered by dilute acids, even with aid of heat, excepting that its rotatory power is diminished to about + 32°, and its reducing action is increased to about that of glucose. (Jodin.)

SUGAR, INVERTED. The mixture of dextrose and lævulose in equal numbers of atoms, produced by the transformation of cane-sugar under the influence of acids (ii. 863).

SUGAR OF FRUITS. This term is applied especially to the uncrystallisable mixtures of dextrose and lævulose contained in many fruits. Some fruits, however, contain crystallisable sugars—viz., dextrose, saccharose, or the two together (p. 468).

SUGAR OF LEAD. Neutral plumbic acetate (i. 16).

SUGAR-CANDY. Cane-sugar crystallised by slow evaporation.

SUGAR-CANE. *Saccharum officinarum.*—This important grass, which yields by far the larger quantity of the sugar at present consumed, thrives only in hot climates. It has been known in India and China from very early times, and its cultivation appears to have been introduced into the West Indies in the fifteenth century. There are several varieties of the cane. The longest known is the creole or common sugar-cane, which grows freely in every region between the tropics on a moist soil, and even at an elevation of 3,000 feet above the sea-level. A superior variety is the Otaheitan cane, which is stronger, taller, quicker in growth, and much more productive in sugar. The cane thrives best on a light rich soil, especially on one manured with nitrogenous refuse.

The fresh cane contains, according to two analyses by Péligot and Dupuy:

Water	72·1	72·0
Sugar	18·0	17·8
Woody fibre	9·9	9·8
Salts		0·4
	100·0	100·0

The creole cane of Havanna has been analysed by Casaseca (Ann. Ch. Phys. [3] xxv. 321), with the following results:

	Cane entire.	Cane peeled.	Rind.
Water	77·0	77·8	69·5
Sugar and other soluble substances	12·0	16·2	11·5
Woody substance	11·0	6·0	19·0
	100·0	100·0	100·0

Casaseca finds that the juice is richer in sugar at the base of the cane, and becomes gradually poorer towards the top.

The specific gravity of cane-juice varies from 1·046 to 1·110, but is generally from 1·070 to 1·090, or from 10° to 13° Bm. It is opaque, frothy, and of a yellowish-green colour. On boiling, a green scum rises, and the liquid remains of a pale-yellow colour. The green scum (dried) consists, according to Arequin, of 50 per cent. of a peculiar wax called cerosie, 10·0 green matter, 22·7 albumin and woody fibre, 3·3 calcic phosphate, and 14·0 silica. The pure juice contains 81·0 per cent. water, 18·20 sugar, 0·45 organic matter precipitated by lead-salts, and 0·35 saline matter.

The ash of the cane contains, according to Stenhouse:

SiO^2.	P^2O^5.	SO^3.	CaO.	MgO.	K^2O.	Na^2O.	KCl.	NaCl.	
46·46	8·23	4·65	8·91	4·50	10·63	. .	7·41	9·21	= 100
41·37	4·59	10·93	9·11	6·92	15·99	. .	8·96	2·18	= 100
46·48	8·16	7·52	5·78	15·61	11·93	0·57	. .	3·95	= 100
50·00	6·56	6·40	5·09	13·01	13·69	1·33	. .	3·92	= 100

The proportion of salts in the juice varies considerably with the soil on which the canes are grown. (*Ure's Dictionary of Arts*, &c. iii. 808.)

SUGAR-CANE, CHINESE. See SORGHO (p. 354).

SUGAR-MAPLE. *Acer saccharinum.*—The stem of this tree, which grows wild in many parts of North America, yields a sugar identical with that of the cane. To obtain it, the trees are bored in the early spring, and the juice, collected in vessels suspended beneath, is boiled as quickly as possible to prevent fermentation. As soon as the syrup flows from the stirrer, in thick drops of the consistence of honey, it is strained through a wooden sieve, then left to stand for eight or ten hours, clarified with a little white of egg, boiled, skimmed, and quickly evaporated to the crystallising-point.

SULPHACETAMIDE. This name is applied by E. Schulze (Zeitschr. Ch. Pharm. 1865, p. 73), to the compound $\left.\begin{matrix}(C^4H^4S''O^2)''\\ H^4\end{matrix}\right\}N^2$, produced by the action of ammonium-sulphide on chloracetamide, the corresponding acid, $\left.\begin{matrix}(C^4H^4S''O^2)''\\ H^2\end{matrix}\right\}O^2$, being called sulphacetic acid (*monosulphacetsäure*); but as this latter name has long been appropriated to the acid, $C^2H^4O^2.SO^3$, produced by the action of sulphuric anhydride on acetic acid, it is better to designate Schulze's acid as thiodiacetic acid, and the amide as thiodiacetyl-diamide, a name which expresses that the radicle, $C^4H^4SO^2$, contained in it is derived from a double molecule of acetyl, $C^4H^6O^2$, by the substitution of S'' for H^2. (See THIODIACETIC ACID.)

SULPHACETIC ACID. $C^2H^4SO^5 = C^2H^4O^2.SO^3$ $\left.\begin{matrix}(C^2H^2SO^3)''\\ H^2\end{matrix}\right\}O^2 = \left.\begin{matrix}(C^2H^2O)''\\ (SO)''\\ H^2\end{matrix}\right\}O^2$. *Glycolyl-sulphurous acid. Sulpho-essigsäure. Essigschwefsäure.* (Melsens, Ann. Ch. Phys. [3], v. 392; x. 370.—Buckton and Hofmann, Chem. Soc. Qu. J. ix. 247.)—This acid is produced: 1. By the action of sulphuric anhydride on acetic acid. Glacial acetic acid is gradually saturated with sulphuric anhydride, the liquid being cooled after each addition; the mixture is diluted with water, and neutralised with lead-carbonate; the filtered solution is evaporated to the crystallising-point; and from the lead-salt thus obtained, the sulphacetic acid is separated by sulphydric acid (Melsens).—2. By the action of fuming sulphuric acid on acetamide or acetonitrile (Buckton and Hofmann):

$$\underset{\text{Acetonitrile.}}{C^2H^3N} + H^2O + 2H^2SO^4 = \underset{\text{Sulphacetic acid.}}{C^2H^4SO^5} + NH^4.H.SO^4.$$

This is the reaction which chiefly takes place when the materials are gradually mixed, and the mixture is cooled from time to time; if, on the other hand, the temperature is allowed to rise, carbonic anhydride is evolved, and disulphometholic acid is produced, instead of sulphacetic acid, according to the equation:

$$C^2H^3N + 3H^2SO^4 = CH^4S^2O^6 + NH^4.H.SO^4 + CO^2.$$

Sulphacetic acid forms deliquescent prisms, which melt at 62°, and decompose at 200°. It is very soluble in water, forming an acid solution, which is not decomposed by boiling (Melsens). The acid, heated with fuming sulphuric acid or sulphuric anhydride, is converted into disulphometholic acid. (Buckton and Hofmann.)

Sulphacetic acid is dibasic. Its salts are all soluble in water, the barium-salt being the least soluble; they are insoluble in alcohol. When heated with strong sulphuric acid, they give off carbonic and sulphurous anhydrides.

Sulphacetate of Potassium, $C^2H^2K^2SO^5.H^2O$, is deposited from a hot solution on cooling, in small, hard, easily pulverisable crystals.—The *barium-salt*, when pure, forms small opaque crystals, $C^2H^2Ba''SO^5.\frac{3}{2}H^2O$, which give off a third of their water at 100°, and the whole at 250°.—The *lead-salt*, $C^2H^2Pb''SO^5$, is deposited, sometimes in radiate groups of short transparent needles, sometimes in opaque nodules, which do not retain any water at 120°.—The *silver-salt*, $C^2H^2Ag^2SO^5$, is deposited from a boiling saturated solution in small flat prisms, bevelled at the ends. In the mother-liquor obtained in the preparation of this salt by saturating the acid with silver-oxide, Melsens found a salt containing $CH^2Ag^2S^2O^6$, doubtless disulphometholate of silver.

SULPHACETYLENIC ACID. *Acetschwefsäure.* $C^2H^4SO^5 = \left.\begin{matrix}(C^2H^2)''\\ (SO^2)''\\ H^2\end{matrix}\right\}O^2$. (Kämmerer and Carius, Ann. Ch. Pharm. cxxxi. 165; Jahresb. 1864, p. 326.)—This acid, isomeric with sulphacetic acid, is produced by heating 1 at. argentic sulphate (mixed with glass powder) with 2 at. chloride of acetyl to 120°, and treating the product with water:

$$\underset{\text{Argentic sulphate.}}{\left.\begin{matrix}(SO^2)''\\ Ag^2\end{matrix}\right\}O^2} + 2(C^2H^3O.Cl) = 2AgCl + \underset{\text{Acetosulphuric anhydride.}}{\left.\begin{matrix}(SO^2)''\\ (C^2H^3O)^2\end{matrix}\right\}O^2} \left[\text{or, } \left.\begin{matrix}(SO^2)''\\ (C^2H^2O)''\\ (C^2H^3O).H\end{matrix}\right\}O^2\right].$$

$$\underset{\text{Acetosulphuric anhydride.}}{\left.\begin{matrix}(SO^2)''\\ (C^2H^2)''\\ (C^2H^3O).H\end{matrix}\right\}O^2} + H^2O = \underset{\text{Sulphacetylenic acid.}}{\left.\begin{matrix}(SO^2)''\\ (C^2H^2)''\\ H^2\end{matrix}\right\}O^2} + \underset{\text{Acetic acid.}}{\left.\begin{matrix}C^2H^3O\\ H\end{matrix}\right\}O}.$$

By neutralising the resulting solution with lead-carbonate, decomposing the filtrate with sulphydric acid, and evaporating in a vacuum, the sulphacetylenic acid is obtained as a viscid liquid, which gradually decomposes into sulphuric and acetic acids. With pentachloride of phosphorus it first yields the chloride, $C^2H^2SO^3Cl^2$ (which boils at 150°, and is resolved by water into hydrochloric and sulphacetylenic acid), and then, as final products, chloride of chloracetyl * and chloride of sulphuryl:

$$\underset{\substack{\text{Sulphacety-}\\\text{lenic acid.}}}{\left.\begin{matrix}SO^2\\C^2H^2\\H^2\end{matrix}\right\}O^4} + 2PCl^5 = \underset{\substack{\text{Sulphacetyle-}\\\text{nic chloride.}}}{\begin{matrix}SO^2\\C^2H^2\end{matrix}\left\{\begin{matrix}O\\Cl^2\end{matrix}\right.} + 2POCl^3 + 2HCl.$$

$$\underset{\substack{\text{Sulphacety-}\\\text{lenic chloride.}}}{\begin{matrix}SO^2\\C^2H^2\end{matrix}\left\{\begin{matrix}O\\Cl^2\end{matrix}\right.} + PCl^5 = \underset{\substack{\text{Chloride of}\\\text{sulphuryl.}}}{SO^2Cl^2} + \underset{\substack{\text{Chloride of}\\\text{chloracetyl.}}}{C^2H^2ClO.Cl} + PCl^3.$$

By this behaviour, according to Kämmerer and Carius, sulphacetylenic acid is distinguished from sulphacetic acid: they do not, however, state distinctly in what manner the latter acid reacts with pentachloride of phosphorus. (Compare SULPHOBENZYLENIC ACID.)

Sulphacetylenic acid is dibasic.—The *potassium-salt*, $C^2H^2K^2SO^5.H^2O$, is easily soluble in water, and crystallises in needles and short prisms.—The *barium-salt*, $C^2H^2Ba''SO^5.H^2O$, is somewhat sparingly soluble, and crystallises in hard right rhombic prisms.

SULPHAMETHYLANE. Syn. with METHYLIC SULPHAMATE (p. 477).

SULPHAMIC ACID. $NH^3SO^3 = \left.\begin{matrix}NH^2(SO^2)''\\H\end{matrix}\right\}O = \left.\begin{matrix}H^2\\(SO^2)''\\H\end{matrix}\right\}\begin{matrix}N\\O\end{matrix}.$—This compound, the amic acid of sulphuric acid, is not known in the free state, that is to say, as a hydrogen-salt; but the so-called anhydrous sulphate of ammonia, called "sulphatammon" by H. Rose, "sulphamide" by Dumas, is probably its neutral ammonium-salt.

Neutral Sulphamate of Ammonium, $N^2H^6SO^3 = 2NH^3.SO^3 = \left.\begin{matrix}H^2\\(SO^2)''\\NH^4\end{matrix}\right\}\begin{matrix}N\\O\end{matrix}.$ (H. Rose, Pogg. Ann. xxxii. 81; xlvii. 471; xlix. 183.)—This salt is produced when dry ammonia-gas is passed over a thin layer of sulphuric anhydride, care being taken to renew the surface frequently by scraping, as otherwise the lower portions will not be attacked by the ammonia. The product is a white crystalline powder, having a bitter taste, and perfectly neutral if it does not contain either free ammonia or free sulphuric anhydride. It is permanent in the air, dissolves without sensible decomposition in 9 pts. of water, and is insoluble in alcohol. The dry salt is decomposed by heat, giving off ammonia and sulphurous anhydride, and leaving a residue of sulphate of ammonium. Platinic chloride added to the aqueous solution, throws down half the nitrogen as ammonium-chloroplatinate. The caustic alkalis and their carbonates decompose the salt, even in the cold, with evolution of ammonia. The aqueous solution is clouded by chloride of barium, the precipitate gradually increasing on standing, and especially if the liquid be heated; but the precipitation is never complete, not more than half the sulphur being separated as sulphate of barium.

The aqueous solution, evaporated over oil of vitriol in a vacuum, yields transparent, colourless, hemihedral crystals, belonging to the quadratic system. These crystals have exactly the same composition as the original pulverulent salt, and were therefore designated by Rose as parasulphatammon. They doubtless consist of the pure neutral sulphamate of ammonium, quite free from adhering sulphuric acid. They dissolve in water more easily than the original salt, forming a perfectly neutral solution, which reacts in the same manner with platinic chloride, but gives no precipitate with chloride of barium, except after prolonged boiling.

The mother-liquor of parasulphatammon yields, by further evaporation, a hydrated salt, $2N^2H^6SO^3.H^2O$, in indistinct deliquescent crystals, very soluble in water, and exhibiting signs of decomposition, as their solution is faintly acid, and immediately gives a slight precipitate with chloride of barium.

Acid Sulphamate of Ammonium, $N^2H^6SO^3.NH^3SO^3$.—Produced, simultaneously with the neutral salt, as a hard vitreous mass, which deliquesces rapidly in the air, and dissolves in water with a hissing noise (H. Rose). According to Woronin (Rép. Chim. pure, ii. 452), an aqueous solution of the neutral sulphamate left to evaporate in the air, yields an abundant crystallisation of the acid sulphamate. Its solution is not precipitated by chloride of barium, excepting after neutralisatien with ammonia (*infra*).

---

* The chloride of chloracetyl is converted, by excess of phosphoric pentachloride, into a colourless liquid, probably $C^2H^2Cl^4$, not decomposible by potash-ley, but resolved by water at 150° into hydrochloric and monochloracetic acid.

Sulphamate of Barium.—When a solution of the neutral ammonium-salt is mixed with an exactly equivalent quantity of baryta-water, ammonia is evolved, and the filtered liquid yields crystals of an easily soluble barium-salt.

The precipitate formed by chloride of barium in a solution of the acid ammonium-salt mixed with ammonia, consists of a *basic sulphamate of barium*, which, when treated with the proper quantity of sulphuric acid, yields a precipitate of barium-sulphate and a solution of *neutral barium-sulphamate*, $N^2H^4Ba''S^2O^6 = \left.\begin{matrix}H^4\\(SO^2)^2\\Ba''\end{matrix}\right\}\begin{matrix}N^2\\O^2\end{matrix}$. This salt forms well-developed crystals, sparingly soluble in cold water, and is decomposed by hot water, with formation of barium-sulphate. (Woronin.)

Sulphamate of Potassium, obtained by decomposing the barium-salt with sulphate of potassium, forms small transparent crystals; on addition of barium-chloride and ammonia to its solution, it is converted into basic sulphamate of barium. (Woronin.)

SULPHAMIC ETHERS. *Methylic Sulphamate*, or *Sulphamethylane*, $CH^5NSO^3 = \left.\begin{matrix}H^2\\(SO^2)''\\CH^3\end{matrix}\right\}\begin{matrix}N\\O\end{matrix}$.—This compound, which has the composition of anhydrosulphate of methylamine, is formed by dissolving methylic sulphate in aqueous ammonia, and crystallises, by evaporation in a vacuum, in large, very deliquescent crystals.

Phenylsulphamic or **Sulphanilic Acid,** $C^6H^7NSO^3 = \left.\begin{matrix}C^6H^5.H\\(SO^2)''\\H\end{matrix}\right\}\begin{matrix}N\\O\end{matrix}$, or $\left.\begin{matrix}NH(C^6H^5)(SO^2)''\\H\end{matrix}\right\}O$. (Gerhardt, J. Pharm. [3], x. 5.—Buckton and Hofmann, Chem. Soc. Qu. J. ix. 259.—R. Schmitt, Ann. Ch. Pharm. cxx. 129.)—This acid, isomeric with amidosulphobenzolic acid, $C^6H^5(NH^2)SO^3$, is formed by the action of sulphuric acid on aniline, or on oxanilide (phenyloxamide):

$$\underset{\text{Oxanilide.}}{C^2H^2(C^6H^5)^2N^2O^2} + 2H^2SO^4 = \underset{\text{Sulphanilic acid.}}{2C^6H^7NSO^3} + CO + CO^2 + H^2O.$$

Preparation.—1. From the mixture of oxanilide and formanilide obtained by heating oxalate of aniline (iv. 427). This mixture is made up into a thick paste with strong sulphuric acid, and gently heated as long as effervescence continues; then exposed to moist air in a shallow dish, till it solidifies to a crystalline pulp of sulphanilic acid, which may be purified by washing with cold, and recrystallising from boiling water (Gerhardt).—2. By dissolving aniline in a slight excess of sulphuric acid, evaporating to dryness, and heating the residue with constant agitation, as long as vapours of aniline (?) continue to escape. The product is purified as before (Gerhardt).—Schmitt mixes 1 pt. of aniline by drops with 2 pts. of fuming sulphuric acid in a porcelain dish, heats the brown syrupy liquid till it becomes dark-brown and gives off a large quantity of sulphurous anhydride; and pours the thick syrup when cold into cold water: the sulphanilic acid then separates as a black crystalline mass, which may be purified by repeated recrystallisation from hot water, with addition of animal charcoal. This, according to Schmitt, is the best mode of preparing sulphanilic acid: Gerhardt, on the other hand, preferred the preparation from oxanilide.

β-Sulphanilic Acid.—Laurent (Compt. rend. xxxi. 538) obtained an acid, having the composition of sulphanilic acid, by treating nitrosulphobenzoate of ammonium with sulphydric acid. Kolbe (Ann. Ch. Pharm. cxiii. 318) suggested that the acid thus obtained was not identical, but only isomeric, with Gerhardt's sulphanilic acid; and this supposition has been corroborated by Schmitt, who has pointed out several differences in the characters of the two acids and their salts (*infra*). Kekulé (*Lehrbuch*, ii. 605) regards it as probable that Laurent's acid is the true phenylsulphamic or sulphanilic acid, and that the acid produced by the action of sulphuric acid on aniline or oxanilide is amidosulphobenzolic acid. Till this question is satisfactorily decided, it may be convenient to designate Laurent's acid as β-sulphanilic acid. Schmitt prepares this acid by mixing 1 pt. of nitrobenzol with 5 or 6 pts. of fuming sulphuric acid, leaving the mixture for several days in a warm place, and shaking it frequently till all the nitrobenzol has disappeared. The viscid mass is then neutralised with carbonate of lead; the colourless solution of plumbic nitrosulphobenzolate, obtained by boiling and filtering the liquid, is decomposed by sulphydric acid; the liquid, filtered from lead-sulphide, is neutralised with carbonate of barium; and the resulting barium-salt (which separates in warty crystals) is dissolved in a large quantity of water, and mixed with a large excess of baryta. Sulphydric acid gas is then passed into the liquid, till the taste of the nitro-acid is completely removed; and the liquid, filtered from hyposulphite of barium, is again treated with sulphydric acid. The filtered solution of the barium-salt, treated with an exactly equivalent quantity of sulphuric acid, yields the aqueous β-sulphanilic acid, which may be obtained in crystals by evaporation.

Properties.—Sulphanilic acid (from aniline or oxanilide) crystallises from hot water in shining rhombic plates, containing, according to Schmitt, $C^6H^7NSO^3.H^2O$. It is slightly soluble in cold water, 1 pt. [of the anhydrous or hydrated acid?] dissolving in 128 pts. of ice-cold water, and in 112 pts. at 15° (Schmitt); still less soluble in alcohol (Gerhardt), insoluble in alcohol and in ether (Schmitt). From a concentrated solution of a sulphanilate, it is precipitated by acids in slender needles.

The crystals give off their water partially on exposure to the air, completely at 100°; the effloresced acid, if exposed for some time to this temperature, assumes a brownish colour, but may be heated to 220° without decomposing. At higher temperatures it decomposes, leaving a carbonaceous residue, and giving off sulphurous anhydride; also, if distilled in a retort, sulphite of aniline, which crystallises in the receiver. Heated with a solid caustic alkali, or with potash-lime, it gives off aniline and leaves an alkaline sulphate. Heated with strong *nitric acid*, it evolves a large quantity of gas, and forms a deep red liquid, but no crystals (Gerhardt). Its aqueous solution is coloured red-brown, without precipitation, by *chromic acid*. *Chlorine-water* colours it pale-crimson, gradually changing to red-brown (Gerhardt). According to Schmitt, the aqueous solution is not altered either by chlorine or by iodine. *Bromine*, added even to a dilute solution of the acid, renders it milky, and throws down after a while a white curdy precipitate (Gerhardt). From a hot solution it throws down white interlaced needles of tribromaniline:

$$\underset{\text{Sulphanilic acid.}}{C^6H^7NSO^3} + Br^6 = \underset{\text{Tribromaniline.}}{C^6H^4Br^3N} + SO^3 + 3HBr.$$

If only 4 at. bromine be added, dibromosulphanilic acid, $C^6H^5Br^2NSO^3$, is likewise formed, and remains dissolved (Schmitt, p. 479).—With *nitrous acid*, it forms diazosulphobenzolic acid (Schmitt):

$$\underset{\text{Sulphanilic acid.}}{2C^6H^7NSO^3} + N^2O^3 = \underset{\text{Diazosulphobenzolic-acid.}}{2C^6H^4N^2SO^3} + 3H^2O.$$

β-Sulphanilic acid crystallises from its aqueous solution by evaporation in long pointed crystals, which contain $2C^6H^7NSO^3.3H^2O$, give off their water partially at ordinary temperatures, completely at 100°, and becoming white and opaque. It is insoluble in ether and alcohol, easily soluble in hot water. With *bromine* it behaves somewhat differently from sulphanilic acid, inasmuch as, though its concentrated solutions are rendered turbid by bromine, the liquid filtered therefrom does not give any precipitate with chloride of barium, as is the case with that obtained in like manner from sulphanilic acid (p. 479).

Sulphanilates.—Sulphanilic acid is a strong acid, and decomposes carbonates with effervescence. Its salts are soluble and crystallisable; their solutions give, with chromic acid and bromine-water, the same reactions as the free acid. The β-sulphanilates differ from the sulphanilates in crystalline form. (Schmitt.)

Sulphanilate of Ammonium, $C^6H^6(NH^4)NSO^3$, is very soluble, and crystallises by spontaneous evaporation, in shining rectangular plates.—The *aniline-salt* is very soluble.—The *barium-salt* forms rectangular prisms, moderately soluble in water.—The *cupric salt*, $C^{12}H^{12}Cu''N^2S^2O^6.4H^2O$, forms small truncated prisms of a very dark green colour, which retain their water at 100°.—The *silver-salt* crystallises in shining scales.—The *sodium-salt*, $C^6H^6NaNSO^3.H^2O$, crystallises from aqueous solution by spontaneous evaporation, in fine octagonal plates, insoluble in ether, but soluble in boiling alcohol, whence it crystallises in white needles.

Dibromosulphanilic Acid, $C^6H^5Br^2NSO^3$ (Schmitt, *loc. cit.*).—Produced when 4 at. bromine are added to a hot solution of 1 at. sulphanilic acid:

$$C^6H^7NSO^3 + Br^4 = C^6H^5Br^2NSO^3 + 2HBr.$$

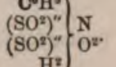
It remains in solution; is separated by filtration from the tribromaniline formed at the same time (p. 478); precipitated as a barium-salt by addition of barium-chloride;

and from this salt, purified by recrystallisation, the dibromosulphanilic acid is separated by sulphuric acid.

Dibromosulphanilic acid crystallises from aqueous solution in large colourless prisms, which contain $2C^6H^5Br^2NSO^3.3H^2O$, and give off their water of crystallisation gradually at ordinary temperatures, more quickly at 110°, becoming dull and opaque. It dissolves readily in *water*, whether hot or cold; sparingly in cold, more easily in hot *alcohol*. The concentrated aqueous solution, mixed with a small quantity of oil of vitriol, immediately yields the pure acid, in the form of a network of needles. The aqueous solution has a very sour and cooling taste: it gives a crystalline precipitate with *chloride of barium*, *acetate of lead*, and *nitrate of silver*. A concentrated solution warmed with *zinc*, gives off hydrogen, forming a zinc-salt, which separates out. The dehydrated acid bears a heat of 180° without alteration, but decomposes at a somewhat higher temperature, yielding tribromaniline and sulphurous anhydride, and leaving a difficultly combustible charcoal. It also gives off tribromaniline (not dibromaniline, as might be expected) when heated with potash or slaked lime. The aqueous solution is coloured brown by *chlorine*, and on heating the liquid, a pungent oil separates out.—*Nitrous acid* passed into the aqueous solution converts the acid into diazo-dibromosulphobenzolic acid, $C^6H^2Br^2N^2SO^3$.

The dibromosulphanilates crystallise in needles, and are more or less soluble in water.—The *barium-salt*, $C^{12}H^8Ba''Br^4N^2S^2O^6.2H^2O$, prepared as above, gives off its water at 110° without alteration of appearance, and does not decompose till very strongly heated.—The *lead-salt*, $C^{12}H^8Pb''Br^4N^2S^2O^6.2H^2O$, is permanent in the air, and gives off its water at 110°.—The *silver-salt*, $C^6H^4AgBr^2NSO^3$, forms somewhat reddish needles.—The *potassium-* and *sodium-salts*, obtained by decomposing the corresponding carbonates with the aqueous acid, are sparingly soluble in alcohol, and separate in needles on addition of alcohol to their aqueous solutions.—The *zinc-salt* is obtained, as above mentioned, by the action of the acid on metallic zinc.

Phenyldisulphamic or **Disulphanilic Acid,** $C^6H^7NS^2O^6$ =



$$\left.\begin{matrix}C^6H^3\\(SO^2)''\\(SO^2)''\\H^2\end{matrix}\right\}\begin{matrix}N\\O^2\end{matrix}.$$

(Buckton and Hofmann, Chem. Soc. Qu. J. ix.—Carius, Zeitschr. Ch. Pharm. 1861, p. 632; Jahresb. 1861, p. 634.)—Two acids having this composition have been obtained, viz.—*a*. By heating sulphanilic acid (p. 477) with fuming sulphuric acid to 160° or 170°, for six or seven hours, till it assumes the consistence of treacle. On dissolving the syrupy residue in water, saturating with carbonate of barium, and evaporating the filtrate, a barium-salt is obtained, which after repeated solution in water, and evaporation under reduced pressure, remains as a mass of microscopic crystals, having, when dried at 190°—200°, the composition, $C^6H^5Ba''NS^2O^6$, showing that the acid is dibasic. From the lead-salt, prepared in a similar manner, the free acid, $C^6H^7NS^2O^6$, may be separated by the action of sulphydric acid. It has a very acid and pungent taste, is very difficult to crystallise, and is insoluble in alcohol, which precipitates it from strong solutions in white grains, especially on addition of a little ether.—The *silver-salt*, $C^6H^5Ag^2NS^2O^6$, prepared by neutralising the aqueous acid with carbonate of silver, crystallises from aqueous solution in small plates, and is precipitated by ether-alcohol in colourless crystalline grains. (Buckton and Hofmann.)

β. By the action of ammonium-sulphite on nitrobenzol (Carius):

$$\underset{\text{Nitrobenzol.}}{C^6H^5NO^2} + 3(NH^4)^2SO^3 = \underset{\beta\text{-Disulphanilate of Ammonium.}}{C^6H^5(NH^4)^2NS^2O^6} + \underset{\text{Sulphate of Ammonium.}}{(NH^4)^2SO^4} + H^2O + 2NH^3.$$

When 1 at. nitrobenzol and 3 at. neutral sulphite of ammonium are boiled together in dilute alcoholic solution, for six or eight hours, in such a manner that the condensed vapours may flow back again, and the resulting solution is evaporated, sulphate of ammonium separates out first, then laminar crystals of *β*-disulphanilate of ammonium, which are difficult to purify. It is best, therefore, to convert this salt, by treatment with baryta, into the *barium-salt*, $C^6H^5Ba''NS^2O^6$. This salt is easily soluble in water, insoluble in absolute alcohol, and crystallises in colourless prisms. It may be boiled, without decomposition, in neutral or alkaline solutions, as also may the other salts of the same acid; but on attempting to separate the *β*-disulphanilic acid from them, it splits up, by assumption of 1 at. water, into aniline and sulphuric acid:

$$C^6H^7NS^2O^6 + 2H^2O = C^6H^7N + 2H^2SO^4.$$

This decomposition, and the dissimilarity of the barium-salts of the two acids just described, shows that these acids are not identical, but only isomeric. The latter, from its mode of formation, and the mode of decomposition just mentioned, is probably the true phenyldisulphamic acid, $\left.\begin{matrix}C^6H^5\\(SO^2)''\\(SO^2)''\\H^2\end{matrix}\right\}\begin{matrix}N\\O^2\end{matrix}$; whereas the former, resulting from the action of sulphuric acid upon aniline (amidobenzol), may rather be regarded as amidodisulphobenzolic acid, $C^6H^5(NH^2)S^2O^6$.

Phenyldisulphodiamic Acid, $C^6H^8N^2S^2O^6 = \left.\begin{matrix}(C^6H^4)''\\(SO^2)^2\\H^2\end{matrix}\right\}\begin{matrix}N^2\\O^2\end{matrix}$.—*Dithiobenzolic Acid.* (Hilkenkamp, Ann. Ch. Pharm. xcv. 86; Jahresb. 1855, p. 636.)—Produced as an ammonium-salt, by the action of sulphite of ammonium on nitrobenzol, probably containing dinitrobenzol:

$$C^6H^4(NO^2)^2 + 6(NH^4)^2SO^3 = C^6H^6(NH^4)^2N^2S^2O^6 + 4(NH^4)^2SO^4 + 2NH^3.$$

The materials (80 grms. nitrobenzol, 340 grms. dry sulphite of ammonium, and 1 litre of anhydrous alcohol, together with a little carbonate of ammonium, to keep the mixture alkaline) were cohobated for several hours; and the liquid decanted from the sulphate of ammonium, which separated, was evaporated to an oily consistence; it then deposited a large quantity of white laminæ (doubtless consisting of phenyldisulphamate of ammonium), together with a small quantity of hard slender needles, consisting of the phenyldisulphodiamate, $C^6H^6(NH^4)^2N^2S^2O^6$. This salt is very soluble in water and in aqueous alcohol, sparingly soluble in absolute alcohol, insoluble in ether; when heated it chars, swells up, and emits the odour of sulphurous acid. Its aqueous solution is slightly acid.

All the phenyldisulphodiamates are easily soluble. The *barium-salt*, $C^6H^6Ba''N^2S^2O^6$, obtained by decomposing the ammonium-salt with baryta-water, forms crystalline crusts, insoluble in alcohol and ether.

Benzyldisulphamic Acid. $C^7H^9NS^2O^6 = \left.\begin{matrix}C^7H^7\\(SO^2)^2\\H^2\end{matrix}\right\}\begin{matrix}N\\O^2\end{matrix}$. *Tolyldisulphamic Acid. Thiotoluolsäure. Disulfuryl-toluylsäure.* (Hilkenkamp, *loc. cit.*—Carius, Zeitschr. Ch. Pharm. 1861, p. 632; Jahresb. 1861, p. 634.)—Obtained in the same manner as phenyldisulphamic acid, by the action of ammonium-sulphite on nitrobenzylene (nitrotoluol). According to Hilkenkamp, the *ammonium-salt*, which is the direct product of the reaction, has the composition $C^7H^8(NH^4)NS^2O^6$; and the *potassium-salt*, obtained by decomposing it with potash, contains $C^7H^8KNS^2O^6$; which would imply either that the acid is monobasic, or that these are acid salts. According to Carius, the *barium-salt*, obtained by decomposing the ammonium-salt with baryta-water, has the composition $C^7H^7Ba''NS^2O^6$, showing that the acid is dibasic, like phenyldisulphamic acid. The other benzyldisulphamates resemble the corresponding phenyl-compounds (p. 479), and the acid, when separated from them, splits up in like manner into sulphuric acid and benzylamine. (Carius.)

Cumenyldisulphamic Acid. $C^9H^{13}NS^2O^6 = \left.\begin{matrix}C^9H^{11}\\(SO^2)^2\\H^2\end{matrix}\right\}\begin{matrix}N\\O^2\end{matrix}$. *Disulfuryl-cumenylsäure.* (Carius, *loc. cit.*).—Prepared in like manner from nitrocumol. The salts are similar to the phenyldisulphamates, the barium-salt having the composition $C^9H^{11}Ba''NS^2O^6$, and the acid separated from it is resolved in like manner into sulphuric acid and cumenylamine.

SULPHAMIDE. $\left.\begin{matrix}(SO^2)''\\H^4\end{matrix}\right\}N^2$.—According to Regnault (Ann. Ch. Phys. [2] lxxix. 170), this body is produced, together with sal-ammoniac, when dry ammonia-gas is passed over sulphuric chloride, SO^2Cl^2; but, according to H. Rose, the product thus formed is a mixture of sal-ammoniac and neutral sulphamate of ammonium (sulphatammon).

SULPHAMIDIC ACID. See SULPHAZOTISED ACIDS (p. 482).

SULPHAMIDOBENZAMINE. $C^7H^8N^2S = \left.\begin{matrix}(C^7H^4S)''\\H^4\end{matrix}\right\}N^2$. (Hofmann, Proc. Roy. Soc. x. 598.)—This base, metameric with phenylsulphocarbamide, $[(CS)''(C^6H^5)H^3]N^2$ (i. 756), and analogous to Chancel's oxybenzodiamide (i. 755), is produced by the action of ammonium-sulphide on nitrobenzonitrile, $C^7H^4(NO^2)N$. When this compound is boiled with an aqueous solution of ammonium-sulphide, a large quantity of sulphur separates at first; and on evaporating the liquid, a yellowish oil is deposited, which solidifies but imperfectly, and is difficult to purify. This oil is a weak base, having the composition of amidobenzonitrile, $C^7H^6N^2 = C^7H^4(NH^2)N$; and by prolonged contact with ammonium-sulphide, it is gradually converted into sulphamidobenzamine:

$$\underset{\text{Nitrobenzo-nitrile.}}{C^7H^4(NO^2)N} + 3H^2S = 2H^2O + S^3 + \underset{\text{Amidobenzo-nitrile.}}{C^7H^6N^2}.$$

and

$$\underset{\text{Amidobenzo-nitrile.}}{C^7H^6N^2} + H^2S = \underset{\text{Sulphamido-benzamine.}}{C^7H^8N^2S}.$$

Sulphamidobenzamine is very soluble in alcohol and in ether, and crystallises from hot water in white shining needles. It dissolves easily in acids, and is precipitated therefrom by potash and ammonia. It forms a crystallisable hydrochlorate and an orange-yellow crystalline chloroplatinate.

SULPHAMIDOCHLOROBENZOIC ACID. $C^7H^4Cl(NH^2)SO^5$.—When chloramidobenzoic acid, $C^7H^4Cl(NH^2)O^2$ (obtained by the action of potassium-cyanide on ethylic chlorobenzoate), is treated with strong sulphuric acid, and the diluted solution is boiled with barium-carbonate, sulphamidochlorobenzoate of barium, $C^7H^2Ba''Cl(NH^2)SO^5$, is produced, and separates from the solution in nodular groups of crystals. (D. Cunze and H. Hübner, Ann. Ch. Pharm. cxxxv. 106; Jahresb. 1865, p. 330.)

SULPHAMIDONIC ACID. A syrupy deliquescent acid, produced by triturating starch with strong sulphuric acid. Its salts are all amorphous, deliquescent, easily soluble in water, and very unstable, so that their composition is difficult to determine. The *calcium-salt* appears to contain $C^{24}H^{46}Ca''O^{24}.2SO^3$. (Gm., xv. 104.—Gerhardt, ii. 549.)

SULPHAMMON. Syn. with SULPHATAMMON.

SULPHAMMONIC ACID. See SULPHAZOTISED ACIDS (p. 482).

SULPHAMYLIC ACID. See SULPHURIC ETHERS.

SULPHAN. A name proposed by Graham for the radicle SO^4.

SULPHANETHIC or **SULPHANETHOLIC ACID.** An acid produced by the action of strong sulphuric acid on anise-camphor (i. 297). Its soluble salts colour ferric solutions deep violet, almost black. The *barium-salt* appears to have the composition $Ba''O.2(C^{10}H^{12}O.SO^3)$. (Gerhardt, J. pr. Chem. xxxvi. 267.)

SULPHANILIC ACID. See SULPHAMIC ACID (p. 477).

SULPHANISIC ACID. See ANISIC ACID (i. 303).

SULPHANISOLIC ACID. $C^7H^8SO^4$. } Products formed by the action of sulphuric acid on anisol (i. 305).
SULPHANISOLIDE. $C^{14}H^{14}SO^4$.

SULPHANTIMONATES. } See ANTIMONY, SULPHIDES OF (i. 334, 335).
SULPHANTIMONITES.

SULPHARSENATES. } See ARSENIC, SULPHIDES OF (i. 388, 391).
SULPHARSENITES.

SULPHARSIN. Syn. with SULPHIDE OF CACODYL (i. 409).

SULPHASATHYDE or **SULPHASATYDE.** Syn. with SULPHISATYDE. (See ISATYDE, iii. 411.)

SULPHATAMMON. Neutral sulphamate of ammonium.

SULPHATES. See SULPHUR, OXYGEN-ACIDS OF.

SULPHATOXYGEN. Syn. with SULPHAN.

SULPHAZALIC, SULPHAZIDIC, SULPHAZILIC, SULPHAZINOUS, and **SULPHAZINIC ACIDS.** See SULPHAZOTISED ACIDS.

SULPHAZOBENZOYL, HYDRIDE OF. *Thiobenzaldin.* $C^{21}H^{19}NS^2$?—A product of the action of ammonia on hydride of thiobenzyl or sulphide of stilbene (i. 571):

$$3C^7H^6S + NH^3 = C^{21}H^{19}NS^2 + H^2S.$$

On mixing 1 vol. bitter-almond oil dissolved in 4 or 5 vols. ether with 1 vol. ammonium-sulphide, and leaving the ether to evaporate in a shallow vessel, the compound separates in large crystals, which melt at 123°, dissolve in 20 to 30 pts. of ether, and are decomposed by boiling alcohol, with evolution of sulphydric acid. (**Laurent**, Ann. Ch. Phys. [3] xxxvi. 342.)

SULPHAZOTISED ACIDS. (**Frémy**, Ann. Ch. Phys. [3] xv. 408; Handw. vii. 679.)—A series of acids, the potassium-salts of which are formed by the action of sulphurous anhydride upon a solution of potassium-nitrite containing a large excess of free alkali. Sulphurous anhydride combines with the elements of potassium-nitrite and water in several proportions, forming compounds which crystallise readily, and in which neither sulphurous nor nitrous acid can be detected by the usual tests. The solutions of these salts form, with salts of barium, precipitates containing the corresponding acids. These compounds are all decomposed by boiling their solutions, ammonia and sulphuric acid being found among the products; some of them even experience a similar decomposition at ordinary temperatures.

The derivation of some of these salts from potash, water, sulphurous and nitrous anhydrides, may be represented by the following formulæ:

Sulphazite of potassium, $3K^2O.S^3H^6N^2O^{12} = 3K^2O + N^2O^3 + 3SO^2 + 3H^2O$
Sulphazate „ $3K^2O.S^4H^6N^2O^{14} = 3K^2O + N^2O^3 + 4SO^2 + 3H^2O$
Sulphazotate „ $3K^2O.S^5H^6N^2O^{16} = 3K^2O + N^2O^3 + 5SO^2 + 3H^2O$
Sulphammonate „ $4K^2O.S^8H^6N^2O^{22} = 4K^2O + N^2O^3 + 8SO^2 + 3H^2O$

Sulphammonate of Potassium is formed by mixing the strong solutions of nitrite and sulphite of potassium; it is then deposited in beautiful silky needles.—The *sulphazate* is formed by the action of sulphurous anhydride on nitrite of potassium in alkaline solution; the *sulphazite* by the action of water on the sulphazate; the *sulphazotate* separates in large rhombohedral crystals, on evaporating an aqueous solution of the sulphazate. Neither of these acids can exist in the free state, *i. e.* as hydrogen-salts.

Frémy also describes:—*Metasulphazotate of potassium*, $3K^2O.S^8H^6N^2O^{22}$, formed, together with the sulphazotate, by the action of sulphurous anhydride on nitrite of potassium: acid not isolated.—*Sulphazilite*, $K^2O.S^2HNO$, produced by the action of silver-oxide in the cold on a solution of the neutral sulphazotate: acid not isolated.—*Metasulphazilite*, $3K^2O.S^6H^6N^2O^{20}$, formed in like manner at the boiling heat.—*Sulphamidate*, $K^2O.S^2H^3NO^5$, formed from the sulphammonate by the action of water: acid not isolated.—*Sulphazidic acid*, $2H^2O.S^2H^6N^2O^7$, is obtained by decomposing the barium-salt (the mode of preparation of which is not given) with an equivalent quantity of sulphuric acid. By saturating it with potash, the potassium-salt, $2K^2O.S^2H^6N^2O^7$, is obtained in regular six-sided laminæ.

SULPHESATYDE. Syn. with DISULPHISATYDE (iii. 412).

SULPHIDES and **SULPHYDRATES.** The term sulphide (formerly *sulphuret*), in its widest sense, includes all compounds in which sulphur forms the electronegative constituent. Sulphur unites in this way with all the metals, with most of the non-metallic elements, and with many organic radicles. The sulphides are, for the most part, analogous in composition to the oxides, and, like the latter, may be divided into acid and basic sulphides, or sulphur-acids and sulphur-bases, which are capable of uniting together and forming sulphur-salts. To the class of acid sulphides belong the sulphides of the non-metallic elements, and those metallic sulphides which are soluble in sulphide of ammonium—viz., the sulphides of antimony, arsenic, tin, molybdenum, tungsten, vanadium, gold, and platinum; the other metallic sulphides and the sulphides of the alcohol-radicles are basic.

METALLIC SULPHIDES.—Precisely as we have oxides and hydrates formed on the type of one or more atoms of water, so we have sulphides and sulphydrates derived from one or more atoms of sulphydric acid. The more or less basylous sulphides, like their corresponding oxides, may be divided into three principal classes, monatomic, diatomic, and triatomic, formed respectively on the types of one, two, and three atoms of sulphydric acid. The first class includes hemisulphides and protosulphides, with the corresponding sulphydrates. Hemisulphide of nickel, Ni^2S, sulphide of zinc, $Zn''S$, and sulphydrate of sodium, $HNaS$, may be taken as examples. The second class includes disulphides and disulphydrates. Disulphide of platinum, $Pt^{iv}S^2$, and sulphydrate of barium, $Ba''H^2S^2$, may be taken as examples. The third class includes the trisulphides with their corresponding sulphydrates, such as trisulphide of bismuth, Bi^2S^3, and trisulphide of chromium, Cr^2S^3. It is observable that while the trioxides constitute a most important class of oxides, the trisulphides are a very unimportant class of sulphides. As a rule, they do not occur native, are scarcely salifiable, and do not result from the ordinary analytical processes which produce the other metallic sulphides with such facility.

The sulphides differ much from one another in the rapidity and completeness with which they are decomposed by acids. When finely pulverised, they are all decomposed more or less perfectly by hydrochloric acid gas, but some of them are attacked very slowly by the boiling liquid acid. All salifiable sulphides, however, behave like their corresponding oxides, when decomposed by hydrochloric acid, and yield one atom of sulphydric acid for every atom of sulphur in the sulphide, thus:

$$\begin{aligned} Fe''S &+ 2HCl &= H^2S &+ Fe''Cl^2. \\ \overset{''}{Sn}{}^2S^2 &+ 4HCl &= 2H^2S &+ 2Sn''Cl^2. \\ \overset{'''}{Sb}{}^2S^3 &+ 6HCl &= 3H^2S &+ 2Sb'''Cl^3. \end{aligned}$$

With reference to the distinction between sulphides and sulphydrates, it may be observed that the sulphydrates of the basylous metals—lithium, sodium, potassium, calcium, strontium, barium, and magnesium—are well-defined compounds, which dissolve in water, forming colourless solutions. The solutions of the sulphydrates of magnesium and calcium are decomposed by ebullition, with evolution of sulphydric acid, thus: $Mg''H^2S^2 + 2H^2O = Mg''H^2O^2 + 2H^2S$. But the other sulphydrate solutions may be evaporated down, whereby they yield colourless transparent crystals of their respective sulphydrates. These basylous sulphydrates are usually made by saturating their corresponding hydrates with sulphydric acid gas. The dry alkaline sulphydrates, when heated to redness out of contact with air, are decomposed into sulphydric acid and metallic sulphide: $Ba''H^2S^2 = H^2S + Ba''S$; but the sulphydrates of potassium and sodium require a very strong heat to effect their decomposition. The sulphides of the acid-forming metals also appear to form definite sulphydrates, corresponding to their respective oxygen-acids; but the nature of these compounds, and still more of the sulphydrates of the intermediate metals, is not well established. It is not clear, for instance, whether the so-called hydrated sulphide of zinc consists of $Zn''H^2S^2$, or $Zn''S.H^2O$, or $Zn''H^2S^2.Zn''H^2O^2$. The hydrated sulphides of the ferric and plumbic families seem indeed not to be sulphydrates; for when soluble salts of the metals of these families are added to solutions of alkaline sulphydrates, sulphydric acid is evolved:

$$Fe''SO^4 + H^2O + 2KHS = K^2SO^4 + Fe''S.H^2O + H^2S.$$

Moreover, it is not clear that all sulphides precipitated from metallic solutions by excess of sulphydric acid, or a sulphydrate, are necessarily either hydrated or sulphydrated, despite their greater solubility in acids, and their difference in colour from the undoubtedly anhydrous sulphides made in the dry way. We know, for instance, that the difference between the native scarlet sulphide of mercury and the precipitated black sulphide, or that between the native grey sulphide of antimony and the precipitated orange sulphide, is not a difference of hydration at all, but one of molecular condition, *i. e.* allotropy.

The protosulphides of the alkali-metals and alkaline earth-metals dissolve in water, forming colourless solutions, from which, by evaporation, the solid sulphides may, it is said, be again procured, and in the crystalline state. It is not improbable that the solutions really contain mixtures of alkaline hydrate and sulphydrate, resulting from the reaction of the sulphide with water, thus: $K^2S + H^2O = KHS + KHO$. At any rate, precisely similar solutions are made by mixing equal quantities of alkaline hydrate and sulphydrate. With the exception of the above sulphides of the basylous metals, all sulphides and hydrated sulphides are insoluble in water, or very nearly so. Those which, like the trisulphide of arsenic, are sparingly soluble in pure water, are insoluble in acidulated water. This trisulphide, when recently precipitated, is slowly but completely decomposed, by boiling with water into arsenious and sulphydric acids.

As a rule, the sulphides and oxides of the same metal have similar formulæ, and correspond in their general behaviour. Occasionally, indeed, we have metallic oxides to which there are no corresponding sulphides (the peroxide of manganese, for example), and more frequently metallic sulphides to which there are no corresponding oxides, —the hemisulphide of iron and the disulphide of arsenic, for example. Among the sulphides to which there are no corresponding oxides, perhaps the most remarkable are the alkaline polysulphides. The metal potassium, for instance, is said to form the compounds K^2S, K^2S^2, K^2S^3, K^2S^4, and K^2S^5 (iv. 707).

When protosulphide of potassium is fused with excess of sulphur, the pentasulphide is formed as a dark liver-coloured mass which sinks beneath the excess of melted sulphur. It is a very definite compound, soluble in water, forming a deep orange liquid, which may also be obtained by boiling an excess of sulphur with a solution of the protosulphide. Its composition corresponds with that of the sulphate and hyposulphite or thiosulphate of potassium, thus:

K^2SO^4, Sulphate.
$K^2S^2O^3$, Thiosulphate.
K^2S^5, Pentasulphide.

It is doubtful whether the three intermediate polysulphides are other than mixtures of proto- and penta-sulphide. They may, however, be definite sulphides corresponding to the polythionic series of oxygen-salts, thus:

K^2S^2, Disulphide.	$K^2S^2O^6$, Dithionate.
K^2S^3, Trisulphide.	$K^2S^3O^6$, Trithionate.
K^2S^4, Tetrasulphide.	$K^2S^4O^6$. Tetrathionate.
K^2S^5, Pentasulphide.	$K^2S^5O^6$, Pentathionate.

It is observable, moreover, that the three intermediate polysulphides result from definite reactions, and that the disulphide and trisulphide correspond to definite oxides. The yellow colour, which solutions of alkaline protosulphide and sulphydrate acquire by exposure to air, is due to the production of polysulphides, thus: $2KHS + O = K^2S^2 + H^2O$. The yellow solutions of the polysulphides eventually become colourless by absorption of oxygen, which produces a thiosulphate, accompanied, in the case of the tri-, tetra-, and penta-sulphides, with a deposit of sulphur. The polysulphides do not appear to form corresponding polysulphydrates; for when sulphur is boiled with solutions of sulphydrates, there is always an evolution of sulphydric acid, thus:

$$2KHS + S = K^2S^2 + H^2S.$$

The distinction between neutral and salifiable sulphides is much less marked even than that between neutral and salifiable oxides. Disulphide of iron, for instance, is obviously the representative of the non-salifiable peroxide of manganese. The two compounds, when heated in close vessels, undergo precisely similar decompositions:

$$\begin{aligned} 3MnO^2 &= Mn^3O^4 + O^2. \\ 3FeS^2 &= Fe^3S^4 + S^2. \end{aligned}$$

On the other hand, the trisulphide of iron is obviously the representative of the salifiable trioxide of that metal, and should correspond with it in its reaction with hydrochloric acid, thus:

$$\begin{aligned} Fe^2O^3 + 6HCl &= 2FeCl^3 + 3H^2O. \\ Fe^2S^3 + 6HCl &= 2FeCl^3 + 3H^2S. \end{aligned}$$

But sulphydric acid has the property of reducing trichloride of iron to the state of dichloride, with a deposition of sulphur, thus: $2FeCl^3 + H^2S = 2FeCl^2 + 2HCl + S$. Hence the actual behaviour of trisulphide of iron, when treated with hydrochloric acid, corresponds, not with that of the salifiable trioxide of iron, but with that of the indifferent trioxide of cobalt:

$$\begin{aligned} Co^2O^3 + 4HCl &= 2CoCl^2 + 2H^2O + O. \\ Fe^2S^3 + 4HCl &= 2FeCl^2 + 2H^2S + S. \end{aligned}$$

The sulphides of the chlorous metals have characters corresponding to those of the corresponding metallic oxides; that is to say, they unite with the sulphides of the basylous metals to form corresponding soluble salts. The disulphide of tin, and the trisulphides and pentasulphides of antimony and arsenic, for instance, dissolve in sulphydrate of potassium or ammonium, just as the corresponding oxides dissolve in oxhydrate of potassium or ammonium. Thus we have stannate of potassium, K^2SnO^3 or $K^2O.SnO^2$, and sulphostannate of potassium, K^2SnS^3 or $K^2S.SnS^2$. When these chlorous sulphides dissolve in alkaline hydrates, they form both sulphosalts and oxysalts, thus:

$$3SnS^2 + 6KHO = 2K^2SnS^3 + K^2SnO^3 + 3H^2O.$$

Respecting the modes of formation and the reactions of metallic sulphides, see further METALS (iii. 940); also Odling's *Manual of Chemistry* (i. 153).

On the sulphides and sulphydrates of alcohol-radicles, see ETHERS (ii. 511).

The individual sulphides, inorganic and organic, are specially described in connection with the several elements and organic radicles.

SULPHINDIGOTIC ACID. See INDIGO-SULPHURIC ACIDS (iii. 258).

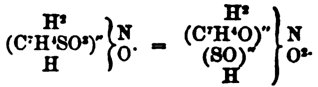
SULPHINDYLIC ACID. Syn. with SULPHINDIGOTIC ACID.

SULPHISATANOUS ACID. An acid produced, according to Laurent, by the action of ammonium-sulphite on disulphisatyde (iii. 412).

SULPHISATIN. Syn. with DISULPHISATYDE.

SULPHITES. See SULPHUR, OXYGEN-ACIDS OF.

SULPHOBENZAMIC ACID, $C^7H^7NSO^4$ =



$$C^7H^7NSO^4 = \left.\begin{matrix} H^2 \\ (C^7H^4SO^3)'' \\ H \end{matrix}\right\} \begin{matrix} N \\ O \end{matrix} = \left.\begin{matrix} H^2 \\ (C^7H^4O)'' \\ (SO)'' \\ H \end{matrix}\right\} \begin{matrix} N \\ O^2 \end{matrix}.$$

(Limpricht and Uslar, Ann. Ch. Pharm. cvi. 27; Jahresb. 1858, p. 275.—Engelhardt, Petersb. Acad. Bull. xvi. 378; Jahresb. 1858, p. 278.)—This acid, the amic acid of sulphobenzoic acid, is produced: 1. By heating sulphobenzamide, or ethylsulphobenzoate of ammonium, with potash (Limpricht and Uslar):

$$\underset{\text{Sulphobenzamide.}}{C^7H^8N^2SO^3} + H^2O = \underset{\text{Sulphobenzamic acid.}}{C^7H^7NSO^4} + NH^3.$$

Also from the compound $C^7H^6N^2SO^2$ (the hydrochlorate of which is formed by treating sulphobenzamide with pentachloride of phosphorus, p. 686), likewise with elimination of ammonia (Limpricht and Uslar):

$$C^7H^6N^2SO^2 + 2H^2O = C^7H^7NSO^4 + NH^3.$$

3. Together with other products, by the action of sulphuric anhydride on benzonitrile. (Engelhardt.)

Preparation.—1. Sulphobenzamide, stirred up to a paste with strong potash-ley, is heated in the water-bath for several hours, till a clear solution is obtained. This is diluted with water, and supersaturated with hydrochloric acid, whereby the sulphobenzamic acid is obtained as a bulky precipitate, which is purified by recrystallisation from boiling water. (Limpricht and Uslar.)

2. Vapour of sulphuric anhydride is slowly passed into well-cooled benzonitrile, whereby a crystalline mass is produced (if the action goes on more quickly, a vitreous mass is formed, which yields other products). On treating the crystalline mass with cold water, to remove excess of sulphuric acid, and dissolving the residue in boiling alcohol, needle-shaped crystals separate at first, but afterwards, on addition of ether, rhombohedral crystals of sulphobenzamic acid. (Engelhardt.)

Properties.—Sulphobenzamic acid crystallises from a boiling saturated solution on cooling, in scales resembling chlorate of potassium (Limpricht and Uslar); in rhombohedral crystals or in needles, consisting of aggregates of small rhombohedrons (Engelhardt). It is very sparingly soluble in cold water, more soluble in ether, easily in hot water and in alcohol. It melts at a temperature above 200°, and solidifies in a crystalline mass on cooling; at a higher temperature it volatilises in white vapours, and finally burns with a luminous flame. It reddens litmus, decomposes carbonates, but does not dissolve zinc.

Decompositions.—1. Sulphobenzamic acid appears to be resolved by prolonged heating into ammonia and sulphobenzoic anhydride. The aqueous solution, when evaporated, leaves sulphobenzoic acid.—2. When 1 at. sulphobenzamic acid is heated to 150°—200° with 1½ at. *pentachloride of phosphorus*, as long as phosphoric oxychloride continues to distil over, a yellow oily liquid is left, consisting of sulphobenzamic chloride, $C^7H^6NSO^3Cl$, which is converted by water into hydrochloric and sulphobenzamic acids, ($C^7H^6NSO^3Cl + H^2O = HCl + C^7H^7NSO^4$), and by ammonia into sulphobenzamide (Limpricht and Uslar). By distilling sulphobenzamic acid with *pentachloride of phosphorus*, a distillate is obtained, containing—besides oxychloride of phosphorus—chlorobenzonitrile, chlorobenzoic chloride (in small quantity), and the chloride of an easily soluble acid, probably isomeric with sulphobenzamic acid.

The same chloride appears to be obtained, together with amorphous sulphobenzamic acid, by heating 1 at. sulphobenzamic acid with 1 at. of the pentachloride. On treating the yellow tumefied residue with ether, the amorphous sulphobenzamic acid remains as a white pulverulent mass, which is insoluble in water, alcohol, and ether, but is converted, by heating with water to 170°—180°, into ordinary crystallised sulphobenzamic acid. (Limpricht and Uslar.)

3. Sulphobenzamic acid treated with *sulphuric anhydride* yields a brown viscid mass, from which, by boiling with plumbic carbonate, a salt is obtained, having the composition of plumbic sulphobenzoate.

Sulphobenzamates.—Sulphobenzamic acid is monobasic. All its salts are more or less soluble in water.—The *ammonium-salt* separates in laminar crystals, on evaporating a solution of the acid in ammonia.—The *barium-salt*, $C^{14}H^{12}Ba''N^2S^2O^8.4H^2O$, separates from the evaporated neutral solution as a soft, wavellitic, crystalline mass, which gives off its water at 110°.—The *calcium-salt*, dried at 120°, has the composition $C^{14}H^{12}Ca''N^2S^2O^8$.—The *silver-salt*, $C^7H^6AgNSO^4.H^2O$, is precipitated by silver-nitrate from the solution of the ammonium-salt, in slender silky needles; it may be recrystallised from boiling water, and does not blacken on exposure to light.

The solution of the ammonium-salt gives, with *neutral lead-acetate*, a precipitate, crystallising in small needles; with *ferrous salts* a white, with *ferric salts* a flesh-coloured, precipitate; with *cupric salts*, a precipitate consisting of small needles, soluble in ammonia; with *mercurous salts*, a white precipitate turning black on boiling; with *mercuric chloride*, a crystalline precipitate separating from water in laminæ; with *zinc-salts* no precipitate.

Ethylic Sulphobenzamate, or *Sulphobenzamic Ether*, $C^7H^6(C^2H^5)NSO^4$, is obtained by passing hydrochloric acid gas into the alcoholic solution of the acid; by decomposing the silver-salt with ethylic iodide; or by treating the alcoholic solution of sulphobenzoic chloride with ammonia-gas. It crystallises in splendid shining needles, which, according to Keferstein, are monoclinic prisms, ∞P . ∞P∞ . oP . —P, having their axes in the ratio of 1 : 2 : 4. When cautiously heated, it melts without decomposition, and solidifies in the crystalline state on cooling; at a higher temperature it gives off white fumes, and burns with a bright flame. It dissolves easily in warm alcohol or ether, somewhat less easily in boiling water. Strong caustic potash dissolves it, at ordinary temperatures, without evolution of ammonia; at 100° with formation of alcohol and potassic sulphobenzamate; at higher temperatures also with evolution of ammonia. It does not dissolve mercuric oxide, and only a small quantity of silver-oxide. (Limpricht and Uslar.)

SULPHOBENZAMIDE. $C^7H^8N^2SO^3 = \left.\begin{matrix}(C^7H^4SO^2)''\\H^4\end{matrix}\right\}N^2 = \left.\begin{matrix}(C^7H^4O)''\\(SO)''\\H^4\end{matrix}\right\}\begin{matrix}N^2\\O\end{matrix}$ (Limpricht and Uslar, Ann. Ch. Pharm. cii. 239; cvi. 27.—Jahresb. 1857, p. 336; 1858, p. 275.)—Obtained by treating sulphobenzoic chloride with strong aqueous ammonia. The product, washed with water, dried, and recrystallised from absolute alcohol, with addition of animal charcoal, yields anhydrous sulphobenzamide; if aqueous alcohol be used, a mixture of the anhydrous amide and a hydrate containing 1 at. water is obtained.

Sulphobenzamide dissolves readily in hot water and hot alcohol. The hydrate, which crystallises in needles, gives off its water at 100°; at 170° the compound fuses, and between 270° and 290° it slowly decomposes, but without formation of sulphobenzimide.—When treated with *potash*, it gives off ammonia, and is converted into sulphobenzamic acid (p. 485).—With *pentachloride of phosphorus* at 100°, it decomposes, according to the equation:

$$C^7H^8N^2SO^3 + PCl^5 = C^7H^6N^2SO^2.HCl + POCl^3 + HCl;$$

forming a yellow syrup, which is further decomposed during the distillation, yielding phosphoric oxychloride and chlorobenzonitrile. The compound $C^7H^6N^2SO^2.HCl$ dissolves in ether and in alcohol, but does not crystallise therefrom; with water or ammonia, however, it yields the crystallisable compound $C^7H^6N^2SO^2$, which dissolves in potash, and by prolonged heating therewith is converted into sulphobenzamic acid.

SULPHOBENZANILIDE. *Diphenylsulphobenzamide*, $C^7H^6(C^6H^5)^2SO^3$, is produced by mixing sulphobenzoic chloride with aniline. When crystallised from alcohol, with aid of animal charcoal, it forms small white fusible crystals, easily soluble in alcohol and ether, slightly soluble in cold water, decomposed by hot potash-ley with separation of aniline.

SULPHOBENZIDE. $C^{12}H^{10}SO^2$. (Mitscherlich, Pogg. Ann. xxxi. 628.—Freund, Ann. Ch. Pharm. cxx. 76.—Otto, *ibid.* cxxxv. 154.)—A compound formed, together with phenylsulphurous acid, by the action of sulphuric anhydride on benzol. On treating the thick liquid product with a large quantity of water, the sulphobenzide separates in the crystalline form, while the phenylsulphurous acid remains in solution. The sulphobenzide may be purified by crystallisation from ether, or by distillation (Mitscherlich). It is also produced, together with benzol, by distilling aqueous phenylsulphurous acid, and crystallises in the receiver. (Freund.)

Sulphobenzide crystallises from alcohol in rhombic plates. It melts at 100° (Mitscherlich), at 128° (Freund), at 128°—129° (Otto), and boils at a much higher temperature. It dissolves in *alcohol* and in *ether*, is insoluble in *alkalis*, but dissolves in *acids*, and is precipitated therefrom by water. Strong *sulphuric acid* dissolves it when heated, and converts it into phenylsulphurous acid. *Chlorine* converts it, at the boiling heat, into trichlorobenzol (Mitscherlich).—With *pentachloride of phosphorus* it forms monochlorobenzol, chloride of sulphophenyl, and trichloride of phosphorus (Otto):

$$C^{12}H^{10}SO^2 + PCl^5 = C^6H^5Cl + C^6H^5SO^2Cl + PCl^3.$$

SULPHOBENZIDIC ACID. Syn. with PHENYLSULPHUROUS ACID.

SULPHOBENZOIC ACID. $C^7H^6SO^5 = C^7H^6O^2.SO^3 = \left.\begin{matrix}(C^7H^4SO^3)''\\H^2\end{matrix}\right\}O^2 = \left.\begin{matrix}(C^7H^4O)''\\(SO)''\\H^2\end{matrix}\right\}O^3$. (Mitscherlich, Pogg. Ann. xxxi. 287.—Fehling, Ann. Ch. Pharm.

xxvii. 322.—**Limpricht** and **Uslar**, *ibid.* cii. 239; cvi. 27.—**Keferstein**, *ibid.* cvi. 385.)—This acid is produced:—1. By passing the vapour of sulphuric anhydride into benzoic acid, or by mixing 1 pt. of the anhydride with 2 pts. benzoic acid. The mass is treated with water, which dissolves sulphuric and sulphobenzoic acids, leaving the excess of benzoic acid undissolved; the solution is saturated with carbonate of barium; and the filtered solution is mixed, while still warm, with a quantity of hydrochloric acid sufficient to combine with half the baryta in solution. Acid sulphobenzoate of barium then separates on cooling, and on decomposing the solution of this salt with the exact quantity of sulphuric acid required to precipitate the barium, and evaporating the filtered solution till it no longer boils at 150°, the sulphobenzoic acid separates on cooling as a crystalline mass.

2. By the action of sulphuric acid on benzonitrile, disulphobenzolic acid being formed at the same time:

$$\underset{\text{Benzo-}}{C^7H^5N} + H^2O + 2H^2SO^4 = \underset{\substack{\text{Sulpho-}\\ \text{benzoic}\\ \text{acid.}}}{C^7H^6SO^5} + (NH^4.H)SO^4.$$

$$\underset{\substack{\text{Benzo-}\\ \text{nitrile.}}}{C^7H^5N} + 3H^2SO^4 = \underset{\substack{\text{Disulpho-}\\ \text{benzolic}\\ \text{acid.}}}{C^6H^6S^2O^6} + (NH^4.H)SO^4 + CO^2.$$

On neutralising the product of the reaction with carbonate of barium, evaporating, redissolving in water, and adding alcohol by separate portions, sulphobenzoate of barium crystallises out first, and afterwards the disulphobenzolate. (**Buckton** and **Hofmann**, Chem. Soc. Qu. J. ix. 255.)

3. By the action of water on sulphobenzoic chloride:

$$C^7H^4SO^3Cl^2 + 2H^2O = C^7H^6SO^5 + 2HCl.$$

Sulphobenzoic acid forms a solid crystalline mass, which may be heated to 150° without decomposition: it deliquesces gradually in damp air, but recovers its solid form in a dry atmosphere. It is not altered by boiling with acids or alkalis, but on fusing it with *solid potash*, the sulphur is converted, partly into sulphuric, partly into sulphurous acid.—By a mixture of 2 pts. oil of vitriol and 1 pt. nitric acid, it is converted into nitrosulphobenzoic acid, $C^7H^5(NO^2)SO^5$.—With 2 at. pentachloride of phosphorus, it forms sulphobenzoic chloride:

$$C^7H^6SO^5 + 2PCl^5 = C^7H^4SO^3Cl^2 + 2POCl^3 + 2HCl.$$

With 1 at. of the pentachloride, the product is sulphobenzoic chlorhydrate:

$$C^7H^6SO^5 + PCl^5 = C^7H^4SO^3\left\{\begin{matrix}Cl\\ HO\end{matrix}\right. + POCl^3 + HCl.$$

Sulphobenzoates.—Sulphobenzoic acid is dibasic, forming acid and neutral salts, the former being for the most part less soluble than the latter.—The *neutral barium-salt*, $C^7H^4Ba''S^2O^5$, obtained by boiling the solution of the acid salt with barium-carbonate, forms indistinct crystals, very soluble in water, and bearing without decomposition a temperature as high as that of boiling oil.—The *acid barium-salt*, $C^7H^4Ba''SO^5.C^7H^6SO^5.3H^2O$, prepared as above described, crystallises in monoclinic prisms: oP . ∞P . ∞P∞, with the angles oP : ∞P = 98°6′; ∞P : ∞P = 82° 21 (**Fehling**). The crystals give off their water at 200°, dissolve in 20 pts. water at 20°, and have an acid reaction.—The *lead-salt*, $C^7H^4Pb''SO^5.2H^2O$, is obtained in solution by boiling the acid with excess of lead-carbonate, and separates on cooling in stellate groups of slender needles. Gives off its water at 200°.—The *neutral potassium-salt*, $C^7H^4K^2SO^5$, forms beautiful deliquescent crystals: the *acid salt* is efflorescent.—The *silver-salt*, $C^7H^4Ag^2SO^5.H^2O$, crystallises in a vacuum in small yellowish prisms, which dissolve easily in water, and give off 1 at. water when dried. (**Fehling.**)

The acid sulphobenzoates of magnesium and zinc, also the acid ferrous, cobaltous, and cupric salts, form beautiful crystals. (**Mitscherlich.**)

Derivatives of Sulphobenzoic Acid.

Nitrosulphobenzoic Acid, $C^7H^5(NO^2)SO^5$. (**Limpricht** and **Uslar.**)—Prepared by adding sulphobenzoic or sulphobenzamic acid to a cold mixture of strong nitric and sulphuric acids, diluting with water after some time, neutralising with carbonate of barium, and decomposing the resulting barium-salt with sulphuric acid. It crystallises from a concentrated solution in well-defined crystals.—The *neutral barium-salt*, $C^7H^3Ba''(NO^2)SO^5$, forms easily soluble, nodular, mostly yellowish crystals, containing 3 or $\frac{3}{2}$ at. water.—The *acid barium-salt*, $C^7H^3Ba''(NO^2)SO^5$.

Ethylic Sulphobenzamate, or *Sulphobenzamic Ether*, $C^7H^6(C^2H^5)NSO^4$, is obtained by passing hydrochloric acid gas into the alcoholic solution of the acid; by decomposing the silver-salt with ethylic iodide; or by treating the alcoholic solution of sulphobenzoic chloride with ammonia-gas. It crystallises in splendid shining needles, which, according to Keferstein, are monoclinic prisms, ∞P . ∞P∞ . oP . —P, having their axes in the ratio of 1 : 2 : 4. When cautiously heated, it melts without decomposition, and solidifies in the crystalline state on cooling; at a higher temperature it gives off white fumes, and burns with a bright flame. It dissolves easily in warm alcohol or ether, somewhat less easily in boiling water. Strong caustic potash dissolves it, at ordinary temperatures, without evolution of ammonia; at 100° with formation of alcohol and potassic sulphobenzamate; at higher temperatures also with evolution of ammonia. It does not dissolve mercuric oxide, and only a small quantity of silver-oxide. (Limpricht and Uslar.)

SULPHOBENZAMIDE. $C^7H^8N^2SO^3 = \left.\begin{matrix}(C^7H^4SO^2)'' \\ H^4\end{matrix}\right\}N^2 = \left.\begin{matrix}(C^7H^4O)'' \\ (SO)'' \\ H^4\end{matrix}\right\}\begin{matrix}N^2 \\ O\end{matrix}$ (Limpricht and Uslar, Ann. Ch. Pharm. cii. 239; cvi. 27.—Jahresb. 1857, p. 336; 1858, p. 275.)—Obtained by treating sulphobenzoic chloride with strong aqueous ammonia. The product, washed with water, dried, and recrystallised from absolute alcohol, with addition of animal charcoal, yields anhydrous sulphobenzamide; if aqueous alcohol be used, a mixture of the anhydrous amide and a hydrate containing 1 at. water is obtained.

Sulphobenzamide dissolves readily in hot water and hot alcohol. The hydrate, which crystallises in needles, gives off its water at 100°; at 170° the compound fuses, and between 270° and 290° it slowly decomposes, but without formation of sulphobenzimide.—When treated with *potash*, it gives off ammonia, and is converted into sulphobenzamic acid (p. 485).—With *pentachloride of phosphorus* at 100°, it decomposes, according to the equation:

$$C^7H^8N^2SO^3 + PCl^5 = C^7H^6N^2SO^2.HCl + POCl^3 + HCl;$$

forming a yellow syrup, which is further decomposed during the distillation, yielding phosphoric oxychloride and chlorobenzonitrile. The compound $C^7H^6N^2SO^2.HCl$ dissolves in ether and in alcohol, but does not crystallise therefrom; with water or ammonia, however, it yields the crystallisable compound $C^7H^6N^2SO^2$, which dissolves in potash, and by prolonged heating therewith is converted into sulphobenzamic acid.

SULPHOBENZANILIDE. *Diphenylsulphobenzamide*, $C^7H^6(C^6H^5)^2SO^3$, is produced by mixing sulphobenzoic chloride with aniline. When crystallised from alcohol, with aid of animal charcoal, it forms small white fusible crystals, easily soluble in alcohol and ether, slightly soluble in cold water, decomposed by hot potash-ley with separation of aniline.

SULPHOBENZIDE. $C^{12}H^{10}SO^2$. (Mitscherlich, Pogg. Ann. xxxi. 628.—Freund, Ann. Ch. Pharm. cxx. 76.—Otto, *ibid.* cxxxv. 154.)—A compound formed, together with phenylsulphurous acid, by the action of sulphuric anhydride on benzol. On treating the thick liquid product with a large quantity of water, the sulphobenzide separates in the crystalline form, while the phenylsulphurous acid remains in solution. The sulphobenzide may be purified by crystallisation from ether, or by distillation (Mitscherlich). It is also produced, together with benzol, by distilling aqueous phenylsulphurous acid, and crystallises in the receiver. (Freund.)

Sulphobenzide crystallises from alcohol in rhombic plates. It melts at 100° (Mitscherlich), at 123° (Freund), at 128°—129° (Otto), and boils at a much higher temperature. It dissolves in *alcohol* and in *ether*, is insoluble in *alkalis*, but dissolves in *acids*, and is precipitated therefrom by water. Strong *sulphuric acid* dissolves it when heated, and converts it into phenylsulphurous acid. *Chlorine* converts it, at the boiling heat, into trichlorobenzol (Mitscherlich).—With *pentachloride of phosphorus* it forms monochlorobenzol, chloride of sulphophenyl, and trichloride of phosphorus (Otto):

$$C^{12}H^{10}SO^2 + PCl^5 = C^6H^5Cl + C^6H^5SO^2Cl + PCl^3.$$

SULPHOBENZIDIC ACID. Syn. with PHENYLSULPHUROUS ACID.

SULPHOBENZOIC ACID. $C^7H^6SO^5 = C^7H^6O^2.SO^3 = \left.\begin{matrix}(C^7H^4SO^3)'' \\ H^2\end{matrix}\right\}O^2 = \left.\begin{matrix}(C^7H^4O)'' \\ (SO)'' \\ H^2\end{matrix}\right\}O^3$. (Mitscherlich, Pogg. Ann. xxxi. 287.—Fehling, Ann. Ch. Pharm.

xxvii. 322.—**Limpricht** and **Uslar**, *ibid.* cii. 239; cvi. 27.—**Keferstein**, *ibid.* cvi. 385.)—This acid is produced:—1. By passing the vapour of sulphuric anhydride into benzoic acid, or by mixing 1 pt. of the anhydride with 2 pts. benzoic acid. The mass is treated with water, which dissolves sulphuric and sulphobenzoic acids, leaving the excess of benzoic acid undissolved; the solution is saturated with carbonate of barium; and the filtered solution is mixed, while still warm, with a quantity of hydrochloric acid sufficient to combine with half the baryta in solution. Acid sulphobenzoate of barium then separates on cooling, and on decomposing the solution of this salt with the exact quantity of sulphuric acid required to precipitate the barium, and evaporating the filtered solution till it no longer boils at 150°, the sulphobenzoic acid separates on cooling as a crystalline mass.

2. By the action of sulphuric acid on benzonitrile, disulphobenzolic acid being formed at the same time:

$$\underset{\text{Benzo-}}{C^7H^5N} + H^2O + 2H^2SO^4 = \underset{\substack{\text{Sulpho-}\\\text{benzoic}\\\text{acid.}}}{C^7H^6SO^5} + (NH^4.H)SO^4.$$

$$\underset{\substack{\text{Benzo-}\\\text{nitrile.}}}{C^7H^5N} + 3H^2SO^4 = \underset{\substack{\text{Disulpho-}\\\text{benzolic}\\\text{acid.}}}{C^6H^6S^2O^6} + (NH^4.H)SO^4 + CO^2.$$

On neutralising the product of the reaction with carbonate of barium, evaporating, redissolving in water, and adding alcohol by separate portions, sulphobenzoate of barium crystallises out first, and afterwards the disulphobenzolate. (**Buckton** and **Hofmann**, Chem. Soc. Qu. J. ix. 255.)

3. By the action of water on sulphobenzoic chloride:

$$C^7H^4SO^3Cl^2 + 2H^2O = C^7H^6SO^5 + 2HCl.$$

Sulphobenzoic acid forms a solid crystalline mass, which may be heated to 150° without decomposition: it deliquesces gradually in damp air, but recovers its solid form in a dry atmosphere. It is not altered by boiling with acids or alkalis, but on fusing it with *solid potash*, the sulphur is converted, partly into sulphuric, partly into sulphurous acid.—By a mixture of 2 pts. oil of vitriol and 1 pt. nitric acid, it is converted into nitrosulphobenzoic acid, $C^7H^5(NO^2)SO^5$.—With 2 at. pentachloride of phosphorus, it forms sulphobenzoic chloride:

$$C^7H^6SO^5 + 2PCl^5 = C^7H^4SO^3Cl^2 + 2POCl^3 + 2HCl.$$

With 1 at. of the pentachloride, the product is sulphobenzoic chlorhydrate:

$$C^7H^6SO^5 + PCl^5 = C^7H^4SO^3\left\{\begin{matrix}Cl\\HO\end{matrix}\right. + POCl^3 + HCl.$$

Sulphobenzoates.—Sulphobenzoic acid is dibasic, forming acid and neutral salts, the former being for the most part less soluble than the latter.—The *neutral barium-salt*, $C^7H^4Ba''S^2O^6$, obtained by boiling the solution of the acid salt with barium-carbonate, forms indistinct crystals, very soluble in water, and bearing without decomposition a temperature as high as that of boiling oil.—The *acid barium-salt*, $C^7H^4Ba''SO^5.C^7H^6SO^5.3H^2O$, prepared as above described, crystallises in monoclinic prisms: oP . ∞P . ∞P∞, with the angles oP : ∞P = 98°6′; ∞P : ∞P = 82° 21 (**Fehling**). The crystals give off their water at 200°, dissolve in 20 pts. water at 20°, and have an acid reaction.—The *lead-salt*, $C^7H^4Pb''SO^5.2H^2O$, is obtained in solution by boiling the acid with excess of lead-carbonate, and separates on cooling in stellate groups of slender needles. Gives off its water at 200°.—The *neutral potassium-salt*, $C^7H^4K^2SO^5$, forms beautiful deliquescent crystals: the *acid salt* is efflorescent.—The *silver-salt*, $C^7H^4Ag^2SO^5.H^2O$, crystallises in a vacuum in small yellowish prisms, which dissolve easily in water, and give off 1 at. water when dried. (**Fehling**.)

The acid sulphobenzoates of magnesium and zinc, also the acid ferrous, cobaltous, and cupric salts, form beautiful crystals. (**Mitscherlich**.)

Derivatives of Sulphobenzoic Acid.

Nitrosulphobenzoic Acid, $C^7H^5(NO^2)SO^5$. (**Limpricht** and **Uslar**.)—Prepared by adding sulphobenzoic or sulphobenzamic acid to a cold mixture of strong nitric and sulphuric acids, diluting with water after some time, neutralising with carbonate of barium, and decomposing the resulting barium-salt with sulphuric acid. It crystallises from a concentrated solution in well-defined crystals.—The *neutral barium-salt*, $C^7H^3Ba''(NO^2)SO^5$, forms easily soluble, nodular, mostly yellowish crystals, containing 3 or $\frac{3}{2}$ at. water.—The *acid barium-salt*, $C^7H^3Ba''(NO^2)SO^5$.

$C^7H^5(NO^2)SO^5$, crystallises in small, limpid, radiating prisms, containing 4 at. water. —The *silver-salt*, obtained by boiling the acid with silver-oxide, crystallises in small nodules, easily soluble in water, insoluble in alcohol.

Amidosulphobenzoic Acid, $C^7H^7NSO^5 = C^7H^5(NH^2)SO^5$, produced by continued digestion of nitrosulphobenzoic acid with aqueous sulphide of ammonium, separates, on supersaturating the concentrated filtrate with hydrochloric acid, in white concentrically-grouped needles, having an acid reaction, easily soluble in hot water, less soluble in alcohol, nearly insoluble in ether. When heated, it chars without previous fusion. It dissolves easily in ammonia, and the solution forms, with nitrate of silver, a white precipitate, which turns black on boiling. Amidosulphobenzoic acid does not appear to unite with other acids, at least not with hydrochloric acid. (Limpricht and Uslar.)

SULPHOBENZOIC CHLORHYDRATE. $C^7H^5ClSO^4 = C^7H^4SO^3\left\{\begin{matrix}Cl\\HO\end{matrix}\right. = \left.\begin{matrix}(C^7H^4O)''\\(SO)''\\H\end{matrix}\right\}\begin{matrix}Cl\\O^2\end{matrix}$. *Chlorwasserstoff-Sulfobenzoesäure.*—This compound, analogous to Williamson's sulphuric chlorhydrate, $SO^2.Cl.HO$, is obtained:—1. By heating 1 at. sulphobenzoic acid with 1 at. pentachloride of phosphorus, till the greater part of the phosphoric oxychloride has distilled off, and adding water to the residue to dissolve out hydrochloric and phosphoric acids.—2. By leaving sulphobenzoic chloride in contact with water for several weeks:

$$C^7H^4Cl^2SO^3 + H^2O = C^7H^5ClSO^4 + HCl.$$

It is a white crystalline powder, soluble in ether, decomposed by alcohol and by boiling water, insoluble in cold water. It melts very easily, and decomposes at a higher temperature. By boiling water and by alkalis it is converted into sulphobenzoic acid. (Limpricht and Uslar.)

SULPHOBENZOIC CHLORIDE. $C^7H^4SO^3Cl^2 = \left.\begin{matrix}(C^7H^4O)''\\(SO)''\end{matrix}\right\}\begin{matrix}Cl^2\\O\end{matrix}$.—Prepared like the preceding, but with 2 at. phosphoric pentachloride to 1 at. sulphobenzoic acid dried at 100°. It is a yellowish-brown, viscid, oily liquid, having a faint unpleasant odour, heavier than water, and very slowly decomposed thereby. Boiling water dissolves it more quickly, forming hydrochloric and sulphobenzoic acids.—*Alkalis* decompose it in a similar manner. When heated to 300° it decomposes with strong intumescence, giving off chloride of chlorobenzoyl (i. 567), and leaving a carbonaceous mass.—*Alcohol* dissolves it, with great rise of temperature and formation of ethylic sulphobenzoate. Anhydrous ether appears to dissolve it without decomposition.—Aqueous *ammonia* converts it into sal-ammoniac and sulphobenzamide: the latter is also formed by passing ammonia-gas into the ethereal solution of the chloride.—With *aniline* it forms sulphobenzanilide and hydrochlorate of aniline. *Alcohol* saturated with *ammonia*, dissolves it with great rise of temperature, forming ethylsulphobenzoic acid. (Limpricht and Uslar.)

SULPHOBENZOIC ETHERS. The only ones known are the acid and neutral ethylic ethers.

Ethylic Sulphobenzoate, $C^{11}H^{14}SO^5 = C^7H^4(C^2H^5)^2SO^5$. (Limpricht and Uslar, Ann. Ch. Pharm. cii. 252.)—Absolute alcohol becomes strongly heated in contact with sulphobenzoic chloride; hydrochloric acid and chloride of ethyl are given off; and on evaporating the liquid over the water-bath, ethylic sulphobenzoate remains in the form of a syrupy residue having a faint ethereal odour. It dissolves in water in all proportions, and cannot therefore be purified, like most compound ethers, by washing with water. On heating the aqueous solution, the ether is resolved into alcohol and sulphobenzoic acid. It cannot be distilled without decomposition; when heated in a retort, it leaves a large quantity of charcoal; swells up considerably, and yields a small quantity of distillate having a disagreeable odour. Treated with gaseous or aqueous ammonia, it yields ethylsulphobenzoate of ammonium.

Ethylsulphobenzoic Acid, $C^9H^{10}SO^5 = C^7H^5(C^2H^5)SO^5$. (Limpricht and Uslar, *loc. cit.*)—Produced in the form of an ammonium-salt, by dissolving sulphobenzoic chloride in alcoholic ammonia, or by dissolving sulphobenzoic ether in alcohol, and passing ammonia through the solution. On evaporating the liquid, the ammonium-salt is obtained in crystals; and by dissolving these in water, precipitating the ammonia with platinic chloride, removing the excess of platinum by sulphuretted hydrogen, and evaporating the filtrate at the heat of the water-bath, ethylsulphobenzoic acid is obtained, in the form of a yellowish syrup, which does not show any signs of crystallisation, even after standing for several days. The acid appears, however, to be crystallisable, but difficult to obtain in the crystalline form, on account of its proneness to decomposition; for on decomposing the barium-salt with an equivalent quantity of sulphuric acid, and evaporating the filtrate over the water-bath, a syrup was obtained, which solidified in a crystalline mass on cooling, but on being saturated with barium-carbonate, yielded a mixture of sulphobenzoate and ethylsulphobenzoate of barium.

The *Ethylsulphobenzoates* are all very soluble: they are most readily prepared from the ammonium-salt by precipitating the ammonia with platinic chloride, removing the excess of platinum with sulphydric acid, and neutralising the filtrate with the required base.—The *ammonium-salt*, $C^9H^9(NH^4)SO^5$, crystallises in large, well-defined, four-sided tables, with very distinct cleavage parallel to the shorter side of the base. It is insoluble in ether, but dissolves readily in water and in alcohol, forming neutral solutions.—The *barium-salt*, $C^{18}H^{18}Ba''S^2O^{10}.xH^2O$, crystallises from a very concentrated aqueous solution, in small rhombic tables, which effloresce over oil of vitriol.—The *silver-salt* forms stellate groups of small needles.—The *sodium-salt*, $C^9H^9NaSO^5$, forms nodular groups of milk-white needles, easily soluble in water and in alcohol.

SULPHOBENZOL. C^7H^6S. Syn. with SULPHIDE OF BENZYLENE (i. 577).

SULPHOBENZOLAMIDE. $C^6H^7NSO^2 = N.H^2.C^6H^5SO^2$. (Stenhouse, Proc. Roy. Soc. xiv. 351.)—Produced by heating sulphobenzolate (phenylsulphite) of ammonium to 200°. Crystallises from alcohol or water in laminæ resembling naphthalene, which melt at 153°.

SULPHOBENZOLENE. $C^6H^{10}SO^2$. (Stenhouse, *loc. cit.*)—A compound isomeric with sulphobenzide (p. 486), produced by heating phenylic sulphide (iv. 417) with strong nitric acid, or more readily by digesting it with acid potassium-chromate and sulphuric acid diluted with 2 pts. of water. When crystallised from benzol, it forms monoclinic prisms, exhibiting the combination $[\infty P\infty] . \infty P\infty . Pn . oP$, with the angles (approximately determined) $[\infty P\infty] : \infty P\infty = 85° 30'$ and $94° 30'$; $[\infty P\infty] : Pn = 71° 40'$; $\infty P\infty : oP = 69° 40'$. The crystals are tabular, from predominance of $[\infty P\infty]$. From hot alcohol it separates in crystals, resembling chlorate of potassium, but for the most part of the same form and with the same angles as from benzol. It dissolves easily in ether and in carbonic disulphide, but with difficulty in boiling water, from which it crystallises completely on cooling. It melts at 126°, and distils at a higher temperature. It dissolves in hot sulphuric acid, and is precipitated therefrom by water. A mixture of nitric and sulphuric acids converts it into an oxidation-product, sparingly soluble in hot alcohol, and crystallising in needles.

SULPHOBENZOLENIC ACID. Syn. with BENZYLSULPHUROUS ACID. (See SULPHUROUS ETHERS.)

SULPHOBENZOLIC ACID. Syn. with PHENYLSULPHUROUS ACID. (See SULPHUROUS ETHERS.)

Disulphobenzolic Acid. Syn. with PHENYLENE-SULPHUROUS ACID. (See SULPHUROUS ETHERS.)

SULPHOBENZOLIC CHLORIDE. Syn. with SULPHOPHENYLIC CHLORIDE.

SULPHOBENZOYL, HYDRIDE OF. C^7H^6S. A compound formed by the action of ammonium-sulphide on an alcoholic solution of bitter-almond oil (i. 571).

SULPHOBUTYLIC ACID. Syn. with TETRYLSULPHURIC ACID. (See SULPHURIC ETHERS.)

SULPHOCACODYLIC ACID. See ARSENIDES OF METHYL (i. 409).

SULPHOCAMPHIC ACID. Syn. with THYMYLSULPHUROUS ACID. (See SULPHUROUS ETHERS.)

SULPHOCAMPHORIC ACID. $C^9H^{16}SO^6$. (Walter, Ann. Ch. Phys. [3], ix. 177.)—An acid produced by the action of sulphuric acid on camphoric anhydride (i. 730):

$$C^{10}H^{14}O^3 + H^2SO^4 = C^9H^{16}SO^6 + CO.$$

To prepare it, camphoric anhydride is introduced by small portions into an excess of strong sulphuric acid, and the clear solution is heated to 65°. Carbonic oxide is then rapidly evolved, and the liquid, after being left at rest to deposit unaltered camphoric anhydride, then filtered and left to evaporate in a vacuum, deposits crystals of sulphocamphoric acid, sometimes having a green colour. For purification they are left to drain in a funnel plugged with asbestos, then pressed between bibulous paper, and crystallised several times from alcohol till they become colourless.

Sulphocamphoric acid crystallises in six-sided prisms, colourless, very bitter, very soluble in water, alcohol, and ether. The crystals contain 2 at. water, which they give off in a vacuum. The acid melts between 160° and 165°, and decomposes at a higher temperature. It dissolves slowly in cold, quickly in boiling nitric acid, without alteration or evolution of red fumes. Strong sulphuric acid dissolves and ultimately chars it.

Sulphocamphoric acid is dibasic, its neutral salts being represented by the formula $C^9H^{14}M^2SO^6$.—The *ammonium-salt*, $C^9H^{14}(NH^4)^2SO^6.H^2O$, forms stellate groups of crystals, which are very soluble in water, and redden litmus.—The *potassium-salt*, $C^9H^{14}K^2SO^6$, crystallises by evaporation in very fine needles, having a cooling styptic taste. It is neutral to test-papers, very soluble in water, slightly soluble in alcohol. Sometimes cauliflower-heads of crystals are obtained, apparently consisting of an acid salt.—The *barium-salt*, $C^9H^{14}Ba''SO^6$, forms a colourless or slightly yellow gummy mass, which faintly reddens litmus-paper, is very soluble in water, slightly soluble in alcohol.—A *bario-cupric salt*, $C^{18}H^{28}Ba''Cu''S^2O^{12}$, is obtained by precipitating a cold solution of the barium-salt with cupric sulphate.—The *lead-salt*, $C^9H^{14}Pb''SO^6$, is an amorphous mass, having a sweet taste, soluble in water, insoluble in alcohol, reddening litmus-paper.—The *silver-salt*, $C^9H^{14}Ag^2SO^6$, is obtained, by saturating the acid with silver-oxide and evaporating, in crystalline crusts, soluble in water, slightly soluble in cold, somewhat more in hot alcohol: this salt likewise reddens litmus.

SULPHOCAPRYLIC ACID. Syn. with OCTYLSULPHURIC ACID. (See SULPHURIC ETHERS.)

SULPHOCARBAMIC ACID. $CH^3NS^2 = \left.\begin{matrix}H^2\\(CS)''\\H\end{matrix}\right\}\begin{matrix}N\\S.\end{matrix}$ (Zeise, Ann. Ch. Pharm. xlviii. 95.—Debus, *ibid.* lxxiii. 26.)—The sulphur-analogue of carbamic acid (i. 749). Its ammonium-salt, $CH^2(NH^4)NS^2$, is produced:—1. By direct combination of ammonia with carbonic disulphide: $CS^2 + 2NH^3 = CH^6N^2S^2$. When a mixture of 1 vol. absolute alcohol saturated with ammonia-gas and a solution of 0·16 vol. carbonic disulphide in 0·4 vol. alcohol, is exposed in a closed flask to a temperature of 15°, it gradually turns brown, and deposits plumose crystals of ammonium-trisulphocarbonate, afterwards larger and more shining prismatic crystals of the sulphocarbamate. The liquid, after it has ceased to deposit crystals, yields a further quantity of the sulphocarbamate by distillation.

2. By the decomposition of ammonium-trisulphocarbonate:

$$\left.\begin{matrix}(CS)''\\(NH^4)^2\end{matrix}\right\}S^2 = \left.\begin{matrix}H^2\\(CS)''\\NH^4\end{matrix}\right\}\begin{matrix}N\\S\end{matrix} + H^2S.$$

To effect this transformation, the trisulphocarbonate is enclosed for 30 or 40 hours with alcohol in a well-closed flask.

Sulphocarbamic acid is obtained in the free state by decomposing the ammonium-salt with dilute sulphuric or hydrochloric acid. It then separates as a colourless or reddish oil, heavier than water, and having a peculiar odour, somewhat like that of sulphydric acid. It is somewhat unstable, being gradually resolved into sulphocyanic and sulphydric acids; in presence of water, it also yields cyanic acid or its products of decomposition:

$$\underset{\text{Sulphocarbamic acid.}}{CH^3NS^2} = \underset{\text{Sulphocyanic acid.}}{CHNS} + H^2S.$$

$$CH^3NS^2 + H^2O = \underset{\text{Cyanic acid.}}{CHNO} + 2H^2S.$$

Metallic Sulphocarbamates.—Sulphocarbamic acid is monobasic; it decomposes carbonates with effervescence. Its salts are easily resolved, especially by heat or by the action of alkalis, into sulphydric acid, sulphocyanic acid, and motallic sulphide:

$$\underset{\text{Sulphocarbamate.}}{2H^2(CS)''MSN} = \underset{\text{Sulphocyanic acid.}}{2(CS)'HN} + H^2S + M^2S.$$

Sulphocarbamate of Ammonium, $CH^2(NH^4N)S^2$, crystallises in long lemon-yellow prisms, easily soluble in water, less soluble in alcohol. Exposed to moist air it deliquesces, and is converted into a liquid, consisting almost entirely of ammonium-sulphydrate. Heated with *potash*, it yields sulphocyanate and sulphide of potassium, together with water and ammonia. *Chlorine*, *bromine*, and *iodine* convert it into hydranzotin or sulphocarbammonium-sulphide (iii. 178):

$$2CH^2(NH^4)NS^2 + Cl^2 = 2NH^4Cl + C^2H^4N^2S^4.$$

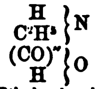
Ammonium-sulphocarbamate. Hydranzotin.

The same transformation is effected by ferric salts mixed with excess of sulphuric or hydrochloric acid.

Cuprous Sulphocarbamate, $CH^2Cu'NS^2$, is a yellow powder, insoluble in water and in alcohol.—The *lead-salt*, $C^2H^4Pb''N^2S^4$, is precipitated by neutral lead-acetate from the solution of the ammonium-salt, in white flocks, which turn red on drying and blacken when boiled with water.—The *zinc-salt*, $C^2H^4Zn''N^2S^4$, is a white pulverulent precipitate.

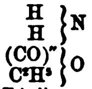
A solution of ammonium-sulphocarbamate is not precipitated by calcium- or barium-salts. It forms a yellowish-green precipitate with *nickel-sulphate*, white with *mercuric chloride*, yellowish-brown with *platinic chloride*; with a dilute solution of *silver-nitrate* a yellow precipitate, which soon turns black. A mixture of the concentrated solutions of ammonium-sulphocarbamate and *chromic sulphate* deposits, after a while, a small quantity of colourless needles containing chromium and sulphur; and the mother-liquor, after some hours, deposits a blue substance.

SULPHOCARBAMIC ETHERS. Sulphocarbamic acid, like other amic acids, may give rise to two isomeric groups of ethers, according as an atom of hydrogen belonging to the ammonia-type or to the water-type in the formula, $\begin{matrix}\left.\begin{matrix}H\\H\end{matrix}\right\}N\\\left.\begin{matrix}(CS)''\\H\end{matrix}\right\}S\end{matrix}$, is replaced by an alcohol-radicle, the relation between the two groups being the same as that which exists between ethylcarbamic acid and ethylic carbamate (i. 750, 751):



$$\begin{matrix}\left.\begin{matrix}H\\C^2H^5\end{matrix}\right\}N\\\left.\begin{matrix}(CO)''\\H\end{matrix}\right\}O\end{matrix}$$

Ethylcarbamic acid.



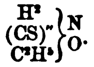
$$\begin{matrix}\left.\begin{matrix}H\\H\end{matrix}\right\}N\\\left.\begin{matrix}(CO)''\\C^2H^5\end{matrix}\right\}O\end{matrix}$$

Ethylic carbamate.

To the first-mentioned group of sulphocarbamic ethers belong amylsulphocarbamic acid, $\left.\begin{matrix}C^5H^{11}.H\\(CS)''\\H\end{matrix}\right\}\begin{matrix}N\\S\end{matrix}$, and its amylammonium-salt, $\left.\begin{matrix}C^5H^{11}.H\\(CS)''\\NH^3(C^5H^{11})\end{matrix}\right\}\begin{matrix}N\\S\end{matrix}$, the latter being produced by the action of amylamine on carbonic disulphide, and the amylcarbamic acid separated from it by hydrochloric acid (see AMYLAMINES, i. 207); also allyl-sulphocarbamic or sulphosinapic acid (*q.v.*).

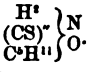
Ethers derived from sulphocarbamic acid, CH^3NS^2, by the substitution of an alcohol-radicle for the hydrogen of the water-type have not yet been obtained; but two compounds are known, which may be derived in this manner from the unknown oxysulphocarbamic acid, CH^3NSO, viz.:

Ethylic Oxysulphocarbamate or Xanthamide . . . C^3H^7NSO =



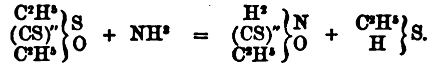
$$\left.\begin{matrix}H^2\\(CS)''\\C^2H^5\end{matrix}\right\}\begin{matrix}N\\O.\end{matrix}$$

Amylic Oxysulphocarbamate or Xanthamylamide . . $C^6H^{13}NSO$ =



$$\left.\begin{matrix}H^2\\(CS)''\\C^5H^{11}\end{matrix}\right\}\begin{matrix}N\\O.\end{matrix}$$

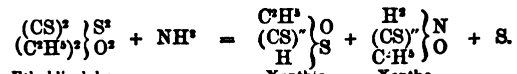
Ethylic Oxysulphocarbamate or **Xanthamide,** C^3H^7NSO. (Debus, Ann. Ch. Pharm. lxxii. 1; lxxv. 127; lxxxii. 253.)—This compound is produced:—1. By the action of ammonia on neutral ethylic disulphocarbonate (xanthic ether):



$$\left.\begin{matrix}C^2H^5\\(CS)''\\C^2H^5\end{matrix}\right\}\begin{matrix}S\\O\end{matrix} + NH^3 = \left.\begin{matrix}H^2\\(CS)''\\C^2H^5\end{matrix}\right\}\begin{matrix}N\\O\end{matrix} + \left.\begin{matrix}C^2H^5\\H\end{matrix}\right\}S.$$

Xanthic ether. Xanthamide. Mercaptan.

2. By the action of ammonia on ethyldisulphocarbonic sulphide (p. 495):



$$\left.\begin{matrix}(CS)^2\\(C^2H^5)^2\end{matrix}\right\}\begin{matrix}S^2\\O^2\end{matrix} + NH^3 = \left.\begin{matrix}C^2H^5\\(CS)''\\H\end{matrix}\right\}\begin{matrix}O\\S\end{matrix} + \left.\begin{matrix}H^2\\(CS)''\\C^2H^5\end{matrix}\right\}\begin{matrix}N\\O\end{matrix} + S.$$

Ethyldisulphocarbonic sulphide. Xanthic acid. Xanthamide.

To prepare the compound in considerable quantity, Debus gradually adds carbonic disulphide to an alcoholic solution of potash till the liquid is completely neutral, then dilutes it with two volumes of water, and passes chlorine into it. The chlorine decomposes the xanthate of potassium, forming chloride of potassium and ethyldisulphocarbonic sulphide, which, being insoluble in the dilute alcohol, falls to the bottom. As this compound is easily decomposed by an excess of chlorine, it is advisable to add to the liquid a small quantity of potassium-iodide, which will not be decomposed as long as there is any xanthate present, but will impart a brown colour to the liquid as soon as the whole of the xanthate is decomposed. The oily ethyldisulphocarbonic sulphide is then washed with water, dissolved in a mixture of 1 pt. ether and 2 pts. alcohol; and dry ammonia-gas is passed into the solution, whereby it gradually becomes turbid, and deposits long needles of sulphur. The filtered liquid, evaporated in a vacuum, leaves a saline residue, consisting of ammonium-xanthate and xanthamide, the latter of which may be dissolved out by ether, and remains, on evaporation, as a yellow oil, which ultimately crystallises, and may be obtained pure by recrystallisation from a small quantity of alcohol.

Xanthamide crystallises by spontaneous evaporation in monoclinic prisms or octahedrons, often of considerable size. Dominant faces, +P and −P with oP. Angle oP : −P = 118°; oP : +P = 105°. The plane angles of oP are nearly = 90°. Cleavage perfect, parallel to oP. The crystals melt at about 36°, dissolve sparingly in water, but are dissolved in all proportions by alcohol and ether.

Xanthamide is resolved by distillation into mercaptan and cyanic acid (or at 150°, cyanuric acid):

$$\underset{\text{Xanthamide.}}{CSO.C^2H^5.H^2N} = \underset{\text{Mercaptan.}}{C^2H^6S} + \underset{\text{Cyanic acid.}}{COHN.}$$

When boiled with *potash* or *baryta-water*, it is resolved into alcohol and sulphocyanic acid:

$$CSO.C^2H^5.H^2N = C^2H^6O + CSHN.$$

When *nitrous acid vapour* is passed into water containing xanthamide in suspension, a crystallisable substance is formed, designated by Debus as oxysulphocyanate of ethyl; its composition is approximately represented by the formula $C^6H^{10}N^4O^2S$, and it is probably formed by the union of 2 at. xanthamide, with elimination of hydrogen and sulphydric acid:

$$2C^3H^7NOS - H^2S - H^2 = C^6H^{10}N^2O^2S.$$

Compounds of Xanthamide with Metallic Salts.—α. With *cuprous chloride*, xanthamide forms four compounds, containing 1, 2, 3, and 4 at. xanthamide to 1 at. CuCl.

The compound $C^3H^7NOS.CuCl$, is obtained as a white crystalline precipitate, on adding hydrochloric acid to an aqueous solution of xanthamide mixed with excess of cupric sulphate. It is nearly insoluble in water, but dissolves in hot alcohol, and crystallises on cooling in small very brilliant rhombohedrons, approaching very closely to the cube. It is likewise formed on mixing an alcoholic solution of xanthamide with a neutral solution of cupric chloride. The liquid first becomes blood-red, then colourless, strongly acid, and deposits sulphur; and the filtrate yields, by spontaneous evaporation, first rhombohedral crystals of the compound $C^3H^7NOS.CuCl$, then long needles of the compound above mentioned as oxysulphocyanate of ethyl.

The compound $2C^3H^7NOS.CuCl$ is deposited, in shining rhombic tables, on adding rather more than 1 at. xanthamide to the preceding compound, and evaporating. It is insoluble in water, very soluble in alcohol, and appears to be dimorphous, inasmuch as a concentrated alcoholic solution deposits it in large hexagonal prisms, whereas from a dilute solution it separates in rhombic tables.

By increasing the proportion of xanthamide, the compounds $3C^3H^7NOS.CuCl$ and $4C^3H^7NOS.CuCl$ may be obtained, both in well-defined crystals. All these compounds are more fusible and more soluble in alcohol, as they contain a larger proportion of xanthamide. The crystals decompose after some weeks, sulphide of copper being set free.

β. With *Cuprous Iodide.*—A boiling alcoholic solution of the compound, $3C^3H^7NOS.CuCl$, mixed with a hot solution of iodide of potassium, deposits, after some hours, concentrically-grouped needles of the compound $2C^3H^7NOS.CuI$; the mother-liquor, on further concentration, yields laminæ of the compound $3C^3H^7NOS.CuI$; and the liquid finally deposits xanthamide and chloride of potassium.

γ. With *Cuprous Sulphocyanate.*—An alcoholic solution of the compound $2C^3H^7NOS.CuCl$, mixed with sulphocyanate of potassium, yields a white crystalline precipitate, which appears to consist of $C^3H^7NOS.10CyCuS$ (?). A hot concentrated solution of the compound $3C^3H^7NOS.CuCl$ yields, with sulphocyanate of potassium, an immediate precipitate, consisting of colourless tables of the compound $2C^3H^7NOS.3CyCuS$. If this compound be left immersed in the mother-liquor for some days, the crystals become larger, acquire a yellowish colour, and are converted into the compound $C^3H^7NOS.CyCuS$.

An alcoholic solution of the compound $C^3H^7NOS.CuCl$ yields with sulphocyanate of potassium, nothing but a white pulverulent precipitate of cuprous sulphocyanate.

δ. With *other Salts*.—The compound $3C^3H^7NOS.CuCl$ is decomposed at the boiling heat by zinc, which precipitates the copper and forms chloride of zinc; but this salt does not combine with the xanthamide, neither does xanthamide appear to unite with ferrous chloride, chloride of barium, or chloride of potassium. With *mercuric chloride*, however, it appears to be capable of forming, under certain circumstances, compounds similar to those which it yields with cuprous chloride.

Amylic Oxysulphocarbamate, Amylxanthamide, or **Xanthamylamide,** $C^6H^{13}NOS = CSO.C^5H^{11}.H^2N$.—This compound, discovered by M. W. Johnson (Chem. Soc. Qu. J. v. 242), and prepared similarly to the ethyl-compound, has been already described among the sulphur-compounds of amyl (i. 206).

SULPHOCARBAMIDE. $CH^4N^2S = \left.\begin{matrix}(CS)''\\H^2\\H^2\end{matrix}\right\}N^2$.—This compound has not yet been obtained. It contains the elements of sulphocyanate of ammonium, $CNS.NH^4$, but is not actually formed from that compound in the same manner as carbamide (urea) from cyanate of ammonium.

Several substitution-derivatives of sulphocarbamide are however known, and have been already described under CARBAMIDE (i. 754), viz.:

Allylsulphocarbamide	$N^2.(CS)''.C^3H^5.H^3$
Naphthyl-allylsulphocarbamide	$N^2.(CS)''.C^{10}H^7.C^3H^5.H^2$
Phenylsulphocarbamide	$N^2(CS)''.C^6H^5.H^3$
Diphenylsulphocarbamide	$N^2.(CS)''.(C^6H^5)^2.H^2$
Phenyl-allylsulphocarbamide	$N^2.(CS)''.C^6H^5.C^3H^5.H^2$.

These compounds are formed by the action of ammonia and alcoholic ammonia on sulphocyanic ethers; and compounds of analogous constitution, but having half the nitrogen replaced by phosphorus, are obtained by the action of triethylphosphine on the sulphocyanates of allyl and phenyl (iv. 611), *e.g.*:

$$\underset{\text{Triethyl-phosphine.}}{P(C^2H^5)^3} + \underset{\text{Phenylic sulphocyanate.}}{(CS)''(C^6H^5)N} = \underset{\text{Phenyl-triethyl-sulphocarbo-phosphamide.}}{\left.\begin{matrix}N\\P\end{matrix}\right\}(CS)''.C^6H^5.(C^2H^5)^3}.$$

SULPHOCARBIMIDE. $\left.\begin{matrix}(CS)''\\H\end{matrix}\right\}N$.—This is the compound more generally called sulphocyanic acid, and otherwise formulated as $\left.\begin{matrix}CN\\H\end{matrix}\right\}S''$. That this acid may really be regarded as the imide of sulphocarbonic acid is shown:—1. By its formation from sulphocarbamic acid, $(CS^2H^3N = CSHN + H^2S)$, and in the decomposition of sulphocarbamic ethers (p. 492).—2. By its formation when carbonic disulphide is heated in a sealed tube with alcoholic ammonia:

$$(CS)''S + NH^3 = \left.\begin{matrix}(CS)''\\H\end{matrix}\right\}N + H^2S;$$

and by the analogous formation of ethylic sulphocyanate, when ethylamine is substituted for ammonia in this reaction.

SULPHOCARBONATES. Carbonic disulphide, CS^2, unites directly with metallic sulphides, forming compounds called trisulphocarbonates, or simply sulphocarbonates, analogous to the carbonates, and represented by the general formula $M^2S.CS^2$ or M^2CS^3.

They are likewise produced, together with carbonates, by the action of carbonic disulphide on hydrated metallic oxides, *e.g.* with aqueous potash:

$$3CS^2 + 6KHO = 2K^2CS^3 + K^2CO^3 + 3H^2O$$

The sulphocarbonates of the alkali-metals and alkaline earth-metals are red, brown, or yellow compounds, soluble in water and in alcohol, and in some cases crystallisable. They are easily converted into carbonates, by boiling their aqueous solutions, water being decomposed and sulphydric acid evolved, *e.g.*:

$$K^2CS^3 + 3H^2O = 3H^2S + K^2CO^3.$$

A similar decomposition takes place slowly in the aqueous solution at ordinary temperatures.

By decomposing a metallic sulphocarbonate with hydrochloric acid, hydric sulphocarbonate, or sulphocarbonic acid, H^2CS^3, is obtained in the form of a yellow oily liquid, thus:

$$K^2CS^3 + 2HCl = 2KCl + H^2CS^3.$$

The sulphocarbonates of the heavy metals are insoluble in water, and are formed by precipitation. Solutions of the alkaline sulphocarbonates give a brown precipitate with cupric salts, yellow with dilute solutions of argentic nitrate and mercuric chloride, red with lead-salts. A solution of calcic sulphocarbonate forms, with auric chloride, a greyish-brown precipitate containing $Au^2S^3.3CS^2$; with platinic salts, a black-brown precipitate containing $PtS^2.2CS^2$. All these precipitates blacken more or less quickly when kept, owing to their conversion into sulphides.

For details respecting the metallic sulphocarbonates, see *Gmelin's Handbook* (vols. iii., iv., v., and vi.), under the several metals.

SULPHOCARBONIC ACID. This term belongs properly to the compound H^2CS^3, obtained as above; but it is sometimes applied to carbonic disulphide, CS^2, which should rather be called carbonic sulphanhydride.

SULPHOCARBONIC ETHERS. These are bodies having the composition of carbonic ethers (i. 799), in which the oxygen is replaced, wholly or partly, by sulphur. The following table exhibits their names and formulæ, the ethyl- and ethylene-compounds being taken as examples:

Ethyl-monosulphocarbonic acid	$CO^2S\left\{\begin{matrix}C^2H^5\\H\end{matrix}\right.$	=	$\left.\begin{matrix}C^2H^5\\(CO)''\\H\end{matrix}\right\}\begin{matrix}O\\S\end{matrix}$
Ethylic monosulphocarbonate	$CO^2S\left\{\begin{matrix}C^2H^5\\C^2H^5\end{matrix}\right.$	=	$\left.\begin{matrix}C^2H^5\\(CO)''\\C^2H^5\end{matrix}\right\}\begin{matrix}O\\S\end{matrix}$
Ethyl-disulphocarbonic acid	$COS^2\left\{\begin{matrix}C^2H^5\\H\end{matrix}\right.$	=	$\left.\begin{matrix}C^2H^5\\(CS)''\\H\end{matrix}\right\}\begin{matrix}O\\S\end{matrix}$
Ethylic disulphocarbonate	$COS^2\left\{\begin{matrix}C^2H^5\\C^2H^5\end{matrix}\right.$	=	$\left.\begin{matrix}C^2H^5\\(CS)''\\C^2H^5\end{matrix}\right\}\begin{matrix}O\\S\end{matrix}$
Ethyl-trisulphocarbonic acid	$CS^3\left\{\begin{matrix}C^2H^5\\H\end{matrix}\right.$	=	$\left.\begin{matrix}C^2H^5\\(CS)''\\H\end{matrix}\right\}\begin{matrix}S\\S\end{matrix}$
Ethylic trisulphocarbonate	$CS^3\left\{\begin{matrix}C^2H^5\\C^2H^5\end{matrix}\right.$	=	$\left.\begin{matrix}C^2H^5\\(CS)''\\C^2H^5\end{matrix}\right\}\begin{matrix}S\\S\end{matrix}$
Ethylenic disulphocarbonate	$COS^2.C^2H^4$	=	$\left.\begin{matrix}(CS)''\\(C^2H^4)''\end{matrix}\right\}\begin{matrix}O\\S\end{matrix}$
Ethylenic trisulphocarbonate	$CS^3.C^2H^4$	=	$\left.\begin{matrix}(CS)''\\(C^2H^4)''\end{matrix}\right\}S^2.$

It is not at present known with certainty whether the mono- and disulphocarbonic ethers contain the radicle CO or CS—whether, for example, ethyldisulphocarbonic acid should be regarded as $\left.\begin{matrix}C^2H^5\\(CS)''\\H\end{matrix}\right\}\begin{matrix}O\\S\end{matrix}$, or as $\left.\begin{matrix}C^2H^5\\(CO)''\\H\end{matrix}\right\}S^2$; but the formulæ above given are those which accord best with the principal reactions of these compounds.

Formation and Reactions.—*a.* The metallic salts of the acid sulphocarbonic ethers are produced in the same manner as those of the oxycarbonic ethers (i. 801): thus carbonic dioxide unites with sulphethylate (mercaptide) of potassium, to form ethyl-monosulphocarbonate of potassium, just as it unites with ethylate of potassium to form the ethyl-carbonate; and, in like manner, carbonic disulphide acts on ethylate of potassium or alcoholic potash, so as to form ethyl-disulphocarbonate of potassium; and on mercaptide of potassium, or an alcoholic solution of the sulphydrate, so as to form the ethyl-trisulphocarbonate, thus:

$CO^2 + (C^2H^5)KO = (C^2H^5)KCO^3.$ Ethyl-carbonate.
$CO^2 + (C^2H^5)KS = (C^2H^5)KCO^2S.$ Ethyl-monosulphocarbonate.
$CS^2 + (C^2H^5)KO = (C^2H^5)KCOS^2.$ Ethyl-disulphocarbonate.
$CS^2 + (C^2H^5)KS = (C^2H^5)KCS^3.$ Ethyl-trisulphocarbonate.

β. The neutral sulphocarbonic ethers (containing monatomic alcohol-radicles), are produced by the action of the chlorides, bromides, &c. of alcohol-radicles on the metallic salts of the corresponding acid ethers, *e.g.*:

$$\underset{\substack{\text{Potassic ethyl-}\\\text{trisulphocarbo-}\\\text{nate.}}}{(C^2H^5)KCS^3} + C^2H^5Cl = KCl + \underset{\substack{\text{Ethylic trisul-}\\\text{phocarbonate.}}}{(C^2H^5)^2CS^3.}$$

γ. The same **neutral ethers** are decomposed by hydrate or sulphydrate of potassium, especially in alcoholic solution, yielding a salt of an acid sulphocarbonic ether, together with alcohol or mercaptan; *e.g.:*

$$\begin{aligned}(C^2H^5)^2CO^2S + KHO &= (C^2H^5)HO + (C^2H^5)KCO^2S.\\(C^2H^5)^2CO^2S + KHS &= (C^2H^5)HS + (C^2H^5)KCO^2S.\\(C^2H^5)^2COS^2 + KHS &= (C^2H^5)HS + (C^2H^5)KCOS^2.\\(C^2H^5)^2COS^2 + KHO &= (C^2H^5)HS + (C^2H^5)KCO^2S.\end{aligned}$$

δ. Ethyldisulphocarbonic acid is resolved by heating (to 24°) into alcohol and carbonic disulphide:

$$(C^2H^5)HCOS^2 = (C^2H^5)HO + CS^2.$$

The decomposition of the free acid is therefore represented by an equation exactly similar to that by which its potassium-salt is formed: it is likewise analogous to that of ethylcarbonic acid (i. 801); but in the latter case the decomposition takes place spontaneously at ordinary temperatures, whereas ethyldisulphocarbonic acid may be separated in the free state from its salts, and decomposes only when heated.

ε. When iodine acts on a metallic salt of an acid sulphocarbonic ether (an ethylsulphocarbonate, for example) in alcoholic solution, peculiar compounds are formed, called **ethylsulphocarbonic sulphides**. A molecule of iodine acts on two molecules of the ethylsulphocarbonate, abstracting the two atoms of metal, while the residues of the two molecules of ethylsulphocarbonate remain united, forming ethylsulphocarbonic sulphide; *e.g.:*

$$\underset{\substack{\text{Potassic ethyl-}\\\text{disulphocarbonate.}}}{2(C^2H^5)KCOS^2} + I^2 = 2KI + \underset{\substack{\text{Ethyl-disulpho-}\\\text{carbonic sul-}\\\text{phide.}}}{(C^2H^5O)^2C^2S^4.}$$

$$\underset{\substack{\text{Potassic ethyl-mono-}\\\text{sulphocarbonate.}}}{2(C^2H^5)KCO^2S} + I^2 = 2KI + \underset{\substack{\text{Ethyl-monosul-}\\\text{phocarbonic}\\\text{sulphide.}}}{(C^2H^5S)^2C^2O^4.}$$

These bodies may be regarded as compounds of carbonic dioxide or disulphide with alcoholic peroxides and persulphides, just as the ordinary sulphocarbonic ethers may be regarded as compounds of carbonic dioxide or disulphide with alcoholic protoxides and protosulphides.

They are decomposed by heat, yielding a neutral sulphocarbonic ether, together with carbonic oxide, dioxide, or disulphide and free sulphur; *e.g.:*

$$\underset{\substack{\text{Ethyl-disul-}\\\text{phocarbonic}\\\text{sulphide.}}}{C^6H^{10}O^2S^4} = \underset{\substack{\text{Ethylic mono-}\\\text{sulphocarbo-}\\\text{nate.}}}{(C^2H^5)^2CO^2S} + CS^2 + S.$$

or:

$$\underset{\substack{\text{Ethyl-disulpho-}\\\text{carbonic sulphide.}}}{C^6H^{10}O^2S^4} = \underset{\substack{\text{Ethylic disul-}\\\text{phocarbonate.}}}{(C^2H^5)^2COS^2} + CO + S^2.$$

$$\underset{\substack{\text{Ethyl-mono-}\\\text{sulphocarbo-}\\\text{nic sulphide.}}}{C^6H^{10}O^4S^2} = \underset{\substack{\text{Ethylic mono-}\\\text{sulphocarbo-}\\\text{nate.}}}{(C^2H^5)^2CO^2S} + CO^2 + S.$$

They are also decomposed by hydrate or sulphydrate of potassium, sulphur being separated, and the potassium-salt of the corresponding acid sulphocarbonic ether being produced.

ζ. The **sulphocarbonic ethers of diatomic alcohol-radicles** are formed by the action of diatomic alcoholic bromides, iodides, &c., on sulphocarbonate of sodium; *e.g.:*

$$\left.\begin{matrix}(CS)''\\Na^2\end{matrix}\right\}S^2 + (C^2H^4)''Br^2 = 2NaBr + \left.\begin{matrix}(CS)''\\(C^2H^4)''\end{matrix}\right\}S^2.$$

These ethers are oxidised by fuming nitric acid, yielding diatomic sulphurous ethers; *e.g.:*

$$\underset{\substack{\text{Ethylenic}\\\text{disulpho-}\\\text{carbonate.}}}{\left.\begin{matrix}CS\\C^2H^4\end{matrix}\right\}\begin{matrix}O\\S\end{matrix}} + O^6 = \underset{\substack{\text{Ethylenic}\\\text{sulphite.}}}{\left.\begin{matrix}SO\\C^2H^4\end{matrix}\right\}O^2} + CO^2 + SO^2.$$

Sulphocarbonic Ethers containing Monatomic Alcohol-radicles.

α. Allyl-compounds.

Allyl-disulphocarbonic Acid, $C^4H^6OS^2 = \left.\begin{matrix}C^3H^5\\(CS)''\\H\end{matrix}\right\}\begin{matrix}O\\S\end{matrix}$.—The potassium-salt of this acid is obtained, in yellow needles, by treating allylic alcohol with potash and carbonic disulphide. (Hofmann and Cahours, i. 146.)

Allylic Trisulphocarbonate, $C^7H^{10}S^3 = \left.\begin{matrix}(CS)''\\(C^3H^5)^2\end{matrix}\right\}S^3$. (Hüsemann, Ann. Ch. Pharm. cxxvi. 269.)—Produced by the action of allylic iodide on sodium-trisulphocarbonate at ordinary temperatures, in the same manner as the corresponding ethyl-compound. It is a yellow oily liquid, having an extremely pungent and offensive odour; specific gravity = 0·943; boiling-point between 170° and 175°. It is converted by strong nitric acid into allylsulphurous acid, and by ammonia into sulphocyanate of ammonium and sulphydrate of allyl.

β. Amyl-compounds.

Amyl-disulphocarbonic or **Xanthamylic Acid,** $C^6H^{12}OS^2 = \left.\begin{matrix}C^5H^{11}\\(CS)''\\H\end{matrix}\right\}\begin{matrix}O\\S\end{matrix}$. (De Koninck, Bull. de l'Acad. de Bruxelles [2], ix. 546.—Erdmann, J. pr. Chem. xxxi. 1.—Balard, Ann. Ch. Phys. [3], xii. 307.—M. W. Johnson, Chem. Soc. Qu. J. v. 142.)—The potassium-salt of this acid is obtained by the action of carbonic disulphide on a solution of potash in amylic alcohol; and on treating this salt with hydrochloric acid, the xanthamylic acid separates as a colourless or pale-yellow oily liquid, having a very disagreeable pungent odour; it must be dried over chloride of calcium, to preserve it from decomposition. It reddens litmus strongly, burns with a very bright flame, colours the skin deep yellow, and appears to be somewhat heavier than water.

Amyldisulphocarbonate, or *Xanthamylate of Ammonium* (obtained in the preparation of xanthamylamide, p. 493), crystallises from alcohol and ether in colourless prisms, which may be sublimed by careful heating. It is decomposed by water, slowly also by exposure to the air, yielding, among other products, sulphocyanate of ammonium and a yellow oil.—The *potassium-salt,* $C^6H^{11}KOS^2$, prepared as above, solidifies to a magma of crystalline scales, having a pale-yellow colour and nacreous lustre. It dissolves in water, alcohol, and ether, and precipitates many metallic solutions.

The *cuprous salt* is obtained by precipitation with cupric sulphate, in lemon-yellow flocks.—The *lead-salt,* $C^{12}H^{22}Pb''O^2S^4$, is a yellowish-white precipitate, which blackens when boiled. On adding an alcoholic solution of lead-acetate to a strong solution of the ammonium-salt mixed with a large quantity of alcohol, and leaving the liquid to evaporate, xanthamylate of lead separates in small shining laminæ (Johnson).—The *mercurous salt,* obtained by precipitation with mercuric chloride, is white, and does not blacken on boiling.—The *silver-salt* is a white precipitate, which blackens on boiling and on exposure to light.

Amyl-disulphocarbonic Sulphide, $C^{12}H^{22}O^2S^4 = (C^5H^{11}O)^2C\,S^4 = (C^5H^{11}S)^2C^2O^2S^2$. *Amyldioxysulphocarbonate.* (M. W. Johnson, Chem. Soc. Qu. J. v. 142.)—Produced by the action of iodine on xanthamylates (p. 495). Hydrate of potassium is triturated in a mortar with amylic alcohol and carbonic disulphide, avoiding an excess of amylic alcohol; and the product, after being mixed with a little water, is treated with powdered iodine. The reaction takes place rapidly, and amyl-disulphocarbonic sulphide separates as a yellowish odorous oil, which must be washed, and then dried over chloride of calcium. It begins to boil at 187°, and decomposes, yielding, amongst other products, an oil having the composition of amylic disulphocarbonate. With ammonia it yields amyldisulphocarbonate (xanthamylate) of ammonium, amylic sulphocarbamate (xanthamylamide), and a deposit of sulphur:

$$C^{12}H^{22}O^2S^4 + NH^3 = \underset{\text{Xanthamy-lic acid.}}{C^6H^{12}OS^2} + \underset{\text{Xanthamyl-amide.}}{C^6H^{13}NOS} + S.$$

Amylic Disulphocarbonate, $C^{11}H^{22}OS^2 = \left.\begin{matrix}(CS)''\\(C^5H^{11})^2\end{matrix}\right\}\begin{matrix}O\\S\end{matrix}$. *Xanthamylic Ether.* (Desains, Ann. Ch. Phys. [2], xx. 505.)—Obtained by distilling the product of the action of iodine on xanthamylate of potassium. It is an amber-coloured oil, having a strong ethereal odour.

Methylamylic Disulphocarbonate, $(CH^3)(C^5H^{11})COS^2$, is obtained, according to Johnson, by distilling a mixture of amyldisulphocarbonate and methylsulphate of potassium. When digested with ammonia, it yields xanthamylamide.

Ethylamylic Disulphocarbonate, $(C^2H^5)(C^5H^{11})COS^2$, obtained in like manner, is a yellow oil.

Amylic Trisulphocarbonate, $C^{11}H^{22}S = \left.\begin{matrix}(CS)''\\(C^5H^{11})^2\end{matrix}\right\}S^2$. (Hüsemann, Ann. Ch. Pharm. cxxvi. 269).—Prepared, like the corresponding ethyl-compound (p. 500), by the action of amylic iodide in alcoholic solution on trisulphocarbonate of sodium. It is a yellowish oily liquid, having an unpleasant odour, insoluble in water, soluble in alcohol, ether, chloroform, and benzol. Specific gravity = 0·877. Boiling-point between 245° and 248°.

γ. *Cetyl-compound.*

Cetyldisulphocarbonic Acid, $C^{17}H^{34}OS^2 = (C^{16}H^{33})HCOS^2$. *Sulphocarbocetic Acid. Xanthocetic Acid.* (Desains and De la Provostaye, Ann. Ch. Phys. [3], vi. 494.)—Known only as a potassium-salt, $C^{17}H^{33}KOS^2$, which is prepared by adding pulverised potassium-hydrate to cetylic alcohol saturated with carbonic disulphide, and gently heating the pasty mass, which forms after some hours, with four times its volume of alcohol of 40°, keeping the temperature below the boiling-point. The solution on cooling deposits the salt in bulky flakes, which may be purified by successive washing with alcohol and ether. After drying in the air, it forms a very fine crystalline powder, having a faint odour, and unctuous to the touch; it is very hygroscopic, but is not wetted by water. When digested with hydrochloric acid it reproduces cetylic alcohol.

The alcoholic solution of the potassium-salt forms, with *mercuric chloride*, a white precipitate; with *acetate of lead* a white, and with *nitrate of silver* a yellow precipitate, both of which blacken rapidly; with *zinc-salts*, a white gelatinous precipitate.

δ. *Ethyl-compounds.*

Ethylmonosulphocarbonic Acid, $C^3H^6O^2S = (C^2H^5)HCO^2S$. (Debus, Ann. Ch. Pharm. lxxv. 130, 136, 142; lxxxii. 253.)—The potassium-salt of this acid is produced by the action of hydrate or sulphydrate of potassium on ethylic monosulphocarbonate, or of potash on ethylic disulphocarbonate (see equations, p. 495, γ). Chancel prepares it by passing carbonic anhydride into an alcoholic solution of potassic mercaptide:

$$C^2H^5KS + CO^2 = (C^2H^5)KCO^2S.$$

Ethylsulphocarbonate of potassium crystallises in long needles or shining colourless prisms, apparently isomorphous with xanthate of potassium. It is very soluble in water, but not deliquescent. Its aqueous solution decomposes gradually at ordinary temperatures, and instantly at the boiling heat, yielding ethylic carbonate, sulphide and sulphydrate, together with alcohol.

Ethylmonosulphocarbonic Sulphide, $C^6H^{10}O^4S^2 = (C^2H^5O)^2.2COS = (C^2H^5S)^2.2CO^2$. *Bicarbonate de bisulphure d'éthyle.* (Chancel, Compt. rend. xxxii. 644.)—Obtained by adding iodine to an alcoholic solution of potassic ethylmonosulphocarbonate (p. 495). It is a colourless, highly refractive oil, insoluble in water, very soluble in alcohol and ether, heavier than water; stains paper. It is decomposed by *alcoholic potash*, yielding ethylmonosulphocarbonate and sulphide of potassium, together with sulphur.—With *alcoholic ammonia*, it yields sulphur, sulphydrate, and carbonate of ammonium, together with crystals, probably consisting of ethylic carbamate (urethane).—When *ammonia-gas* is passed into its ethereal solution, crystals of sulphur are deposited, and the liquid retains in solution sulphide and allophanate of ethyl (i. 133):

$$2C^6H^{10}O^4S^2 + 4NH^3 = \underset{\substack{\text{Ethylic allo-}\\\text{phanate.}}}{2C^4H^8N^2O^3} + \underset{\substack{\text{Ethylic}\\\text{sulphide.}}}{C^4H^{10}S} + S^2 + H^2S + 2H^2O.$$

Ethylic Monosulphocarbonate, $C^5H^{10}O^2S = (C^2H^5)^2CO^2S$. (Debus, Ann. Ch. Pharm. lxxv. 136.)—Produced: 1. In small quantity by the action of ethylic chloride on ethylmonosulphocarbonate of potassium (see equations, p. 494, β).—2. In larger quantity by dry distillation of ethyldisulphocarbonic sulphide, obtained by the action of iodine on xanthate of potassium. The decomposition begins at 130°, and becomes violent at 170°; so that it becomes necessary to remove the source of heat, and leave the action to go on by itself. The first portion of the distillate thus obtained is a mixture of carbonic disulphide and ethylic monosulphocarbonate; the latter consists of ethylic disulphocarbonate, distilling at 200° (see equations, p. 494, ε). The monosulphocarbonate must be rectified till it boils constantly at 162°.

Ethylic monosulphocarbonate is a strongly refracting liquid, having a pleasant ethereal odour. Specific gravity = 1·032 at 1°. It is insoluble in water, but dissolves easily in alcohol and ether. Mixed with alcoholic *sulphydrate of potassium* and cooled to 0°, it deposits crystals of potassic ethylmonosulphocarbonate, while ethylic sulphydrate remains in solution; with alcoholic *potash*, the same products, together with alcohol and potassic carbonate (see equations, p. 495, γ). When saturated with ammonia-gas and concentrated, it yields yellow needles, mixed with a gelatinous substance.

Ethyldisulphocarbonic or **Xanthic Acid,** $C^3H^6OS^2 = (C^2H^5)HCOS^2$. (Zeise, Schw J. xxxvi. 1; xliii. 160; Pogg. Ann. xxxv. 457.—Couerbe, Ann. Ch. Phys. [2] lxi. 225.—Sacc, Ann. Ch. Pharm. li. 345.—Debus, *ibid.* lxxii. 1; lxxv. 121; lxxxii. 253.—Desains, Ann. Ch. Phys. [3] xx. 496.—Hlasiwetz, Ann. Ch. Pharm. cxxii. 87.)—The potassium-salt of this acid is produced by adding carbonic disulphide to alcoholic potash, or by the action of potassic sulphydrate on neutral ethylic disulphocarbonate (xanthic ether).

When fused hydrate of potassium is dissolved in half its weight of absolute alcohol, carbonic disulphide then slowly added till the liquid no longer exhibits an alkaline reaction, and the mixture cooled to 0°, xanthate of potassium separates in colourless needles, and an additional quantity may be obtained by evaporating the mother-liquor in a vacuum, after the excess of carbonic disulphide has been separated by water. To obtain the free acid, the potassium-salt is placed in a large cylindrical vessel, and treated with dilute sulphuric or hydrochloric acid; a milky liquid is then formed, from which the acid may be more completely separated by further addition of water.

Xanthic acid is a colourless oil, heavier than water, and insoluble therein; it has a strong odour, and its taste is acid, astringent, and bitter. It first reddens litmus, and then bleaches it. It is very inflammable, and gives off, in burning, the odour of sulphurous acid. It cannot be heated without decomposition, becoming turbid at 24°, then beginning to boil, and being resolved into alcohol and carbonic disulphide: $C^3H^6OS^2 = C^2H^6O + CS^2$. When exposed to the air, it becomes covered with a white crust. It expels carbonic acid from its alkaline salts.

The xanthates or ethyldisulphocarbonates, $\left.\begin{matrix}C^2H^5\\(CS)''\\M\end{matrix}\right\}\begin{matrix}O,\\S\end{matrix}$ are decomposed by distillation, yielding chiefly carbonic anhydride, sulphydric acid, carbonic disulphide, and a sulphuretted oil, and leaving a residue of metallic sulphide mixed with charcoal. The oil, called by Zeise *xanthogenöl*, appears to be a mixture of ethylic sulphide and sulphydrate with another sulphuretted body.

The xanthates of the alkali-metals are very soluble in water and in alcohol. The *ammonium-salt* is obtained by saturating the acid with ammonium-carbonate, or by decomposing the barium-salt with ammonium-sulphate.

Xanthate of Potassium, $(C^2H^5)KCOS^2$, is most easily prepared by adding to absolute alcohol an excess of very pure caustic potash and an excess of carbonic disulphide. The mixture immediately solidifies to a mass of interlaced silky needles, which must be washed on a filter with ether, then pressed between bibulous paper, and dried over oil of vitriol.

The salt crystallises in shining colourless prisms, which turn slightly yellow on exposure to the air. It is very soluble in water and alcohol, but insoluble in ether. Its aqueous solution decomposes when heated above 50°, yielding potassic trisulphocarbonate, alcohol, sulphydric acid, and carbonic anhydride:

$$2C^3H^5KOS^2 + 2H^2O = K^2CS^3 + 2C^2H^6O + H^2S + CO^2.$$

In the dry state, it may be heated to 200° without alteration; at higher temperatures, it gives off ethylic sulphydrate (mercaptan), sulphydric acid, water, and carbonic oxide, leaving a residue of potassic sulphide mixed with charcoal. The solution, heated with *potash*, is resolved into mercaptan and potassic ethylmonosulphocarbonate (p. 497). With *chlorine*, it yields chloride of potassium and a sulphuretted acid oil. With *iodine*, it yields ethyldisulphocarbonic sulphide, $C^6H^{10}O^2S^4$ (pp. 497, 499). Fuming nitric acid decomposes the xanthate with violence.

Xanthate of Sodium forms yellow needles.—The *barium-salt*, $C^6H^{10}Ba''O^2S^4.2H^2O$, forms very unstable laminæ, soluble in water.—The *calcium-salt* is a gummy mass.

The soluble xanthates form a white precipitate with lead-salts, yellow with cupric salts (hence the name of the acid), light-yellow with argentic and mercurous salts, the last-mentioned precipitate, however, quickly becoming brown and black.

The xanthates of the heavy metals may be obtained in the crystalline form, by decomposing a solution of sodium-ethylate in a large quantity of carbonic disulphide with the solid chlorides of the heavy metals, the mixture being kept at the boiling-point till the reaction is complete.

The liquid chlorides of antimony, arsenic, and tin, mixed with 3 pts. carbonic disulphide, are introduced into the solution of sodium-ethylate by a dropping apparatus, the action being moderated by cooling. The liquid is separated from the resulting chloride of sodium by pressure through fine linen, and the crystals obtained by its spontaneous evaporation are purified by recrystallisation from carbonic disulphide, and finally by rapid washing with ether. The antimony-, arsenic-, and iron-salts dissolve readily in carbonic disulphide, even in the cold; the chromium-, cobalt-, and nickel-salts on warming; the tin- and mercury-salts, which crystallise most quickly, require prolonged boiling to dissolve them. These salts are likewise soluble in ether and in alcohol. (Hlasiwetz.)

Xanthate of Antimony, $\left.\begin{matrix}(C^2H^5)^3\\ Sb'''\end{matrix}\right\}(COS^2)^3 = \left.\begin{matrix}(\overset{\prime\prime}{CS})^3\\ (C^2H^5)^3Sb'''\end{matrix}\right\}\begin{matrix}O^3\\ S^3\end{matrix}$, prepared as above with pentachloride of antimony, forms large, lemon-yellow, triclinic crystals, which behave like the following.—*Xanthate of Arsenic,* $(C^2H^5)^3As'''(COS^2)^3$, forms nearly colourless monoclinic tables, which melt easily, are decomposed by heat, leaving a residue of arsenious sulphide, and are decomposed by warm hydrochloric acid.—*Xanthate of Bismuth,* $(C^2H^5)^3Bi'''(COS^2)^3$, crystallises in shining golden-yellow laminæ and tables.—*Xanthate of Chromium,* $(C^2H^5)^3Cr'''(COS^2)^3$, forms shining dark-blue crystals, dissolving with violet-blue colour in carbonic disulphide.—*Xanthate of Cobalt,* $(C^2H^5)^2Co''(COS^2)^2$, forms large, well-defined, black crystals, dissolving in carbonic disulphide with dark grass-green colour. (Hlasiwetz.)

Copper-salts.—Xanthate of potassium, added to the solution of a cupric salt, forms at first a black-brown precipitate of *cupric xanthate,* which quickly changes into beautiful yellow flocks of *cuprous xanthate*. This salt is not sensibly attacked by sulphydric acid, but alkaline sulphides decompose it immediately. It is decomposed by hot hydrochloric and sulphuric acids, and strongly attacked by nitric acid. (Zeise.)

Ferric Xanthate, $(C^2H^5)^3Fe'''(COS^2)^3$, crystallises in very fine, regularly formed, monoclinic crystals, having a black colour, and dissolving in carbonic disulphide with brown-black colour. (Hlasiwetz.)

Xanthate of Lead, $(C^2H^5)^2Pb''(COS^2)^2$, prepared by adding carbonic disulphide and hydrate of lead to alcoholic potash, crystallises in colourless silky needles, very stable, insoluble in water and in ether, moderately soluble in boiling alcohol. It is slowly decomposed by sulphydric acid, immediately by sulphide of ammonium. Its solution is gradually decomposed by boiling, more quickly on addition of potash, depositing sulphide of lead. A solution of cupric sulphate poured on the crystals immediately transforms them into yellow cuprous xanthate. (Debus.)

Mercuric Xanthate, $(C^2H^5)^2Hg''(COS^2)^2$, prepared by the method of Hlasiwetz, crystallises in scales having a satiny lustre.—The *nickel-salt,* $(C^2H^5)^2Ni''(COS^2)^2$, crystallises in large, black, monoclinic tables, dissolving in carbonic disulphide with yellowish-green colour. (Hlasiwetz.)

Concentrated solutions of *silver-salts* form with soluble xanthates, a black precipitate; dilute solutions give a yellowish precipitate, which quickly blackens. (Zeise.)

Stannous Xanthate, $(C^2H^5)^2Sn''(COS^2)^2$, prepared, according to the method of Hlasiwetz, with stannic chloride, crystallises in shining golden-yellow laminæ and tables.

Ethyldisulphocarbonic Sulphide, $C^6H^{10}O^2S^4 = (C^2H^5O)^2.2CS^2$. *Aethyldioxysulphocarbonat.* (Desains, Ann. Ch. Phys. [3] xx. 469.—Debus, Ann. Ch. Pharm. lxxii.1; Jahresb. 1849, p. 419.)—Produced by the action of iodine on xanthates. If an alcoholic solution of potassic xanthate, exactly decolorised by iodine, be left to evaporate at a moderate temperature, this compound is deposited, after a few days, in lamellar crystals, which may be purified by washing with water. It may also be prepared from xanthate of lead.

Ethyldisulphocarbonic sulphide melts at the heat of the hand to a yellowish oil, insoluble in water, and having a very persistent but not unpleasant odour. It is very soluble in absolute alcohol and in ether. Its solution does not precipitate acetate of lead; when boiled with nitrate of silver, it gives a precipitate of sulphur. With mercuric chloride it forms a white precipitate, which blackens at 40°; and with platinic chloride, after a while, a brown pulverulent precipitate.

It is decomposed by heat, the decomposition commencing at about 130°, and two modes of decomposition going on simultaneously, viz.:

$$C^6H^{10}O^2S^4 = \underset{\substack{\text{Ethylic mono-}\\ \text{sulphocarbonate.}}}{C^5H^{10}O^2S} + CS^2 + S.$$

and

$$C^6H^{10}O^2S^4 = \underset{\substack{\text{Ethylic disul-}\\ \text{phocarbonate.}}}{C^5H^{10}OS^2} + CO + S^2.$$

With alcoholic *potash*, it yields a deposit of sulphur and a solution of potassic xanthate, carbonate, and sulphide:

$$C^6H^{10}O^2S^4 + 2K^2O = \underset{\text{Xanthate.}}{C^3H^5KOS^2} + \underset{\substack{\text{Ethyl-car-}\\ \text{bonate.}}}{C^3H^5KO^3} + K^2S + S.$$

$$\underset{\text{Ethyl-carbonate.}}{C^3H^5KO^3} + KHO = \underset{\text{Carbonate.}}{K^2CO^3} + \underset{\text{Alcohol.}}{C^2H^6O}.$$

With *sulphydrate of potassium*, it yields sulphur, a large quantity of sulphydric acid gas, and a solution of xanthate:

$$C^6H^{10}O^2S^4 + 2KHS = 2C^3H^5KOS^2 + H^2S + S.$$

Ammonia-gas passed into its alcoholic solution forms xanthate of ammonium and ethylic sulphocarbamate (xanthamide, p. 491):

$$C^6H^{10}O^2S^4 + NH^3 = \underset{\text{Xanthic acid.}}{C^3H^6OS^2} + \underset{\text{Xanthamide.}}{C^3H^7NOS} + S.$$

Hydrochloric acid may be distilled over ethyl-disulphocarbonic sulphide without decomposing it. *Sulphuric acid* attacks it in the cold, evolving sulphurous anhydride.

Potassium or *sodium* added to its ethereal solution mixed with a little alcohol unites rapidly with it, forming a xanthate (Drechsel, Zeitschr. f. Chem. 1865, p. 853):

$$(C^2H^5O)^2C^2S^4 + K^2 = 2(C^2H^5)KCOS^2.$$

Ethylic Disulphocarbonate or **Xanthate. Xanthic Ether.** $C^5H^{10}OS^2 = \left.\begin{matrix}C^2H^5\\(CS)''\\C^2H^5\end{matrix}\right\}\begin{matrix}O\\S\end{matrix}$. (Zeise, Ann. Ch. Pharm. lvi. 29.—Debus, *ibid.* lxxv. 121.)—Produced:—1. By the action of ethylic chloride on potassic xanthate.—2. By the dry distillation of ethyl-disulphocarbonic sulphide (p. 499). It has a pale-yellow colour, a sweetish taste, and a not very disagreeable odour; is neutral to test-paper, and has a specific gravity of 1·0703 at 18°. It boils at 200°; burns with difficulty, if not previously heated.

Xanthic ether is quite insoluble in water; *alcohol* and *ether* dissolve it in all proportions. It dissolves *iodine*, forming a brown liquid. Potassium attacks it but slightly, and only when heated. It is decomposed by strong *sulphuric acid*, and by a mixture of that acid with fuming *nitric acid*, forming oily products: it is not attacked by hydrochloric acid. Its alcoholic solution forms a white precipitate with *mercuric chloride.* It is not decomposed by mercuric oxide, or by protoxide or peroxide of lead, even when heated therewith. With an alcoholic solution of *hydrate* or *sulphydrate of potassium*, it yields mercaptan and ethylmono- or ethyl-disulphocarbonate of potassium.—When *ammonia-gas* is passed into its alcoholic solution, and the liquid then left to itself for a day, it yields a distillate of ethylic sulphide and ammonium-sulphydrate, and a residue of ethylic sulphocarbamate (xanthamide):

$$2C^5H^{10}OS^2 + 2NH^3 = H^2S + (C^2H^5)^2S + 2C^3H^7NOS.$$

Ethyl-methylic Disulphocarbonate, $C^4H^8OS^2 = (CH^3)(C^2H^5).COS^2$. (Chancel, Ann. Ch. Phys. [3] xxxv. 468.)—Obtained by distilling together 1 at. xanthate and 1 at. methylsulphate of potassium. It is a pale-yellow limpid liquid, having a specific gravity of 1·123 at 11°, a sweet taste, and a strong, ethereal, not unpleasant odour. It boils at 179°, and distils entirely without decomposition. Vapour-density = 4·652. It easily takes fire, and burns with the blue flame of sulphur, emitting large quantities of sulphurous anhydride. It is insoluble in water, but soluble in alcohol and ether. Ammonia converts it into xanthamide and methylic sulphydrate.

Ethyl-trisulphocarbonic Acid. $C^3H^6S^3 = (C^2H^5)HCS^3$. *Trisulphuretted Carbovinic Acid. Sulphoxanthic Acid.* (Chancel, Compt. rend. xxxii. 642.)—The potassium-salt of this acid, $C^3H^5KS^3$, is formed by the direct union of carbonic disulphide with sulphethylate (mercaptide) of potassium. It is a white salt, soluble in water and in alcohol; forms yellow precipitates with silver-, mercury-, and lead-salts; and with copper-salts a precipitate of a very brilliant scarlet colour, resembling mercuric iodide. These precipitates decompose quickly when heated, yielding metallic sulphides. The precipitate formed in a solution of cupric sulphate, is a cuprous salt, whose formation is accompanied by that of a persulphide, probably containing $C^6H^{10}S^6 = (C^2H^5S)^2.2CS^2$. The potassium-salt decomposes at 100° into pentasulphide of potassium, and an oil having the composition of allylic sulphide:

$$2C^3H^5KS^3 = K^2S^5 + (C^3H^5)^2S.$$

Ethylic Trisulphocarbonate. $C^5H^{10}S^3 = (C^2H^5)^2CS^3$. *Sulphocarbonate of Ethylic Sulphide.* (Schweitzer, J. pr. Chem. xxxii. 254.—Debus, Ann. Ch. Pharm. lxxv. 147.—Hüsemann, Göttinger Nachrichten, 1861, p. 275; Jahresb. 1861, p. 344.)—This ether is produced: 1. By the action of ethylic chloride or iodide on trisulphocarbonate of potassium. Vapour of ethylic chloride is passed into the red liquid precipitated on saturating an alcoholic solution of neutral potassic sulphide with carbonic disulphide; the liquid is then left at rest for a while, and the vapour again passed into it. Chloride of potassium is then gradually deposited, and on adding water to the decanted liquid, ethylic trisulphocarbonate separates as an oil, which may be purified from excess of carbonic disulphide by washing, rectification, and agitation with aqueous potash (Schweitzer).—2. Trisulphocarbonate of sodium is mixed in a long-necked flask provided with an upright condensing-tube, with an alcoholic solution of ethylic bromide or iodide. The mixture soon becomes heated to the boiling-point, and the reaction is complete in about a quarter of an hour. The ethylic trisulphocarbonate thus produced is separated from the alcoholic solution by water, then dried over chloride of calcium, and distilled till it exhibits a constant boiling-point. (Hüsemann.)

Ethylic trisulphocarbonate is a yellow oil, heavier than water, insoluble therein, very soluble in alcohol and in ether: it has a slightly alliaceous odour, and an agreeable saccharine taste, somewhat like that of anise. According to Schweitzer, it becomes red when heated, and boils between 237° and 240°. According to Hüsemann, it boils constantly at 240°. It burns with a blue flame. Alcoholic potash quickly decomposes it into trisulphocarbonate of potassium and sulphydrate of ethyl.

According to Berend (Ann. Ch. Pharm. cxxviii. 333), this ether unites directly with *bromine*, without evolution of hydrobromic acid, forming the compound $C^5H^{10}S^3Br^2$, which dissolves in ether, benzol, carbonic disulphide, and excess of bromine, and crystallises from the latter by slow evaporation in large six-sided prisms. It is decomposed by water, with formation of hydrobromic acid; potash also abstracts the bromine, reproducing the original ether. The bromine is also separated by strong nitric or sulphuric acid.

ε. *Methyl-compounds.*

Methyl-disulphocarbonic Acid. $(CH^3)HCOS^2$. *Xanthomethylic Acid.* (Dumas and Peligot, Ann. Ch. Pharm. [2] xxiv. 55.—Desains, *ibid.* [3] xx. 504.)—The *potassium-salt* of this acid, $(CH^3)KCOS^2$, obtained by adding carbonic disulphide to a solution of potash in wood-spirit, crystallises in silky fibres.—The *lead-salt* contains $(CH^3)^2Pb''C^2O^2S^4$.

The aqueous solution of the potassium-salt, treated with a solution of iodine in wood-spirit, deposits oily drops of methyl-disulphocarbonic sulphide, $C^4H^6O^2S^4 = (CH^3O)^2C^2S^4$:

$$2(CH^3)KCOS^2 + I^2 = 2KI + C^4H^6O^2S^4.$$

Methylic Disulphocarbonate, $C^3H^6OS^2 = (CH^3)^2COS^2$. *Xanthomethylic Ether.* (Cahours, Ann. Ch. Phys. [3], xix. 158.—Zeise, *ibid.* p. 123.)—When the mixture of potassic methyl-disulphocarbonate and iodine just mentioned is heated, the methyl-disulphocarbonic sulphide first formed is decomposed, sulphur and potassium-iodide being deposited, and carbonic oxide evolved; and on adding water to the mixture, methylic disulphocarbonate is deposited in the form of an oil:

$$C^4H^6O^2S^4 = (CH^3)^2COS^2 + CO + S^2.$$

This ether is a very mobile, slightly yellowish liquid, having a strong, persistent, slightly aromatic odour. It boils at 170°—172°. Specific gravity of the liquid = 1·143 at 15°; of the vapour, 4·266. With alcoholic potash, it yields methylic sulphydrate and carbonate of potassium.

Methylic Trisulphocarbonate, $(CH^3)^2CS^3$. (Cahours, Ann. Ch. Phys. [3], xix. 163.)—Obtained by distilling a mixture of the concentrated solutions of calcic methylsulphate and potassic trisulphocarbonate. It is a yellow liquid, having a strong pungent odour, nearly insoluble in water, but dissolved in all proportions by alcohol and ether. Boils at 200°—205°. Specific gravity = 1·159 at 18°. Vapour-density = 4·652. With *bromine* it forms red crystals, containing, according to Cahours, $C^3H^4Br^2S^3 = (CH^2Br)^2CS^3$; according to Berend, on the contrary (Ann. Ch. Pharm. cxxviii. 333), the methylic trisulphocarbonate unites directly with the bromine, without elimination of hydrogen.

Sulphocarbonic Ethers containing Diatomic Alcohol-radicles.

Amylenic Trisulphocarbonate, $\left.\begin{matrix}(CS)''\\(C^5H^{10})''\end{matrix}\right\}S^2$, obtained by the action of an alcoholic solution of amylenic bromide on trisulphocarbonate of sodium, is a somewhat viscid liquid, of more or less yellow-brown colour, and specific gravity = 1·073. (Hüsemann, Jahresb. 1862, p. 434.)

Ethylenic Trisulphocarbonate, $CS.C^2H^4.S^2$. (Hüsemann, Ann. Ch. Pharm.

cxxiii. 83; Jahresb. 1861, p. 651.)—Obtained by the action of alcoholic bromide of ethylene on trisulphocarbonate of sodium. It is but slightly soluble in alcohol, and separates, during the reaction, as a thick golden-yellow liquid; and by dissolving it in ether or ether-alcohol, and leaving the solution to evaporate, it is obtained in large, transparent, yellow crystals, which are combinations of a rhombic prism with a rhombic octahedron resting on the prismatic faces, and a macrodome. It has an unpleasant alliaceous odour, dissolves slowly in alcohol, better in ether-alcohol and in ether, very easily in carbonic disulphide, benzol, and chloroform. It melts at 56·5°, and when once fused, solidifies again but slowly. Specific gravity = 1·476.

Ethylenic trisulphocarbonate is converted by *ammonia* into sulphocyanate of ammonium and ethylenic sulphydrate:

$$\left.\begin{matrix}CS\\C^2H^4\end{matrix}\right\}S^2 + 2NH^3 = \left.\begin{matrix}CS\\NH^4\end{matrix}\right\}N + \left.\begin{matrix}C^2H^4\\H^2\end{matrix}\right\}S^2.$$

Heated with *sulphydrate of potassium*, it yields ethylenic sulphydrate and potassium-trisulphocarbonate. *Chlorine* acts strongly upon it, producing great heat, which causes the crystals to melt, and forming a dark-red, very fetid liquid. Moderately dilute *nitric acid* removes one-third of the sulphur, and converts the ether into ethylenic disulphocarbonate (*infra*); but fuming nitric acid heated with it as long as nitrous fumes are evolved, removes the whole of the carbon, as well as one-third of the sulphur, and converts it into ethylene-sulphurous acid, $\left.\begin{matrix}(S''O)^2\\(C^2H^4)''.H^2\end{matrix}\right\}O^4$ (Buckton and Hofmann's disulphetholic acid). See Sulphurous Ethers.

Ethylenic Disulphocarbonate or **Xanthate,** $\left.\begin{matrix}(CS)''\\(C^2H^4)''\end{matrix}\right\}\begin{matrix}O\\S\end{matrix}$. (Hüsemann, Ann. Ch. Pharm. cxxvi. 269.)—Ethylenic trisulphocarbonate, treated, as above mentioned, with moderately dilute nitric acid, yields this compound as a white crystalline mass, which, after pressure between paper, crystallises from alcohol in long thin rectangular tables. It distils in a stream of hydrogen, without decomposition; is insoluble in water, but dissolves easily in alcohol, ether, chloroform, and benzol; and separates from the last two liquids as an oil, which does not solidify till touched with the crystallised ether.

Methylenic Trisulphocarbonate, $CS.CH^2.S^2$. (Hüsemann, Ann. Ch. Pharm. cxxvi. 269; Jahresb. 1862, p. 433.)—This compound separates, on gently heating an alcoholic solution of methylenic iodide with trisulphocarbonate of sodium, as an amorphous, yellowish-white, inodorous powder, which is insoluble in water, and is converted by fuming nitric acid into methylene-sulphurous or disulphometholic acid, $(SO)^2.CH^2.H^2.O^4$.

Tritylenic or **Propylenic Trisulphocarbonate,** $CS.C^3H^6.S^2$, obtained in like manner with bromide of tritylene, is a thick brownish-yellow liquid, insoluble in water, and having an offensive odour. It has a specific gravity of 1·31 at 20°; cannot be distilled without decomposition, except in a stream of hydrogen; is converted, by moderately dilute nitric acid, into a light-yellow resinous mass; by the strong acid into tritylene-sulphurous (disulphopropolic) acid. (Hüsemann.)

Tetrylenic or **Butylenic Trisulphocarbonate,** $CS.C^4H^8.S^2$, obtained in like manner, is a more mobile liquid, having a somewhat yellowish-brown colour, and a specific gravity of 1·26 at 20°. (Hüsemann.)

SULPHOCARBOVINIC ACID. Syn. with Ethyl-disulphocarbonic or Xanthic Acid (p. 498).

SULPHOCETIC ACID. Syn. with Cetylsulphuric Acid. (See Sulphuric Ethers.)

SULPHOCHLOROBENZAMIDE. $C^7H^7ClN^2SO^3 = \left.\begin{matrix}(C^7H^3ClSO^3)''\\H^4\end{matrix}\right\}N^2 = \left.\begin{matrix}(C^7H^3ClO)''\\(SO)''\\H^4\end{matrix}\right\}\begin{matrix}N^2\\O\end{matrix}$. (R. Otto, Ann. Ch. Pharm. cxxiii. 216.)—An amide produced by the action of alcoholic ammonia on sulphochlorobenzoic chloride, $C^7H^3ClSO^3.Cl^2$. It forms yellowish crystalline grains, easily soluble in absolute alcohol and in ether.

SULPHOCHLOROBENZOIC ACID. $C^7H^5ClSO^5 = \left.\begin{matrix}(C^7H^3ClSO^3)''\\H^2\end{matrix}\right\}O^2 = \left.\begin{matrix}(C^7H^3ClO)''\\(SO)''\\H^2\end{matrix}\right\}O^3$—(Otto, *loc. cit.*)—Produced by treating monochlorobenzoic acid with phuric anhydride. The viscid mass is gently warmed with a little ordinary sulphuric acid, till, on diluting with water, only a small quantity of chlorobenzoic acid remains undecomposed. The dilute solution is neutralised with carbonate of lead, and the filtrate is evaporated; whereupon *sulphochlorobenzoate of lead*, $C^7H^3Pb''ClSO^5.3H^2O$, is at first deposited in concentric groups of silky needles, afterwards a granular mass, probably a mixture of the neutral and acid lead-salts.

Sulphochlorobenzoic acid, obtained by decomposing the lead-salt with sulphuretted hydrogen, is easily soluble in water, alcohol, and ether, and crystallises from the aqueous solution in long white hydrated needles.

The *neutral potassium-salt*, $C^7H^3K^2ClSO^5.3H^2O$, forms small needles, which dissolve readily in water and in alcohol, and give off their water at 120°.—The *acid salt*, $2C^7H^4KClSO^5.3H^2O$, crystallises from alcohol in concentric groups of needles, somewhat less soluble than the neutral salt.

The *neutral barium-salt*, $C^7H^3Ba''ClSO^5.2H^2O$, forms indistinct crusts; the *acid salt*, $C^{14}H^8Ba''Cl^2S^2O^{10}.4H^2O$, sometimes forms solid, well-developed, wavellitic crystals, sometimes granular crystals.

The *acid calcium-salt*, $C^{14}H^8Ca''Cl^2S^2O^{10}.3H^2O$, separates from hot dilute alcohol in large crystals resembling cupric sulphate.

Disulphochlorobenzoic Acid, $C^7H^5ClS^2O^8 = \left.\begin{array}{c}(C^7H^2ClO)''' \\ (SO)^2 \\ H^3\end{array}\right\}O^3$, is obtained, together with sulphochlorobenzoic acid, by heating the product of the action of sulphuric anhydride on chlorobenzoic acid for some time with ordinary sulphuric acid.

SULPHOCHOLEIC ACID. Syn. with Taurocholic Acid.

SULPHOCINNAMIC ACID. $C^9H^8SO^5 = \left.\begin{array}{c}(C^9H^6SO^3)'' \\ H^2\end{array}\right\}O^2 = \left.\begin{array}{c}(C^9H^6O)'' \\ (SO)'' \\ H^2\end{array}\right\}O^3.$

(Herzog, J. pr. Chem. xxix. 51.)—Obtained by mixing 1 pt. cinnamic acid with 8 to 12 pts. fuming sulphuric acid of specific gravity 1·92 to 1·87, saturating the diluted solution with carbonate of barium, decomposing the filtered liquid with basic acetate of lead, and treating the precipitate with sulphuretted hydrogen.

Sulphocinnamic acid remains, on evaporation in vacuo, as an amorphous slightly hygroscopic mass, very soluble in water and in alcohol. From its alcoholic solution it is deposited, by spontaneous evaporation, in elongated prisms containing $C^9H^8SO^5.3H^2O$. It precipitates the solutions of basic lead-acetate and mercurous nitrate, also that of barium-chloride after some time.

Sulphocinnamates.—Sulphocinnamic acid is dibasic, forming neutral salts, $C^9H^6M^2SO^5$, and acid salts, $C^9H^7MSO^5$, or, for diatomic metals, $C^{18}H^{14}M''S^2O^{10} = C^9H^6M''SO^5.C^9H^8SO^5$. The sulphocinnamates are for the most part very soluble in water. Those of the alkali-metals and alkaline earth-metals yield, when heated, a mixture of sulphate and sulphite, and after strong calcination, a residue from which acids eliminate sulphuretted hydrogen.

The *neutral barium-salt*, $C^9H^6Ba''SO^5.H^2O$, is nearly insoluble in water. When boiled with water acidulated with nitric acid, it deposits needles of the *acid salt*, $C^{18}H^{14}Ba''S^2O^{10}.2H^2O$. The latter is slightly soluble in water and in alcohol, permanent in the air at ordinary temperatures, but becomes dull and gives off its water at 100°. The crystals dissolve readily in dilute aqueous ammonia, and the solution, after a short time, deposits prisms, which give off water and ammonia on exposure to the air.

The *neutral potassium-salt*, $C^9H^6K^2SO^5$, obtained by double decomposition, is amorphous, and very soluble in water.—The *acid salt*, $C^9H^7KSO^5$, obtained by adding hydrochloric acid to the solution of the neutral salt, crystallises in agglomerated needles.

The *silver-salt*, $C^9H^6Ag^2SO^5$, is obtained by decomposing the barium-salt with silver-sulphate, and evaporating in a vacuum, as a grey amorphous shining crust, easily decomposed by heat.

SULPHOCUMENIC ACID. Syn. with Cumenyl-sulphurous Acid. (See Sulphurous Ethers.)

SULPHOCUMIDE. $(C^9H^{11})^2SO^2$.—This compound appears to be formed, together with cumenyl-sulphurous acid, when cumol is treated with fuming sulphuric acid, and separates, on dilution with water, as a solid body, insoluble in water, alcohol, ether, and benzol. (Beilstein and Kögler, Jahresb. 1865, p. 559.)

SULPHOCYANACETIC ACID. $C^3H^3NSO^2 = \left.\begin{array}{c}(C^2H^2O)'' \\ CN \\ H\end{array}\right\}\begin{array}{l}S \\ O.\end{array}$ Syn. with Thiocyanoglycollic Acid (*q. v.*).

SULPHOCYANIC ACID. CNHS = $\left.\begin{matrix}CN\\H\end{matrix}\right\}S$ = $\left.\begin{matrix}(CS)''\\H\end{matrix}\right\}N$. *Hydrosulphocyanic Acid. Sulphocyanhydric Acid. Sulphocarbimide.—Sulphuretted Chyazic Acid* (**Porrett**).—*Schwefelblausäure, Blutsäure, Andrazothionsäure* (**Grotthus**).—*Rhodanwasserstoffsäure* (**Berzelius**).

This acid, the sulphur-analogue of cyanic acid, was first observed by **Bucholz** in 1799 (*Beiträge zur Erweiterung und Berichtigung der Chemie*, i. 88), and by **Rink** (1804, A. Gehl. ii. 460), afterwards more distinctly recognised by **Porrett** (Phil. Trans. 1814, p. 527), determined as to its chemical constitution by **Berzelius** (Schw. J. xxxi. 42), and further examined by **Wöhler** (Gilb. Ann. lxix. 271), **Liebig** (Ann. Ch. Pharm. x. 9; xxvi. 174; xxxix. 199; l. 337; liii. 330), **Parnell** (*ibid.* xxxix. 178), **Völckel** (*ibid.* xliii. 80), and others. The metallic sulphocyanates have been analysed chiefly by **Claus** (J. pr. Chem. xv. 401) and **Meitzendorff** (Pogg. Ann. lvi. 63).

Occurrence.—Sulphocyanate of potassium or sodium occurs in very small quantity in the saliva of man, and of the sheep (**L. Gmelin**). Göbel found it in a human salivary calculus. The distilled waters of certain cruciferous plants (cochlearia, mustard, radish, &c.) give with ferric salts the characteristic reaction of sulphocyanic acid.

Formation.—Sulphocyanic acid and its salts are produced: 1. By the direct combination of cyanides with sulphur, just as cyanates are formed by the combination of cyanides with oxygen; *e.g.*, by the calcination of cyanide or ferrocyanide of potassium, &c. with sulphur, or by boiling a solution of potassic cyanide with sulphur; also by calcining azotised charcoal with potassic sulphate, or with a mixture of potassic carbonate and sulphur.

2. By the action of cyanogen-gas on monosulphides or persulphides. In the former case, a cyanide is also formed, just as the action of cyanogen on a protoxide gives rise to the formation of a cyanide and a cyanate:

$$CN + K^2S = CNK + CNKS.$$

In the case of a disulphide, the action is one of simple combination; with higher sulphides a separation of sulphur takes place; thus:

$$2CN + K^2S^2 = 2CNKS\ ;\ 2CN + K^2S^5 = 2CNKS + S^3.$$

3. By the reaction of certain cyanides with metallic persulphides; *e.g.*, mercuric cyanide and potassic trisulphide mixed in aqueous solution:

$$Hg''Cy^2 + K^2S^3 = 2CyKS + Hg''S.$$

A similar reaction is produced when Prussian-blue is boiled for a long time with potassic liver of sulphur; also when aqueous pentasulphide of potassium is mixed with hydrocyanic acid, sulphydric acid being then evolved and sulphur precipitated:

$$2HCy + K^2S^5 = 2CyKS + H^2S + S^3.$$

In like manner hydrocyanic acid, sulphur, and aqueous ammonia, to which a small quantity of ammonium-sulphydrate is added to facilitate the solution of the sulphur, yield sulphocyanate of ammonium:

$$HCy + NH^3 + S = Cy(NH^4)S.$$

A solution of hydrocyanic acid saturated with sulphydric acid, is converted, on exposure to the air, into sulphocyanic acid, in proportion as the hydrogen of the sulphydric acid is taken up by the oxygen of the air. Hence the contamination of Vauquelin's prussic acid (prepared by decomposing mercuric cyanide with sulphydric acid) with sulphocyanic acid.

4. By the action of carbonic disulphide on alcoholic ammonia, the two liquids being heated together in a sealed tube:

$$(CS)''S + NH^3 = (CS)''.H.N + H^2S.$$

5. By the decomposition of aqueous sulphocarbamic acid (p. 490):

$$\left.\begin{matrix}(CS)''\\H^3\end{matrix}\right\}\begin{matrix}N\\S\end{matrix} = \begin{matrix}(CS)''\\H\end{matrix}N + H^2S.$$

6. By the action of alkalis on ethylic sulphocarbamate (xanthamide, p. 491):

$$\left.\begin{matrix}H^2\\(CS)''\\C^2H^5\end{matrix}\right\}\begin{matrix}N\\O\end{matrix} = \left.\begin{matrix}(CS)''\\H\end{matrix}\right\}N + \left.\begin{matrix}C^2H^5\\H\end{matrix}\right\}O.$$

These last three reactions indicate that sulphocyanic acid has the constitution of sulphocarbimide (p. 493).

7. When animal substances are charred by heating with oil of vitriol, the residue,

on being subjected to a stronger heat, yields, amongst other products, sulphocyanate of ammonium. (O. Henry, J. Chim. méd. xxi. 301.)

8. Sulphocyanic acid is formed, together with carbamide (urea), by the action of sulphydric acid on ammonio-cupric fulminate. (Gladstone, Ann. Ch. Pharm. lxvi. 1):

$$\underset{\text{Ammonio-cupric fulminate.}}{(NH^4)^2Cu''C^4N^4O^4} + 3H^2S = \underset{\text{Carbamide.}}{2CN^2H^4O} + \underset{\text{Sulphocyanic acid.}}{2CNH\overset{\bullet}{S}} + 2H^2O + Cu''S.$$

9. Sulphocyanic acid is formed in certain decompositions of volatile oil of mustard (allyl-sulphocyanic ether).

Preparation.—Sulphocyanic acid, or hydric sulphocyanate, is separated from the metallic sulphocyanates by the action of stronger acids. It may be obtained in the anhydrous state by heating dry mercurous sulphocyanate in a stream of sulphydric or hydrochloric acid gas; and in aqueous solution by the same reaction, the mercurous cyanide being suspended in water,—or by decomposing the barium-salt with an exactly equivalent quantity of sulphuric acid.

Properties.—Anhydrous sulphocyanic acid is a colourless liquid, which crystallises at 12·5° in six-sided prisms. It boils at 85° (Artus), at 102·5° (Vogel), has a pungent odour like that of acetic acid, reddens litmus strongly, and has a very acid taste. The aqueous solution exhibits similar properties.

Decompositions.—1. The anhydrous acid is very unstable, and is quickly resolved into hydrocyanic and persulphocyanic acids (iv. 378):

$$3CSHN = CHN + C^2H^2N^2S^3.$$

The aqueous solution decomposes slowly in the cold, quickly when heated, partly into carbonic dioxide, carbonic disulphide, and ammonia:

$$2CSHN + 2H^2O = CO^2 + CS^2 + 2NH^3;$$

partly into carbonic dioxide, sulphydric acid, and ammonia:

$$CSHN + 2H^2O = CO^2 + H^2S + NH^3;$$

partly also in the same manner as the anhydrous acid, yielding a solution of hydrocyanic acid and a yellow precipitate of persulphocyanic acid. In consequence of this last decomposition, sulphocyanic acid acts poisonously, like hydrocyanic acid. All these reactions are accelerated by boiling the sulphocyanic acid with concentrated acids.

Sulphocyanic acid saturated with *sulphydric acid*, yields after a while carbonic disulphide and ammonia.—With *chlorine* and *nitric acid*, it yields a yellow precipitate of persulphocyanogen (iv. 380).—Gently heated with metallic *zinc*, it gives off sulphydric acid; more slowly with iron.

Metallic Sulphocyanates. *Sulphocyanides. Rhodanides.*—Sulphocyanic acid is monobasic, forming, with monatomic metals, salts represented by the general formula $\left.\begin{matrix}CN\\M\end{matrix}\right\}S$ or $\left.\begin{matrix}(CS)''\\M\end{matrix}\right\}N$. The sulphocyanates are for the most part soluble in water and in alcohol. They are decomposed by the stronger *acids*, with elimination of sulphocyanic acid, which then generally undergoes further decomposition. Cold dilute acids, however, exert this action only on sulphocyanates corresponding to sulphides which are decomposed by the same acids: thus they do not decompose the sulphocyanates of mercury, copper, and silver.—*Nitric acid* and *chlorine* decompose the solutions of sulphocyanates, precipitating persulphocyanogen. All sulphocyanates are decomposed by *heat*, more or less strong, into nitrogen, cyanogen, carbonic disulphide, and metallic sulphide. Calcined with *potassic hydrate*, they give off carbonate of ammonium.—Sulphocyanate of potassium ignited with metallic *iron*, yields sulphide of iron and cyanide of potassium.

Soluble sulphocyanates give, with a mixture of *cupric* and *ferrous sulphates*, a white precipitate of cuprous sulphocyanate insoluble in water; they also give white precipitates with *mercurous*, *argentic*, and *auric salts*.—With *ferric salts* they give no precipitate, but a blood-red coloration, or reddish-yellow in case of very great dilution. The reaction is extremely delicate. A piece of ordinary paper held over a solution of potassic sulphocyanate mixed with concentrated hydrochloric acid, becomes reddened by the action of the evolved sulphocyanic acid on the small quantity of iron-salt contained in it. The red colour of ferric sulphocyanate may be distinguished from that of other ferric salts by two characters: 1. It is not turned yellow by addition of hydrochloric acid, even in large quantity.—2. On immersing a piece of zinc in the liquid, sulphydric acid is given off, and may be detected by its power of blackening a strip of paper impregnated with solution of lead-acetate.

SULPHOCYANATE of ALUMINIUM is a gummy mass, the solution of which is decomposed by evaporation.

Sulphocyanate of Ammonium, $NH^4CNS = NH^4CyS$.—This salt is obtained:—1. By decomposing the cupric salt with sulphydrate of ammonium, and evaporating the filtrate.—2. By mixing hydrocyanic acid with polysulphide of ammonium (a solution of sulphur in sulphydrate of ammonium), and separating the resulting sulphocyanate of ammonium from precipitated sulphur by water or alcohol. (This mode of formation is employed as a test for hydrocyanic acid, ii. 219). The prussic acid, prepared by distilling 180 pts. potassic ferrocyanide with 90 pts. strong sulphuric acid and 40 pts. water, is digested with the sulphide of ammonium obtained by saturating 60 pts. aqueous ammonia of specific gravity 0·95 with sulphydric acid, adding 60 pts. more of the ammonia-solution and 60 pts. sulphur; the mixture is boiled till the whole of the ammonium-sulphide is decomposed with precipitation of sulphur; and the liquid is filtered and evaporated. The product amounts to 40—50 pts. of dry sulphocyanate of ammonium. (Liebig.)

3. By treating carbonic disulphide with excess of ammonia:

$$CS^2 + 4NH^3 = (NH^4)CSN + (NH^4)^2S.$$

A mixture of 1500 c.c. aqueous ammonia [of what strength?] and 200 c.c. carbonic disulphide and 1500 c.c. alcohol of 86 per cent. is distilled down to one-half, after standing for 24 hours; the residual liquid is evaporated to the crystallising-point: and the sulphocyanate thus obtained is purified by one recrystallisation. The alcoholic distillate, which contains a large quantity of ammonium-sulphide, may be used for a second and even a third preparation. (Millon, J. Pharm. [3], xxxviii. 401.)

For preparation on the large scale, Gélis has patented a similar process, in which, however, the use of alcohol is avoided, and the carbonic disulphide is made to act upon a mixture of concentrated ammonia and sulphide of ammonium, the materials being mixed in the cold, and a small quantity of fixed oil (amounting to 2 or 3 per cent. of the carbonic disulphide) added, to form an emulsion with the ammonia and facilitate the admixture. An ammoniacal solution of ammonium-sulphocarbonate is thus formed, which, after separation from the layer of oil which floats on its surface (to be used in a subsequent operation), is subjected to distillation. The sulphocarbonate of ammonium is thereby resolved into sulphocyanate of ammonium and sulphydric acid:

$$(NH^4)^2CS^3 = (NH^4)CNS + 2H^2S;$$

the former remaining in the retort, while the latter passes over, together with excess of ammonium-sulphide, and may be condensed in a receiver containing aqueous ammonia, thereby supplying material for future operations.—The sulphocyanate of ammonium thus obtained is easily converted into other sulphocyanates by distillation with fixed bases. (Rép. Chim. App. 1862, p. 146; see also Sulphocyanate of Potassium, p. 513.)

4. Together with mercaptan, by the action of alcoholic ammonia on ethylic trisulphocarbonate (Hüsemann):

$$(C^2H^5)^2CS^3 + 2NH^3 = (NH^4)CNS + 2C^2H^6S.$$

Sulphocyanate of ammonium crystallises in colourless deliquescent plates, which are very soluble in water and in alcohol, melt at 147°, and decompose at a higher temperature, giving off carbonic disulphide, sulphydric acid, and ammonia, and leaving a residue of melam, which is finally converted into hydromellone. According to Liebig's formula (iii. 865, 874):

$$\underset{\text{Sulphocyanate of ammonium.}}{8(NH^4)CNS} = 2CS^2 + 4H^2S + 5NH^3 + \underset{\text{Melam.}}{C^6N^{11}H^9}.$$

and

$$\underset{\text{Melam.}}{C^6N^{11}H^9} = 2NH^3 + \underset{\text{Hydromellone.}}{C^6N^9H^3}.$$

Sulphocyanate of Barium, $Ba''Cy^2S^2.2H^2O$, crystallises in long, shining, deliquescent needles, very soluble in water and alcohol, and containing 12·4 per cent. water, which they give off between 160° and 170°.—A compound of this salt with *mercuric cyanide*, $Ba''Cy^2S^2.Hg''Cy^2$, separates in small nacreous laminæ, from a warm solution of the component salts. (Böckmann, Ann. Ch. Pharm. xxii. 153.)

Sulphocyanate of Bismuth, $Bi'''Cy^3S^3$, is a yellow powder.

Sulphocyanate of Cadmium, $Cd''Cy^2S^2$, forms shining, colourless, anhydrous crystals, slightly soluble in water. Ammonia dissolves them, and the solution yields crystals of *cadmammonium-sulphocyanate*, $(N^2H^6Cd'')''Cy^2S^2$, which are decomposed by water.

Sulphocyanate of Calcium, $Ca''Cy^2S^2.3H^2O$, forms deliquescent needles, very soluble in water and in alcohol.—The compound $Ca''Cy^2S^2.Hg''Cy^2$, obtained like the corresponding barium-salt, forms shining white laminæ. (Böckmann.)

Chromic Sulphocyanate, $Cr'''Cy^3S^3$.—Chromic hydrate dissolves easily in dilute sulphocyanic acid, forming a greenish-violet solution, which dries up over oil of vitriol to a blackish-green, amorphous, deliquescent mass. (Clasen, J. pr. Chem. xcvi. 349.)

Chromo-diammonio-sulphocyanic Acid, $N^2CrH^7Cy^4S^4 = \left.\begin{matrix}[N^2(Cr'''H^3)]'' \\ H^2\end{matrix}\right\}(CyS)^4 = \left.\begin{matrix}Cy^4 \\ Cr''' \\ H^7\end{matrix}\right\}\begin{matrix}N^2 \\ S^4\end{matrix}$. (A. Reinecke, Ann. Ch. Pharm. cxxvi. 113.)—The *ammonium-salt* of this acid, $N^2CrH^{10}Cy^4S^4 = N^2CrH^6(NH^4)Cy^4S^4$, is obtained by gradually adding pulverised dichromate of potassium to fused sulphocyanate of ammonium, till the mass becomes solid. Ammonia is then given off, with strong intumescence; and on treating the product with hot water, filtering to separate an amorphous substance, and introducing lumps of sal-ammoniac into the filtrate, the ammoniacal compound above mentioned separates in small shining scales. Its formation may be represented by the equation:

$$8(NH^4)CyS + Cr^2O^3 = 2(N^2CrH^{10}.Cy^4S^4) + 2NH^3 + 3H^2O.$$

This compound dissolves with ruby-red colour in water, alcohol, and ether, and crystallises from water in small rhombic dodecahedrons resembling garnets. It bears, without decomposition, a heat of 120°, but decomposes at a red heat, leaving sulphide of chromium; and when heated with water, yields sulphocyanate of ammonium, sulphocyanate of chromium, and chromic oxide. It is easily decomposed also by dilute acids and alkalis—in the latter case, according to the equation:

$$2(N^2CrH^{10}.Cy^4S^4) + 8KHO = 8KCyS + 6NH^3 + Cr^2O^3 + 5H^2O.$$

The same compound appears to have been obtained by Morland (Chem. Soc. Qu. J. xiii. 252), who, however, assigned to it the formula, $Cr'''Cy^3S^3.(NH^4)^2O$.

The molecule, NH^4, in the salt just described, may be replaced by other metals. The *potassium-salt*, $\left.\begin{matrix}(N^2Cr'''H^3)'' \\ H \\ K\end{matrix}\right\}Cy^4S^4$, is obtained by treating the ammonium-salt with strong potash-ley, and recrystallising from hot water. It forms ruby-coloured laminæ or cubes, dissolves with deep ruby colour in water, alcohol, and ether, and decomposes like the ammonium-salt, when boiled with water, acids, and alkalis.—The *sodium-salt*, $N^2(Cr'''H^3)HNaCy^4S^4$, prepared in like manner, crystallises in unctuous scales.—The *mercuric salt*, $N^4(Cr'''H^3)^2H^2Hg''Cy^8S^8$, is obtained, by precipitation with mercuric chloride, as a flocculent rose-coloured precipitate, insoluble in water and in dilute acids. It decomposes above 150° into sulphide of mercury and sulphide of chromium, and by boiling with potash into ammonia, sulphocyanic acid, mercuric oxide, and chromic oxide.—The *cuprous salt*, $N^2(Cr'''H^3)HCuCy^4S^4$, is obtained, by treating the ammonium-salt with cupric sulphate and sulphurous acid, as a yellow pulverulent precipitate, decomposed by heat and by potash similarly to the mercuric salt.—The ammonium-salt forms, with *nitrate of silver*, a rose-coloured precipitate quite insoluble in water and in dilute acids; and with *lead-salts*, a yellowish-red precipitate soluble in boiling water.

The *hydrogen-salt*, or free acid, is obtained, by decomposing the mercuric salt suspended in water with sulphydric acid, as a deep red solution, which is decomposed by boiling, but dries up at low temperatures to a red amorphous mass. The solution has an acid reaction, decomposes carbonates, and acquires a still darker red colour when mixed with ferric chloride.

SULPHOCYANATE OF COBALT.—Recently precipitated cobaltous hydrate dissolves in aqueous sulphocyanic acid, forming a brown-red liquid, which turns blue on concentration, and finally leaves a crystalline yellowish-brown mass, very soluble in water and in alcohol, and forming a compound with ammonia.

SULPHOCYANATES OF COPPER.—The *cupric salt*, $Cu''Cy^2S^2$, is a black crystalline powder, obtained by precipitating a concentrated solution of a cupric salt with sulphocyanate of potassium, care being taken not to add the latter in excess. The precipitate is converted by washing into a cuprous salt, and is not formed in dilute solutions. It dissolves in ammonia, and the solution yields small needles of *cuprammonium-sulphocyanate*, $(N^2H^6Cu'')''Cy^2S^2$.

The *cuprous salt*, $Cu''CyS$, is precipitated as a white powder, on adding a solution of potassium-sulphocyanate to a mixture of cupric and ferrous sulphates. It is insoluble in water and in acids, which do not decompose it, but dissolves in ammonia, forming a crystalline compound.

SULPHOCYANATES OF GOLD.—On mixing the solutions of potassium-sulphocyanate and auric chloride, a flesh-coloured precipitate is formed, soluble in ammonia.

When a solution of auric chloride neutralised with acid potassium-carbonate, is added to a solution of potassium-sulphocyanate kept in excess, a bulky orange-red precipitate is formed, consisting of *potassio-auric sulphocyanate*, $\mathrm{KAu'''Cy^4S^4 = KCyS.Au'''Cy^3S^3}$. On heating the liquid, the precipitate dissolves, and partly separates on cooling in orange-red needles of unaltered composition: the greater part, however, remains in solution, and decomposes on evaporation, with reduction of metallic gold and evolution of sulphocyanic acid, so that, finally, chloride of potassium and potassio-aurous sulphocyanate crystallise out. The precipitate of potassio-auric sulphocyanate is decomposed by water, and dissolves in alcohol and in ether. The alcoholic solution, mixed with hydrochloric acid, deposits after a while copper-red needles; soda decolorises the solution, and separates a black-blue powder; ammonia causes the formation of white needles; ferric chloride colours the solution blood-red; other metallic salts form dark-coloured precipitates.—*Potassio-aurous sulphocyanate*, $\mathrm{KAu'Cy^2S^2}$, is most readily obtained by mixing a solution of potassium-sulphocyanate, warmed to 80°, with small quantities of neutral auric chloride, as long as the red precipitate disappears on stirring. The salt, separated by evaporation and purified by recrystallisation, forms long, straw-yellow, truncated prisms, which melt at 100°, and are resolved into sulphur, carbonic disulphide, metallic gold, and sulphocyanate of potassium. The aqueous solution, mixed with hydrochloric acid, sometimes deposits copper-red needles; it forms white precipitates with ammonia, ferric chloride, mercuric chloride, argentic nitrate, and neutral plumbic acetate; yellow-brown with cupric sulphate; black-brown with stannous chloride; black with mercurous nitrate.—It is coloured red by ferrous sulphate, with precipitation of gold; brown by sulphydric acid; it blackens slowly on exposure to light.—The precipitate formed by ammonia, $\mathrm{NH^3.AuCyS}$, gradually decomposes and turns black; hot water abstracts ammonia from it, leaving a green powder. (P. T. Cleve, Kongl. Vetenskap. Akad. Förhandlingar, xx. 233; Jahresb. 1855, p. 295.)

SULPHOCYANATES OF IRON.—The *ferrous salt* is soluble, of pale-green colour, and very unstable.

The *ferric salt* is blood-red, nearly black, deliquescent, soluble in water and in alcohol. The blood-red colour of this salt is produced whenever a sulphocyanate is mixed with a ferric salt. It is destroyed by alkalis which precipitate ferric oxide; also by many acids (*e.g.* phosphoric, arsenic, iodic, oxalic), even in small quantity; but restored by addition of a ferric salt; hydrochloric acid, even when concentrated, does not decolorise the liquid; nitric acid, on the other hand, decomposes the sulphocyanate, and destroys the colour (p. 505).

SULPHOCYANATES OF LEAD.—The *neutral salt*, $\mathrm{Pb''Cy^2S^2}$. is gradually deposited in opaque shining-yellow crystals, on mixing a solution of lead-acetate with sulphocyanate of potassium. The crystals are monoclinic, exhibiting the dominant combination, $+P\ .\ -3P.\ oP\ .\ \infty P2\ .\ +3P\infty$. Angle $\infty P2 : \infty P2$ (clinod.) = 120° 38′; $oP : \infty P2$ = 111° 31′; $oP : +P$ = 116° 55′; $oP : -3P$ = 119° 3′; $oP : 3P\infty$ = 87° 45′. Axes, $a : b : c = 0{\cdot}923 : 1{\cdot}1162 : 1$. Angle $b : c$ = 65° 20′. Specific gravity of crystals = 3·82. The salt is but slowly decomposed by sulphydric acid. It is insoluble in water, but boiling water converts it into a *basic salt*, $\mathrm{Pb''Cy^2S^2.Pb''H^2O^2}$. The latter is likewise obtained on mixing sulphocyanate of potassium with ammoniacal plumbic acetate, or with the basic acetate, as a white curdy precipitate, becoming yellowish and pulverulent when dry.

SULPHOCYANATE OF MAGNESIUM, $\mathrm{Mg''Cy^2S^2.4H^2O}$.—Confused crystals, very soluble in water and in alcohol. The compound $\mathrm{Mg''Cy^2S^2.Hg''Cy^2}$, prepared like the corresponding barium-salt, is a white crystalline powder. (Böckmann.)

SULPHOCYANATE OF MANGANESE.—Very soluble.

SULPHOCYANATES OF MERCURY.—The *mercurous salt*, $\mathrm{Hg'CyS}$, is a white precipitate, formed on mixing mercurous nitrate with sulphocyanate of potassium (Wöhler); according to Claus, the solutions should be very dilute. The dry precipitate swells up suddenly when heated, giving off nitrogen, carbonic disulphide, and vapour of mercury, and leaving a grey mass resembling graphite, which by calcination is converted into mellone. On account of this property, the salt is used for the preparation of the toys called "Pharaoh's serpents." It is resolved by boiling water into metallic mercury and mercuric sulphocyanate.

The *mercuric salt*, $\mathrm{Hg''Cy^2S^2}$, is obtained as a white precipitate, composed of anhydrous needles, on mixing mercuric chloride with sulphocyanate of potassium; it is very slightly soluble in water, moderately soluble in alcohol (Crookes). A solution of mercuric oxide in sulphocyanic acid yields, by evaporation, needles containing water (Berzelius).—An *oxysulphocyanate*, $\mathrm{Hg''Cy^2S^2.2Hg''O}$, is obtained, by adding ammonia to the solution of mercuric sulphocyanate, as a lemon-yellow powder, which decomposes quickly at 180°, and leaves mellone when calcined.

Mercuric sulphocyanate forms several double salts, which have been examined chiefly by Cleve (Kongl. Vetenskap. Akad. Förhandlingar, xxii. 9; J. pr. Chem. xci. 227). —The *cobalt-salt*, $\mathrm{Hg''Co''Cy^4S^4 = Hg''Cy^2S^2.Co''Cy^2S^2}$, is formed by direct union of its component salts, or by gradually adding mercuric cyanide to a solution of cobaltous sulphocyanate acidulated with sulphocyanic acid, separates in indigo-blue four-sided prisms, permanent in the air, slightly soluble in water and in dilute hydrochloric acid, easily in nitric acid. The same compound is sometimes also formed (together with the yellow salt, $\mathrm{Hg''Cy^2.Co''Cy^2S^2.4H^2O}$), on mixing mercuric cyanide with sulphocyanate of cobalt.—The *ferrous salt*, $\mathrm{Hg''Fe''Cy^4S^4}$, separates, from a mixture of mercuric sulphocyanate and ferrous chloride left for some time in a vacuum, as a brown crystalline powder, permanent in the air.—The *nickel-salt*, $\mathrm{Hg''Ni''Cy^4S^4.2H^2O}$, separates from a mixture of the component salts, in small sky-blue needles, which dissolve readily in hot water, and give off their water of crystallisation at 120°. *Zinc-mercuric sulphocyanate*, $\mathrm{Hg''Zn''Cy^4S^4}$, is formed, on mixing mercuric sulphocyanate with a zinc-salt, as a white precipitate, nearly insoluble in cold water. (Cleve.)

A *potassio-mercuric sulphocyanate*, $\mathrm{Hg''KCy^3S^3 = Hg''Cy^2S^2.KCyS}$, is prepared by triturating mercurous chloride with a strong solution of potassium-sulphocyanate. The liquid, filtered from the black magma thus produced, yields by evaporation a mixture of yellow tables, cubes, and octahedrons, easily separated by mechanical selection. The yellow tables, which constitute the potassio-mercuric sulphocyanate, are purified by crystallisation from boiling alcohol; whence the salt separates in radiate groups of white nacreous needles. It dissolves sparingly in cold, more easily in hot water; very easily in aqueous chloride of ammonium or potassium; easily in alcohol, especially at the boiling heat; also in ether. Ammonia added to the aqueous solution throws down the oxysulphocyanate above described. (Claus, J. pr. Chem. xv. 407.)

SULPHOCYANATE OF NICKEL is obtained, as a yellow crystalline powder, by evaporating the green solution of nickel-oxide in sulphocyanic acid. It dissolves in ammonia, forming a blue liquid, which yields blue efflorescent crystals, $\mathrm{(N^2H^6Ni')Cy^2S^2.2NH^3}$, decomposible by water.

SULPHOCYANATE OF PALLADIUM is easily soluble in water.

SULPHOCYANATES OF PLATINUM.—*Platinic sulphocyanate* does not appear to be known in the separate state.—The *platinous salt*, $\mathrm{Pt''Cy^2S^2}$, probably constitutes the red or brown non-crystalline substance obtained by decomposing one of the following double salts with chlorine or nitric acid; *e.g.*, with chlorine and sulphocyanate of potassium:

$$\mathrm{K^2Pt^{iv}Cy^6S^6 + 11Cl^2 + 16H^2O = Pt''Cy^2S^2 + 2KHSO^4 + 2H^2SO^4 + 22HCl + 4HCy.}$$

It is insoluble in water and in alcohol, is not attacked by potash, but is coloured yellow by ammonia. It gave by analysis 8·53 and 8·72 per cent. carbon, 9·92 nitrogen, 18·77 sulphur, 62·27 and 62·02 platinum, besides 0·39 and 1·5 hydrogen, the formula $\mathrm{PtCy^2S^2}$ requiring 7·64 carbon, 8·93 nitrogen, 20·38 sulphur, and 63·05 platinum.

Double Salts of the Platinum-sulphocyanates. (G. B. Buckton, Chem. Soc. Qu. J. vii. 22.)—The sulphocyanates of platinum form two series of double salts, called sulphocyanoplatinites and sulphocyanoplatinates, analogous to the chloroplatinites and chloroplatinates, and represented by the following general formulæ, M denoting a monatomic, and N a diatomic, metal:

$$\text{Sulphocyanoplatinites . . . } \left.\begin{matrix}\mathrm{M^2}\\ \mathrm{N''}\end{matrix}\right\}\mathrm{Pt''Cy^4S^4} = \left.\begin{matrix}\mathrm{2MCyS}\\ \mathrm{N''Cy^2S^2}\end{matrix}\right\}\mathrm{Pt''Cy^2S^2}.$$

$$\text{Sulphocyanoplatinates . . . } \left.\begin{matrix}\mathrm{M^2}\\ \mathrm{N''}\end{matrix}\right\}\mathrm{Pt^{iv}Cy^6S^6} = \left.\begin{matrix}\mathrm{2MCyS}\\ \mathrm{N''Cy^2S^2}\end{matrix}\right\}\mathrm{Pt^{iv}Cy^4S^4}.$$

The potassium-salts are formed by the action of potassic sulphocyanate on platinous and platinic chloride respectively. The salts of the alkali-metals and alkaline earth-metals are soluble in water; those of the heavy metals are insoluble, and are formed by double decomposition. All these salts are strongly coloured, exhibiting various shades of colour, from light-yellow to dark-red. They are quickly decomposed by heat, emitting a peculiar odour. Ammonia attacks the salts of both series, forming sulphocyanate of platosammonium (p. 513). Their decomposition by chlorine and by nitric acid has been mentioned above.

The following table exhibits the reactions of the soluble salts of the two series with various metallic solutions:—

Reagents.	Sulphocyanoplatinites.	Sulphocyanoplatinates.
Neutral Lead-salts	No change	Soluble golden laminæ
Basic Lead-salts	Pale-yellow precipitate	Fine red precipitate
Ferrous salts	No change	Black shining grains
Cobalt-salts	No change	Orange-red precipitate
Cuprous salts	Purplish-black precipitate	Rich brown precipitate
Cupric salts	Purplish-black precipitate	Brick-red precipitate
Mercurous salts	No precipitate: liquid changes colour when heated	Orange precipitate
Silver-salts	Pale-yellow precipitate	Red or orange precipitate
Auric salts	Salmon-coloured precipitate	Salmon-coloured precipitate
Salts of Platosamine	Fine yellow precipitate	Copious orange precipitate
Salts of Diplatosamine	Flesh-coloured precipitate	Fine vermilion-red precipitate
Chromic acid	Copious reddish precipitate, with evolution of hydrocyanic acid	No precipitate
Ferrocyanide of Potassium	Nearly white precipitate on boiling	Prussian-blue formed on boiling

1. *Sulphocyanoplatinites*, $M^2Pt''(CyS^2)^4$.

Hydric Sulphocyanoplatinite or *Sulphocyanoplatinous Acid*, $H^2Pt''Cy^4S^4$.—Obtained by cautiously decomposing sulphocyanoplatinite of barium with dilute sulphuric acid. The aqueous solution is speedily decomposed by evaporation, even in vacuo, the sulphur being oxidised at the expense of the water. The chief products of the decomposition are sulphocyanic acid and a red or yellow deposit rich in platinum.

Sulphocyanoplatinite of Potassium.—Obtained: 1. By dissolving platinous chloride in sulphocyanate of potassium, the solution being attended with considerable rise of temperature.—2. Better, by the action of sulphocyanate of potassium on chloroplatinate of potassium, the sulphocyanate being in excess. As sulphocyanoplatinite of potassium is extremely soluble, and does not crystallise well by evaporation, it is best to use the sulphocyanate of potassium in the form of a concentrated solution, and to add the platinum-salt by small quantities at a time, so as to avoid too great a rise of temperature. The liquid on cooling deposits a mass of small needles, which must be purified from chloride of potassium by solution in strong alcohol, from which again the salt is best recovered by spontaneous evaporation. The crystals are then pressed between paper to remove the excess of sulphocyanate of potassium, and the salt once more crystallised from an aqueous solution.

It forms stellar groups of crystals, which when examined by the microscope appear like six-sided prisms of a fine red colour. They dissolve readily in 2½ pts. of water at 15·5°, and are soluble to any extent in warm alcohol. The solution of the pure salt is orange-red; a port-wine colour denotes impurity. The crystals are not deliquescent, and when perfectly dry, do not appear to be affected by a temperature of 100°. The salt is decomposed by ammonia, yielding sulphocyanate of platosammonium which crystallises out, and sulphocyanate of potassium which remains in solution.

Sulphocyanoplatinite of Silver, $Ag^2Pt''Cy^4S^4$.—Curdy precipitate, somewhat resembling sulphocyanate of silver, partially soluble in ammonia, with decomposition. It dissolves in sulphocyanate of potassium, but the solution is decomposed by water.

Tetrammonioplatinous Sulphocyanoplatinite, $\left.\begin{matrix}(N^4H^{12}Pt'')''Cy^2S^2\\ Pt''Cy^2S^2\end{matrix}\right\}$, or *Sulphocyanoplatinite of Diammo-platoso-diammonium*, $\left.\begin{matrix}[N^2H^4(NH^4)^2Pt'']''\\ Pt''\end{matrix}\right\}Cy^4S^4$.—Obtained, as a bulky flesh-coloured precipitate, by decomposing the chloride of diplatosammonium with a soluble sulphocyanoplatinite.—Heated on platinum-foil, it gives off ammoniacal gas, fuses into a black bubbling mass, and then burns like tinder, leaving bright spongy platinum. It is quite insoluble in water and in alcohol, but dilute hydrochloric acid dissolves it rather freely. It is polymeric with sulphocyanate of platosammonium (p. 513).

2. *Sulphocyanoplatinates.*

Sulphocyanoplatinic Acid, $H^2Pt^{iv}Cy^6S^6$.—Obtained by precipitating a warm and concentrated solution of the lead-salt with sulphuric acid. The filtered liquid is of a deep-red colour, and has a strongly acid taste. It displaces carbonic acid from its alkaline salts, and dissolves metallic zinc, with evolution of hydrogen, and production of a yellow insoluble substance. When rapidly evaporated in vacuo, it leaves a confused semi-crystalline mass. When concentrated over the water-bath, it is quickly decomposed, leaving a brown amorphous mass, rich in platinum. On distilling it at a gentle heat, an acid liquid passes over, containing hydrocyanic and sulphocyanic acids. It combines directly with bases.

Sulphocyanoplatinate of Ammonium.—The acid does not combine rapidly with free ammonia; but the salt is easily prepared by boiling 1 pt. of ammonium-sulphate for a few minutes in a strong solution of 3·5 pts. potassic sulphocyanoplatinate; it may be separated, after cooling, from the sulphates of ammonium and potassium, by means of alcohol, and purified by recrystallisation from hot water. It crystallises in hexagonal plates of a fine crimson colour. It is stable at ordinary temperatures, but gives off the odour of sulphocyanic acid when its aqueous solution is boiled.

Sulphocyanoplatinate of Potassium.—Prepared: 1. By the action of potassic sulphocyanate on platinic chloride. When platinic chloride is added to a cold solution of potassic sulphocyanate, a precipitate of potassic chloroplatinate is formed, with evolution of sulphocyanic acid. But if the platinic chloride be poured into a strong solution of the sulphocyanate previously heated to 70° or 80°, no precipitate is formed; but the liquor acquires a deep-red colour, and on cooling deposits beautiful laminæ of potassic sulphocyanoplatinate. This process involves a considerable waste of potassic sulphocyanate, in consequence of the presence of free hydrochloric acid, which likewise, if the temperature rises above a certain point, decomposes the product, forming a brown flocculent precipitate (platinous sulphocyanate).

2. Better: a solution of 4 pts. chloroplatinate of potassium is added to a solution of 5 pts. pure sulphocyanate of potassium (weighed in the fused state) in a moderate quantity of water, and the mixture is heated nearly to the boiling-point:

$$K^2Pt^{iv}Cl^6 + 6KCyS = K^2Pt^{iv}Cy^6S^6 + 6KCl.$$

A deficiency of the sulphocyanate must be avoided, as in that case an insoluble brown substance is formed, which renders the purification of the crystals very difficult. The filtered liquid, on cooling, deposits the sulphocyanoplatinate in beautiful crystals, often of large size. To remove traces of chloride of potassium, the crystals may be redissolved in boiling alcohol, and the solution passed through a filter surrounded with hot water, to prevent too rapid crystallisation.

Sulphocyanoplatinate of potassium forms six-sided prisms or laminæ, of a deep carmine colour and very nauseous taste. The aqueous solution yields the salt in hexagonal plates, but from the alcoholic solution it is often deposited in double six-sided pyramids united base to base, and with truncated summits. Permanent in the air at ordinary temperatures. It dissolves in 12 pts. water at 60°, much more freely in boiling water, and still more in boiling alcohol. The solutions have a deep-red colour, becoming yellow when very dilute. One drop of the saturated solution gives a distinct yellow tinge to a gallon of water.

Decompositions.—1. Sulphocyanoplatinate of potassium is decomposed at a red heat, yielding sulphocyanate of potassium, gaseous products, and reduced platinum.—2. When gently heated in contact with the air, it burns with a blue sulphurous flame and peculiar odour.—3. Sulphuric acid converts it into sulphocyanic acid, suphocyanate of potassium, and platinic sulphide:

$$K^2Pt^{iv}Cy^6S^6 + 2H^2S = PtS^2 + 2KCyS + 4HCyS.$$

Similarly, with sulphide of ammonium:

$$K^2Pt^{iv}Cy^6S^6 + 2(NH^4)^2S = PtS^2 + 2KCyS + 4NH^4CyS.$$

4. The salt is decomposed by strong sulphuric and hydrochloric acid. Nitric acid and chlorine likewise decompose it, yielding platinous sulphocyanate, $Pt''Cy^2S^2$, and other products (p. 509).—5. Ammonia and carbonate of ammonia added to a saturated solution of the salt, quickly decompose it, changing the colour to pale-yellow in a few minutes, and precipitating *sulphocyanate of platosammonium*, in fine yellow needles, the liquid retaining in solution sulphate and sulphocyanate of potassium, together with sulphocyanate and cyanide of ammonium:

$$3K^2Pt^{iv}Cy^6S^6 + 8NH^3 + 4H^2O = 3(N^2H^6Pt'')''Cy^2S^2 + K^2SO^4 + 4KCyS + \\ 2NH^4CyS + 5HCyS + HCy.$$

6. Potash converts the salt into a red gelatinous mass, without evolution of ammonia.—7. When it is gently heated with carbonate of potassium, carbonic anhydride is evolved; the mixture becomes partially decolorised; sulphocyanoplatinite of

potassium is deposited, and the liquid retains in solution sulphate, sulphocyanate of potassium, and cyanide of potassium:

$$\mathrm{3K^2Pt^{iv}Cy^6S^6 + 4K^2CO^3 = 3K^2Pt''Cy^4S^4 + K^2SO^4 + 5KCyS + KCy + 4CO^2.}$$

—8. A pure solution of potassic sulphocyanoplatinate does not produce a blood-red colour with ferric salts; but the mixture becomes nearly black and opaque when heated, from formation of a substance which separates in heavy lustrous grains.

Sulphocyanoplatinate of Sodium, obtained by precipitating the lead-salt with sulphate of sodium, crystallises readily in broad garnet-coloured tables, soluble in water and in alcohol.

Sulphocyanoplatinate of Barium.—Prepared by dissolving 3 pts. of the dry potassium-salt in an aqueous solution of 1 pt. of chloride of barium (or, as an excess of the latter is desirable, 9 pts. $\mathrm{K^2PtCy^6S^6}$ to 4 pts. $\mathrm{BaCl^2}$), evaporating the solution, and extracting with alcohol.—Crystallises in long flattened prisms of a deep-red colour, and often of considerable size. Not so stable as the potassium-salt.

Cupric Sulphocyanoplatinate.—Precipitated on mixing a solution of the potassium-salt with cupric sulphate. Exhibits a brick-dust colour when first precipitated, but changes at a boiling heat to a black insoluble powder. Forms a fine green solution with ammonia, but on the addition of hydrochloric acid, the copper-salt is reproduced, with dark-brown colour.

Sulphocyanoplatinates of Iron.—*a. Ferrous salt*, $\mathrm{Fe''Pt^{iv}Cy^6S^6}$.—Obtained by adding a slightly acidulated solution of ferrous sulphate to a concentrated solution of potassic sulphocyanoplatinate. Black crystalline precipitate, which, when examined by the microscope, is seen to be composed of shining six-sided laminæ with rounded edges. It is not affected by dilute sulphuric, hydrochloric, or nitric acid; but strong nitric acid dissolves it, with formation of sulphuric acid. Cold solution of potash converts it into ferric oxide and a yellow liquid containing platinum and sulphocyanic acid. It is insoluble in water and in alcohol.

β. Ferric Salt.—Prepared in like manner with ferrous salt, but not precipitated till the mixture is boiled. Resembles the ferrous salt.

Sulphocyanoplatinates of Lead.—*a. Neutral*, $\mathrm{Pb''Pt^{iv}Cy^6S^6}$.—Precipitated in the form of brilliant golden hexagonal plates, on mixing the concentrated solutions of neutral acetate of lead and sulphocyanoplatinate of potassium. Soluble in alcohol; less soluble in cold water, with which it may be washed; cannot be crystallised from hot water without decomposition.

β. Basic, $\mathrm{Pb''O.Pb''Pt^{iv}Cy^6S^6}$.—Obtained as a brilliant red precipitate, on mixing the concentrated solutions of potassic sulphocyanoplatinate and basic lead-acetate. Insoluble in water; readily soluble in dilute nitric and in acetic acid.

Mercurous Sulphocyanoplatinate, $\mathrm{Hg^2Pt^{iv}Cy^6S^6}$.—Heavy curdy precipitate, obtained by adding mercurous nitrate to sulphocyanoplatinate of potassium. Its colour is deep orange at first, but changes to a pale primrose-yellow when the liquid is heated to the boiling-point. In the dry state, it bears a considerable degree of heat without alteration. Heated in the air-bath to between 140° and 150°, it suddenly swells up into a substance having a peculiar metallic and arborescent appearance, somewhat like coarse tea, and emits a jet of spontaneously inflammable gas. No further change is observed till the temperature rises to 250°; but at a heat below redness, mercurial vapours and cyanogen-gas are liberated; and finally the mass, if exposed in an open crucible, burns away like tinder, leaving a residue of platinum. The salt, when subjected to dry distillation, in a retort, yields a mixture of nitrogen-gas and vapour of carbonic disulphide.

Sulphocyanoplatinate of Silver, $\mathrm{Ag^2Pt^{iv}Cy^6S^6}$.—Prepared by decomposing a solution of the potassium-salt with nitrate of silver. Heavy, curdy, deep orange-coloured precipitate, which shrinks and agglutinates into a tenacious mass when boiled with water, but hardens again on boiling. The dry salt, when gently heated, swells up considerably, and if in contact with the air, takes fire and burns with a blue flame. Before the blowpipe, it fuses into a metallic bead of silver and platinum.—Nitric acid decomposes it rapidly, with formation of sulphuric acid, evolution of nitric oxide, and precipitation of a yellow substance.—When recently precipitated, it dissolves in cold aqueous ammonia, but the solution decomposes at a higher temperature. The salt is decomposed by hot caustic potash, yielding sulphocyanate of potassium, platinic oxide, and oxide of silver:

$$\mathrm{Ag\,Pt^{iv}Cy^6S^6 + 6KHO = 6KCyS + PtO^2 + Ag^2O + 3H^2O.}$$

It dissolves in sulphocyanate of potassium, but, on adding water to the liquid, sulphocyanate of silver is precipitated, and sulphocyanoplatinate of potassium remains in solution:

$$\mathrm{Ag^2Pt^{iv}Cy^6S^6 + 2KCyS = 2AgCyS + K^2Pt^{iv}Cy^6S^6.}$$

Sulphocyanate of Platosammonium, $C^2H^6N^4S^2Pt = N^2H^6Pt''.Cy^2S^2$.—This salt, polymeric and metameric with tetrammonioplatinous sulphocyanoplatinite (p. 510), is obtained: 1. By the action of ammonia on sulphocyanoplatinite of potassium:

$$K^2Pt''Cy^4S^4 + 2NH^3 = N^2H^6Pt''.Cy^2S^2 + 2KCyS.$$

2. By the action of ammonia, or its carbonate, on sulphocyanoplatinate of potassium (see p. 511). Caustic ammonia acts more quickly than the carbonate, but must not be used in the concentrated state, as the product is then contaminated with an insoluble substance. The crystals are collected on a filter, washed with cold water, and recrystallised from hot alcohol.—3. By double decomposition with sulphocyanate of potassium and chloride of platosammonium:

$$N^2H^6Pt''Cl^2 + 2KCyS = N^2H^6Pt''.Cy^2S^2 + 2KCl.$$

One part of sulphocyanate of potassium and 1·6 pt. chloride of platosammonium are dissolved together in water; the mixture heated nearly to its boiling-point; an equal volume of alcohol added, to increase the solubility of the product; and the liquid filtered hot. Sulphocyanate of platosammonium is then deposited in crystals, on cooling.

This salt forms straw-yellow needles, which, when examined by the microscope, appear to be rhomboïdal prisms. Melts between 100° and 110°, to a clear garnet-coloured syrup, which hardens again as it cools. It dissolves sparingly in cold water, more readily in alcohol. It decomposes at 180°, giving off ammonia and hydrocyanic acid; and if exposed to the air, evolves also sulphurous anhydride and leaves metallic platinum; no sulphide of carbon is given off. It is not attacked by hydrochloric or by dilute sulphuric acid. The aqueous solution produces no change in salts of copper, lead, or mercury; but when added to a solution of sulphate or nitrate of silver, it forms a light-yellow precipitate containing platinum. When boiled, it gives off ammonia, and deposits the yellow insoluble matter above mentioned; the same effect appears to be produced by caustic potash.

Sulphocyanate of Potassium, $CNKS = KCyS$.—This salt is prepared: 1. By fusing cyanide of potassium with sulphur, or 2 pts. of the ferrocyanide with 1 pt. sulphur; or by fusing 17 pts. of potassic carbonate with 32 pts. sulphur, and adding 46 pts of dry potassic ferrocyanide. The heat must be continued till the melted mass gives off bubbles, which burn in the air with a red flame; and it must be carefully regulated, as if it is insufficient, part of the ferrocyanide will remain undecomposed; and if it be too much raised, part of the resulting sulphocyanate will be converted into mellanide. The fused mass, when cold, is dissolved in water; the iron contained in the solution is precipitated by carbonate of potassium; the filtrate is evaporated to dryness; the residue digested with alcohol, and the alcoholic solution left to evaporate. To avoid the use of alcohol, **Meillet** (J. Pharm. xxvii. 628) neutralises the filtrate separated from the iron precipitate with acetic acid, evaporates, and purifies the sulphocyanate by crystallisation.—2. Sulphocyanate of potassium may also be prepared, in the same manner as the sodium-salt, by fusing 1 pt. of anhydrous potassic ferrocyanide with 3 pts. of the anhydrous hyposulphite (**Fröhde**).—3. Gelis prepares sulphocyanate of potassium on the large scale by heating sulphocyanate of ammonium with potash, or sulphocarbonate of ammonium with sulphide of potassium (p. 506):

$$2(NH^4)^2CS^3 + K^2S = 2KCNS + 2(NH^4)HS + 3H^2S.$$

Sulphocyanate of potassium crystallises in long striated prisms, or in needles with four-sided summits, very much like saltpetre. They are anhydrous, and have a specific gravity of 1·866—1·906 (**Bödeker**). The salt is very deliquescent, fusible, and very soluble in boiling alcohol. It has a cooling pungent taste, somewhat like that of radishes, and is poisonous.

The aqueous solution of potassic sulphocyanate decomposes, with evolution of ammonia, gradually at ordinary temperatures, more quickly at the boiling heat. The alcoholic solution is more stable. The concentrated solution dissolves recently precipitated *argentic cyanide*, which is thrown down from it in the crystalline state on dilution. It likewise dissolves a considerable quantity of recently precipitated *argentic chloride*, also of *argentic sulphocyanate*, forming therewith a crystalline compound.

Sulphocyanate of potassium, when melted in close vessels, bears a dull red heat without decomposition, but when calcined in contact with the air, it yields sulphate; if the salt is moist, sulphide of potassium is obtained, with evolution of ammonium-carbonate.

When dry *chlorine* is passed into melted sulphocyanate of potassium, chloride of sulphur is given off, together with solid chloride of cyanogen, which sublimes in needles. At a certain stage of the decomposition, a thick red vapour is evolved, which condenses into a red or yellowish-red sublimate containing 67·9 per cent. sulphur; and a residue is left, consisting, according to Liebig, of chloride of potassium and impure mellone. According to Völckel (Pogg. Ann. lviii. 152), neither the red sublimate nor the mellone is produced if the chlorine is quite dry and free from hydrochloric acid. Chlorine passed into an aqueous solution of the sulphocyanate, not too dilute, throws down an orange-coloured precipitate of persulphocyanogen (iv. 380). An alcoholic solution of *iodine* is not decolorised by an alcoholic solution of potassic sulphocyanate, even at the boiling heat.

Strong *nitric acid* added to the aqueous solution throws down persulphocyanogen. Dilute nitric acid, nitrous acid, and other oxidising agents, also impart to the solution a deep but transient blood-red colour, which is distinguished from that produced by ferric salts by its greater instability. (Jahresb. 1852, p. 429; 1857, p. 237; 1865, p. 294.)

Permanganate of potassium, peroxide of manganese, and peroxide of lead, oxidise only the sulphur of the sulphocyanate, converting it into sulphuric acid, the formation of which is probably preceded by that of a cyanogen-compound containing a smaller proportion of sulphur than the sulphocyanate. (Hadow, Chem. Soc. Qu. J. xi. 174.)

When dry *hydrochloric acid* is passed over fused sulphocyanate of potassium, great heat is produced; hydrocyanic acid, carbonic disulphide, and sal-ammoniac are given off; and a thick yellowish-red sublimate is formed, which, when exposed to moist air, gives off acid vapours capable of reddening ferric salts. (Liebig.)

Sulphocyanate of potassium gently heated with *pentachloride of phosphorus*, yields gaseous chloride of cyanogen, phosphoric sulphochloride, and chloride of potassium:

$$\mathrm{KCyS} + \mathrm{PCl^5} = \mathrm{CyCl} + \mathrm{KCl} + \mathrm{PSCl^3}.$$

At a higher temperature other products are formed. (Schiff, Ann. Ch. Pharm. cvi. 116.)

An aqueous solution of potassic sulphocyanate yields, by *electrolysis*, sulphuric acid, sulphurous acid, hydrocyanic acid, and sulphur. (Schlagdenhauffen, J. Pharm. [3], xlix. 100.)

Dry sulphocyanate of potassium heated with metallic iron is converted into ferrocyanide of potassium, together with ferrous and potassic sulphides:

$$6\mathrm{KCyS} + \mathrm{Fe^6} = \mathrm{K^4Fe''Cy^6} + 5\mathrm{Fe''S} + \mathrm{K^2S}.$$

This process is applied by Gelis to the manufacture of the ferrocyanide. (See Rép. Chim. App. 1862, p. 370; Richardson and Watts's *Chemical Technology*, [5], i. 399.)

SULPHOCYANATE OF SILVER, AgCyS.—White curdy precipitate, insoluble in water but soluble in ammonia, whence it crystallises in shining scales free from ammonia. Dry chlorine free from hydrochloric acid, converts it into solid chloride of cyanogen, chloride of sulphur, and chloride of silver; with moist acid chlorine, it yields also a red sublimate. It dissolves easily in aqueous sulphocyanate of potassium, and the saturated solution left over sulphuric acid, deposits rhomboïdal octahedrons of the double salt KCyS.AgCyS, which is completely decomposed by water, melts without decomposition at 140°, but decomposes at a higher temperature.

SULPHOCYANATE OF SODIUM, NaCyS.—This salt may be produced in the same manner as sulphocyanate of potassium, also by fusing cyanide or ferrocyanide of potassium with hyposulphite of sodium:

$$4\mathrm{KCy} + 4\mathrm{Na^2S^2O^3} = 4\mathrm{NaCyS} + 2\mathrm{K^2SO^4} + \mathrm{Na^2SO^4} + \mathrm{Na^2S};$$
$$2\mathrm{K^4Fe''Cy^6} + 12\mathrm{Na^2S^2O^3} = 12\mathrm{NaCyS} + 4\mathrm{K^2SO^4} + 5\mathrm{Na^2SO^4} + \mathrm{Na^2S} + 2\mathrm{Fe''S}.$$

A convenient mode of preparation is to heat 1 pt. of potassic ferrocyanide with 3½ pts. anhydrous sodic hyposulphite in a porcelain dish, till the hyposulphurous acid is decomposed, and dissolve out the resulting sodic sulphocyanate with hot alcohol or water. Ferricyanide of potassium heated with hydrated sodic hyposulphite is first converted, with separation of sulphur and evolution of sulphurous anhydride, into ferrocyanide, which is then converted, as above, into sulphocyanate and sulphide of sodium. (A. Fröhde, Pogg. Ann. cxix. 317.)

Sulphocyanate of sodium crystallises in rhombic tables, very deliquescent, and very soluble in alcohol.

SULPHOCYANATE OF STRONTIUM, $\mathrm{Sr''Cy^2S^2.3H^2O}$, forms deliquescent nodules, very soluble in water and in alcohol.

SULPHOCYANATE OF THALLIUM, TlCyS, is obtained. by mixing the solution of the carbonate with sulphocyanate of potassium, in small shining needles (Kuhlmann. Compt. rend. xv. 607). The crystals are quadratic, having however a monoclinic aspect, in consequence of irregular development. Observed combinations, $\infty P \,.\, P\infty$; and $\infty P\infty \,.\, \infty P \,.\, P\infty$. Angle $\infty P : P\infty = 128°\ 20{\cdot}3'$; $\infty P : P\infty = 116°\ 1'$; $P\infty : P\infty$, in the basal principal section[*] = 76° 40·6′. Twins with the combination-face $P\infty$. No distinct cleavage. (W. H. Miller, Proc. Roy. Soc. xiv. 555.)

SULPHOCYANATE OF TIN.—*Stannous hydrate* precipitated by ammonia, dissolves for the most part in sulphocyanic acid, leaving a light orange-coloured residue; the solution, when boiled, deposits stannous oxide, and leaves, on further evaporation, lemon-yellow *stannous sulphocyanate*, $Sn''Cy^2S^2$. This salt, when heated, becomes brown and black without change of form, and finally melts, leaving a black residue, which burns away with a glimmering violet-red light. It dissolves in water and in absolute alcohol, the aqueous solution appearing blue by reflected light. Potash separates black stannous oxide, and the evaporated solution yields tabular crystals of a double salt. Stannous sulphocyanate dissolves in sulphocyanate of potassium, with separation of brown stannous sulphide; and the filtrate first yields crystals of stannous sulphocyanate, then decomposes on further evaporation.—*Stannic hydrate* dissolves but very slightly in sulphocyanic acid. (L. Clasen, J. pr. Chem. xcvii. 349.)

SULPHOCYANATES OF URANIUM.—The *uranous salt* is dark-green, soluble, and crystalline.—The *uranic salt* is soluble in water, insoluble in alcohol.

SULPHOCYANATE OF ZINC, $Zn''Cy^2S^2$.—Deposited from alcohol in anhydrous crystals, very soluble in water. It dissolves also in ammonia, and the solution yields, by evaporation, rhomboïdal prisms of *sulphocyanate of zincammonium*, $(N^2H^6Zn'')''Cy^2S^2$, which are decomposed by water.

SULPHOCYANIC ANHYDRIDE, $C^2N^2S = Cy^2S$. *Cyanic Sulphide. Sulphide of Cyanogen.* (F. Linnemann, Ann. Ch. Pharm. cxx. 36.)—This compound is formed by the action of cyanic iodide on argentic sulphocyanate:

$$AgCyS + CyI = AgI + Cy^2S.$$

It is most easily prepared by mixing an ethereal solution of cyanic iodide with an equivalent quantity of argentic sulphocyanate, evaporating with constant stirring, and leaving the residual powder to itself for some hours in small closed vessels. The sulphocyanic anhydride may be separated from the argentic iodide by sublimation, or better, by extraction with boiling carbonic disulphide. The solution, if quickly filtered at the boiling heat, and then cooled to 0°, deposits the compound in crystals, which may be purified by drying in a vacuum over oil of vitriol.

Sulphocyanic anhydride is likewise produced by the action of sulphide of iodine, I^2S, on cyanide of silver; of sulphide of chlorine, Cl^2S, on cyanide of mercury; and of iodide of cyanogen on sulphide of silver. The product which Lassaigne obtained (in 1828) by treating cyanide of mercury with sulphide of chlorine, was nothing else than sulphocyanic anhydride. In preparing the compound by this process, a secondary product is likewise obtained, consisting of a white powder, insoluble in carbonic disulphide, but soluble in ether, and having, according to Linnemann's analyses, the composition $Cy^2S.HgCy$.

Sulphocyanic anhydride forms limpid rhombic tables or laminæ, which smell like iodide of cyanogen, and volatilise slowly on exposure to the air. It sublimes between 30° and 40°, melts at 60°, and solidifies in the crystalline form. When heated for some time in moist air, it decomposes. It dissolves in *ether*, *alcohol*, and *water*, and crystallises from solutions supersaturated while hot. It is easily decomposed by dilute *sulphuric acid*, also by *nitric* and by *hydrochloric acid*. With *iodide of potassium*, it gives off iodine; with aqueous *cyanide of potassium*, it evolves hydrocyanic acid; by fusion with *hydrate of potassium*, it yields ammonia, carbonic anhydride, sulphide, and sulphocyanate of potassium; with *potassium*, it forms cyanide and sulphocyanate of potassium; with *alcoholic potash-solution*, cyanate and sulphocyanate of potassium. With *nascent hydrogen*, *sulphydric acid*, and *monosulphide of potassium*, it decomposes as shown by the equations:

$$\begin{aligned} Cy^2S + H^2 &= HCy + HCyS \\ Cy^2S + H^2S &= HCy + HCyS + S \\ Cy^2S + K^2S &= KCy + KCyS + S. \end{aligned}$$

With *ammonia*, sulphocyanic anhydride forms the compound $(NH^3)^2Cy^2S = \left.\begin{matrix}NH^3Cy\\H\end{matrix}\right\}S$ (just as sulphydric acid, H^2S, forms $\left.\begin{matrix}NH^4\\H\end{matrix}\right\}S$), which separates as a crystalline powder on passing dry ammonia-gas into an ethereal solution of the anhydride. This compound dissolves easily in absolute alcohol; melts without decomposition at 94°; gives off ammonia with alkalis, and decomposes, in aqueous solution, into sulphocyanate of ammonium, and probably cyanamide.

The aqueous solution of sulphocyanic anhydride decomposes very quickly, depositing a yellow or orange-red powder, resembling persulphocyanogen (iv. 380), but of different composition, and perhaps consisting, for the most part, of a polymeric modification of sulphocyanic anhydride—namely, the anhydride of sulphocyanuric acid: this compound appears also to be the chief product of the decomposition of sulphocyanic anhydride in moist air. The acid solution remaining after the deposition of this powder, contains sulphocyanic acid (as chief product), hydrocyanic acid, sulphocyanate and sulphate of ammonium; it, moreover, gives off carbonic anhydride, and probably also carbonic oxide. (Linnemann.)

Iodocyanic Sulphide, CyIS.—This appears to be the composition of a red-brown, very volatile, and easily decomposible liquid, formed, together with iodide of silver, by treating sulphocyanate of silver with an ethereal solution of iodine. (Linnemann.)

SULPHOCYANIC ETHERS. Several sulphocyanates of monatomic alcohol-radicles are known, also the sulphocyanate of ethylene.

Allylic Sulphocyanate. *Volatile Oil of Mustard. Essence de Moutarde. Senföl.* $C^4H^5NS = C^3H^5.CyS = \left.\begin{matrix}Cy\\C^3H^5\end{matrix}\right\}S = \left.\begin{matrix}(CS)''\\C^3H^5\end{matrix}\right\}N$. (Boutron and Robiquet, J. Pharm. xvii. 296.—Henry and Plisson, *ibid.* xvii. 451.—Dumas and Pelouze, Ann. Ch. Phys. [2], liii. 181.—Aschoff, J. pr. Chem. iv. 314.—Robiquet and Bussy, Ann. Ch. Phys. [2], lxxxii. 328.—Boutron and Frémy, J. Pharm. xvi. 112.—Löwig and Weidmann, J. pr. Chem. xix. 218.—Will, Ann. Ch. Pharm. lii. 1.—Wertheim, *ibid.* lv. 297.—Gerhardt, Ann. Ch. Phys. [3], xiv. 125; *Traité*, ii. 409.—Gm. x. 41.)

This ether, or essential oil, is obtained from the seeds of black mustard by distillation with water, and exists, together with oil of garlic, in the oils produced in like manner from other cruciferous plants. It does not exist ready-formed in these plants, at least not in the dry parts, such as the seed. Its production requires the presence of water, and appears to depend upon the action of myrosin, a substance analogous to the emulsion of bitter almonds, or another substance, myronic acid, likewise existing in these plants in the form of a potassium-salt. [See MYRONIC ACID and MYROSIN, iii. 1073, 1075.] The seed of white mustard, which contains myrosin but not myronic acid, does not yield allylic sulphocyanate when distilled with water.

Allylic suphocyanate is formed artificially: 1. From myronic acid, by distilling myronate of barium or potassium with a caustic alkali (iii. 1070).—2. From allylic iodide, by the action of potassic or argentic sulphocyanate.—3. From allylic sulphide (i. 143), by treating the precipitate formed by the action of mercuric chloride on oil of garlic with potassic sulphocyanate (Wertheim). According to Hlasiwetz (Ann. Ch. Pharm. lxxi. 28), the precipitate formed by mixing the alcoholic solutions of oil of asafœtida and mercuric chloride, also yields allylic sulphocyanate when distilled with sulphocyanate of potassium.

Preparation.—*a.* From mustard-seed. The seed of black mustard is bruised and macerated for about twelve hours with 3 to 6 pts. of cold water, and then distilled, as long as any oil passes away with the water. The distillation is best conducted by passing steam into the still. A saturated solution of mustard-oil in water then passes over, and the excess of oil settles to the bottom. The aqueous solution, which contains a considerable quantity of the oil, may be advantageously used for macerating fresh portions of seed. 1000 pts. of mustard-seed macerated with fresh water yield from 2 to 7 pts. of oil; but if water saturated with the oil by repeated distillation be used, the product may amount to 10 or 11 parts.

The crude oil is mostly yellowish; it is purified by rectification, after drying over chloride of calcium. Pure sulphocyanate of allyl then passes over, between 145° and 150°.

b. From allylic iodide.—The iodide dissolved in alcohol is distilled with sulphocyanate of potassium; and the distillate mixed with water is rectified, the pure oil passing over, between 145° and 150° (Zinin, Ann. Ch. Pharm. xcv. 128). Or 1 at. iodide of allyl and 1 at. sulphocyanide of potassium are enclosed, together with a little water, in a sealed glass tube, and heated for some hours to 100°; water is then added, which dissolves the iodide of potassium and separates the allylic sulphocyanate; and the latter is rectified. (Berthelot and De Luca, Ann. Ch. Phys. [3], xliv. 495.)

Allylic sulphocyanate is obtained with still greater facility by the action of allylic iodide on sulphocyanate of silver. The action takes place at ordinary temperatures, iodide of silver being formed; while the iodide of allyl disappears, and is replaced by oil of mustard. At 100° sulphide of silver is formed. (Berthelot and De Luca.)

Properties.—Allylic sulphocyanate is a transparent colourless oil, of strong refracting power, and possessing in the highest degree the sharp penetrating odour of black mustard. The smallest quantity of the vapour excites tears, and is apt to produce inflammation of the eyes. It has a burning taste, and rapidly blisters the skin. Specific gravity = 1·015 at 20° (Dumas and Pelouze), 1·009 to 1·010 at 15° (Will). Boils at 148° (Will). Vapour-density, 3·54 (Will); calculated, 3·42. Refracting power = 1·516 (Will).

It is sparingly soluble in *water*, but dissolves very readily in *alcohol* and *ether*. It dissolves *sulphur* and *phosphorus* with tolerable facility when heated, these bodies separating in the crystalline form on cooling.

Decompositions.—1. Oil of mustard kneaded with alumina yields, by *dry distillation*, carbonic anhydride, carburetted hydrogen, and a small quantity of sulphydric acid, together with water. (Fontenelle.)

2. Exposed to daylight for three years in well-closed vessels, it gradually becomes brownish-yellow, and deposits an orange-yellow amorphous substance having the aspect of persulphocyanogen. This substance, when heated, swells up, assumes a dark colour, gives off a strong odour of mustard-oil, and leaves a dull but perfectly combustible charcoal. It dissolves in warm potash-solution, forming a yellow liquid, from which acetic acid precipitates light-yellow flocks; and the liquid filtered therefrom still gives a light-yellow precipitate with acetate of lead, but does not redden ferric salts, and therefore does not contain sulphocyanic acid. (Will.)

3. The aqueous solution of the oil, after exposure to the air for some hours, loses its sharpness, but retains its taste and mustard odour, and deposits a grey powder containing sulphur (Thibierge). The oil undergoes no change by exposure to the air or to oxygen, even for a considerable time, becoming neither acid nor alkaline. (Boutron and Robiquet.)

4. When *chlorine-gas* is very slowly passed into a retort filled with oil of mustard, very volatile crystals are formed, having a silky lustre (with evolution of hydrochloric acid, according to Dumas and Pelouze). These crystals become coloured and decompose when exposed to the air, and are dissolved by a large excess of chlorine, yielding a viscid, no longer crystallisable liquid. Potash-ley converts them into a resinous substance insoluble in potash. They are insoluble in water and in ether, but dissolve in alcohol in all proportions. (Boutron and Frémy.)

5. *Bromine* acts upon oil of mustard with frothing and evolution of heat, and forms a brown resin nearly insoluble in water; the solution contains sulphuric and hydrobromic acid. (Aschoff.)

6. *Iodine* dissolves quickly in the oil, forming a dark red-brown liquid. (Aschoff.)

7. When oil of mustard is treated with moderately strong *nitric acid*, a brisk reaction takes place, the oil becoming thick, assuming a green colour, and being converted into a resinous substance called nitrosinapylic resin. The mother-liquor contains oxalic acid and a nitro-acid called nitrosinapylic acid, of waxy consistence, soluble in water, insoluble in alcohol and ether. The solution gives yellow precipitates with lead- and silver-salts. The barium-salt is a yellow powder, soluble in water, and gives by analysis 18·23 per cent. carbon, 1·66 hydrogen, 39·25 baryta, 2·74 sulphur, and 21·96 oxygen, which, if the small quantity of sulphur be neglected, may be represented by the formula $C^{12}H^6Ba''(NO^2)^2N^2O^4$, making that of the acid $C^6H^4(NO^2)NO^2$.

8. When oil of mustard is completely oxidised by *nitric* or by *chromic acid*, large quantities of formic and acetic acids are produced, together with a small quantity of propionic acid.

9. *Aqueous potash*, *soda* and *baryta*, also the *oxides of lead*, *silver*, and *mercury*, in presence of water, convert oil of mustard into sinapoline (p. 311), with formation of a metallic sulphide and carbonate: *e.g.*,

$$\underset{\substack{\text{Oil of}\\\text{mustard.}}}{2C^4H^5NS} + 3Pb''O + H^2O = \underset{\text{Sinapoline.}}{C^7H^{12}N^2O} + 2Pb''S + Pb''CO^3.$$

For this decomposition the presence of water is absolutely necessary; the same oxides, in the dry state, abstract the sulphur but slowly and imperfectly from oil of mustard.

When oil of mustard is boiled for some time with strong *soda-ley*, in such a manner that the vapour may be condensed and flow back again, a large quantity of ammonia is evolved, and an oil of fishy odour is produced, which may be freed from the last traces of sulphur by means of potash and hydrate of lead; after washing with dilute acid and with water, and subsequent rectification, it is colourless, and exhibits the composition of allylic peroxide, C^3H^5O. It forms a crystalline compound with nitrate of silver. (Hlasiwetz, J. pr. Chem. li. 369.)

10. An *alcoholic solution of potash* or *soda* acts very differently from the aqueous solution. When oil of mustard is dropped into a concentrated alcoholic solution of potash, great heat is produced, which, if care be not taken to add the liquid slowly, may rise in a few seconds to violent ebullition, and occasion the projection of the contents of the vessel. No permanent gas is evolved, excepting perhaps a little ammonia.

The brown-red mixture exhibits, instead of the pungent odour of oil of mustard, merely a mild garlic odour; deposits, after a while, crystals of neutral potassic carbonate with 1 at. water; and when decanted from these crystals and mixed with water, is resolved, with milky turbidity, into aqueous sulphosinapic acid (p. 526), holding in solution a certain quantity of oil which may be dissolved out by ether, and an oil which sinks to the bottom; and if the mixture has been heated to the boiling-point, is dark-coloured, and contains insoluble flakes. (Will.)

The *peculiar oil* obtained by keeping the mixture cold, after being separated from the aqueous sulphuric acid by collecting it on a wet filter, purified from potash by washing with water, rectified with solution of common salt, and freed from the water, which makes it turbid, by standing for several days over chloride of calcium, and decantation, is transparent and colourless; has a density of 1·036 at 14°; a mild alliaceous odour; a taste which is not burning, but cooling; boils between 115° and 118°; but is partially decomposed by distillation, even in a stream of gas, ammonia being formed, as shown by the vapour browning turmeric-paper slightly, and a brown resin remaining, which gives off a large quantity of ammonia when more strongly heated, and from which, by continued boiling with water, a volatile alkaloïd, not yet further examined, may be extracted. The oil, when boiled with baryta-water, forms sulphide of barium, and a non-volatile substance, which remains in solution, and appears to be an alkaloïd. From lead-salts and silver-salts it also precipitates the sulphides on boiling. It forms a precipitate with alcoholic mercuric chloride, and, if the solution be not too dilute, likewise with alcoholic stannic chloride. It is sparingly soluble in water, but dissolves in all proportions in alcohol and ether. (Will.)

Its composition, as determined by analysis, is as follows :—

			The oil once,	*twice,*	*three times rectified.*
C^{14}	168	50·76	50·35	50·20	
N^{3}	42	12·69	12·30	10·40	9·73
H^{25}	25	7·55	7·88	7·84	
S^{2}	64	19·33	20·50		
O^{2}	32	9·67	8·97		
	331	100·00	100·00		

As the oil gives off ammonia after each rectification, whereby the amount of nitrogen is diminished in greater proportion than that of the other elements, it is probable that the original oil before the first rectification was $C^{14}H^{25}N^{3}S^{2}O^{2}.NH^{3} = C^{14}H^{28}N^{4}S^{2}O^{2}$ (or $C^{7}H^{14}N^{2}SO$), and therefore $= C^{7}H^{12}N^{2}O$ (sinapoline) + $H^{2}S$. (Will.)

According to this assumption, the equation for the decomposition of oil of mustard by alcoholic potash should be the following:

$$3C^{4}NH^{5}S + 3KHO + H^{2}O = K^{2}CO^{3} + C^{4}H^{6}NKS^{2} + C^{7}H^{14}N^{2}SO.$$

11. When oil of mustard is mixed with pulverised *soda-lime*, and heated for some time to 120° in a sealed tube, the sharp mustard odour is found, on opening the tube, to be replaced by an aromatic alliaceous odour; and on distilling the liquid, oxide of allyl (i. 142) is obtained, while sulphocyanate of sodium remains, often mixed with sulphide of sodium, produced by the secondary action of the excess of soda on the sulphocyanate (Wertheim):

$$2(C^{3}H^{5}.CNS) + Na^{2}O = (C^{3}H^{5})^{2}O + 2NaCNS.$$

12. From an alcoholic solution of the oil, metallic salts, e. g. *mercuric* and *platinic chloride*, also *silver-* and *lead-salts* (the latter at the boiling heat), separate metallic sulphides. (Will.)

Dry pulverised *hydrate of potassium* decomposes oil of mustard in a similar manner to the alcoholic solution of potash; but the products are less definite, because it is difficult to prevent too great a rise of temperature.

13. *Monosulphide of potassium* heated with oil of mustard in a sealed tube, to 100° or a little higher, forms sulphocyanate of potassium and oil of garlic:

$$2(C^{3}H^{5})CNS + K^{2}S = 2KCNS + (C^{3}H^{5})^{2}S.$$

If a polysulphide of potassium be heated in a similar manner with oil of mustard, and the product distilled, a solution is obtained which yields delicate crystalline needles, having a most intense odour of asafœtida.

14. *Potassium* decomposes dry oil of mustard completely, even at ordinary temperatures; on applying a gentle heat, sulphocyanate of potassium and sulphide of allyl are formed, together with a gas, which has not been examined.

Many of the *heavy metals* decompose oil of mustard, abstracting the sulphur. Mercury is quickly blackened when shaken up with the oil and water; and copper vessels in which mustard-oil is distilled, become coated with sulphide of copper.

Combinations—Allylic sulphocyanate unites with alkaline sulphides, forming compounds of the form $C^4H^5NS.M^2S$.—The *potassium-salt*, $C^4H^5NS.K^2S$, is deposited as a white granular powder, on mixing the alcoholic solutions of potassic monosulphide and allylic sulphocyanate, the former slightly in excess, and evaporating at a gentle heat.—Another salt, containing $2C^4H^5NS.K^2S$, separates from the mother-liquor of the preceding, when left over oil of vitriol, in needle-shaped crystals having a scarcely perceptible yellowish tinge.—The *barium-salt*, $C^4H^5NS.Ba''S$, is formed by gradually adding oil of mustard to a warm yellow solution of barium-sulphide, till its odour becomes permanent. The filtrate yields, on cooling, laminar efflorescent crystals containing 3 at. water. (Will.)

With alkaline sulphydrates it unites in like manner, forming salts of allylsulphocarbamic or sulphosinapic acid (*q.v.*); *e.g.*, $C^3H^5.CNS + KHS = \left.\begin{matrix}C^3H^5.H\\(CS)''\\K\end{matrix}\right\}\begin{matrix}N\\S\end{matrix}$.

Allylic sulphocyanate unites readily with *ammonia*, forming thiosinamine, $C^4H^5NS.NH^3$ = sulphocyanate of allylammonium, $\left.\begin{matrix}CN\\NH^3(C^3H^5)\end{matrix}\right\}S$, or allyl-sulphocarbamide, $\left.\begin{matrix}(CS)''\\C^3H^5\\H^3\end{matrix}\right\}\begin{matrix}N\\N\end{matrix}$. With the *alcoholic ammonia*, in like manner, it forms thiosinamines in which the typic hydrogen is more or less replaced by alcohol-radicles: thus with *ethylamine*, it forms ethylthiosinamine or ethyl-allylsulphocarbamide, $C^4H^5NS.NH^2(C^2H^5) = \left.\begin{matrix}(CS)''\\C^3H^5\\C^2H^5.H^2\end{matrix}\right\}\begin{matrix}N\\N\end{matrix}$ (see THIOSINAMINE); and with *triethylphosphine*, it forms triethyl-allyl-sulphocarbophosphamide, $C^4H^5NS.P(C^2H^5)^3 = \left.\begin{matrix}(CS)''\\C^3H^5\\(C^2H^5)^3\end{matrix}\right\}\begin{matrix}N\\P\end{matrix}$. See PHOSPHORUS-BASES (iv. 616).

Amylic Sulphocyanate, $C^6H^{11}NS = \left.\begin{matrix}CN\\C^5H^{11}\end{matrix}\right\}S = \left.\begin{matrix}(CS)''\\C^5H^{11}\end{matrix}\right\}N$. (Henry, Ann. Ch. Phys. [3] xxv. 248.—Medlock, Ann. Ch. Pharm. lxix. 214.)—Obtained by distilling, in a capacious retort, about equal volumes of crystallised amylsulphate and sulphocyanate of potassium. It is a colourless very mobile liquid, which after drying and rectification, boils constantly at 197°. Specific gravity = 0·905 at 20°. It has a pungent alliaceous odour, and burns with white smoky flame. It is but little attacked by sulphuric acid. By boiling with nitric acid, it is converted into amylsulphurous acid.

Ethylic Sulphocyanate, $C^3H^5NS = \left.\begin{matrix}CN\\C^2H^5\end{matrix}\right\}S = \left.\begin{matrix}CS''\\C^2H^5\end{matrix}\right\}N$. (Cahours, Ann. Ch. Phys. [3] xviii. 264.—Löwig, Pogg. Ann. lxvii. 101.—Muspratt, Ann. Ch. Pharm. lxv. 253.)—This ether is prepared:—1. By saturating a concentrated solution of potassic sulphocyanate with ethylic chloride. As soon as the reaction, which is slow, (but may be accelerated by sunshine) is complete, the liquid is to be diluted with an equal bulk of water and distilled, the distillate mixed with twice its volume of pure ether, and sufficient water added to separate the ethereal solution of ethylic sulphocyanate. The ether is then drawn off by distillation, and the remaining ethylic sulphocyanate is purified by rectification over chloride of calcium.—2. By distilling equal parts of calcic ethylsulphate and potassic sulphocyanate, both in concentrated solution.

Ethylic sulphocyanate is a mobile, colourless, strongly refracting liquid, having a taste of anise, and a pungent odour like that of mercaptan. Boils at 146°. Specific gravity of liquid = 1·020 at 16°; of vapour = 3·018. It is insoluble in *water*, but *alcohol* and *ether* dissolve it in all proportions.

Ethylic sulphocyanate is rapidly decomposed by *nitric acid*, yielding ethylsulphurous acid, with only a small quantity of sulphuric acid. The same acid is formed on treating the ether with *hydrochloric acid* and *chlorate of potassium*, the reaction being often so violent as to set the volatile products on fire.

Chlorine gradually attacks ethylic sulphocyanate, forming chloride of cyanogen, and a heavy oil soluble in water.—*Bromine* attacks it violently, forming crystallisable products.

When heated to 100° in a sealed tube with *aqueous potash*, it is converted into ethylic disulphide, with formation of potassic cyanide and cyanate (Brüning, Ann. Ch. Pharm. civ. 193):

$$2C^2H^5CyS + 2KHO = (C^2H^5)^2S^2 + KCy + KCyO + H^2O.$$

On boiling [the ether with *alcoholic potash*, ammonia is given off, together with ethylic disulphide. With an alcoholic solution of potassic monosulphide, it forms sulphide of ethyl and sulphocyanate of potassium, without evolution of ammonia.

The alcoholic solution of ethylic sulphocyanate does not precipitate metallic solutions.

Dry *ammonia-gas* forms, with ethylic sulphocyanate, a small quantity of a body having the composition of ethyl-sulphocarbamide, $(CS)''(C^2H^5)H^3N^2$.—With aqueous ammonia of ordinary strength, black uncrystallisable products are formed; with excess of dilute aqueous ammonia, the products formed are cyanide of ammonium, carbamide, and disulphide of ethyl:

$$2(C^2H^5.CNS) + 2NH^3 + H^2O = (NH^4)CN + CN^2H^4O + (C^2H^5)^2S^2.$$

Ethylamine likewise decomposes ethylic sulphocyanate. (Jeanjean, Compt. rend. lv. 330; see also Kremer, J. pr. Chem. lxxiii. 365; Jahresb. 1858, p. 401.)

With *triethylphosphine* at 100°, it forms a large quantity of triethylphosphine-sulphide, together with cyanide of triethylphosphonium (Hofmann, iv. 611):

$$C^2H^5.CNS + 2(C^2H^5)^3P = (C^2H^5)^3PS + (C^2H^5)^4P.CN.$$

Ethylenic Sulphocyanate, $C^4H^4N^2S^2 = \left.\begin{matrix}(CN)^2\\(C^2H^4)''\end{matrix}\right\}S^2 = \left.\begin{matrix}(\overset{''}{C}S)^2\\(C^2H^4)''\end{matrix}\right\}N^2.$ (Sonnenschein, J. pr. Chem. lxv. 257.—Buff, Ann. Ch. Pharm. xcvi. 302, c. 219; Jahresb. 1855, p. 610; 1856, p. 597.)—Produced by heating an alcoholic solution of ethylenic chloride (Dutch liquid), with an equivalent quantity of potassic sulphocyanate, to 100° in a sealed tube. Chloride of potassium then separates out, and on distilling off the volatile products from the filtered liquid, removing the remaining chloride and sulphocyanate of potassium with a little cold water, and dissolving the residue in hot water, a solution is obtained which yields crystals of ethylenic sulphocyanate on cooling.

Ethylenic sulphocyanate is moderately soluble in boiling water, and separates therefrom in stellate groups of small needles; easily soluble in warm alcohol, whence it crystallises in large, white, shining, rhombic plates. It melts at 90°, and solidifies at 83°; decomposes at a stronger heat, giving off a pungent odour, like that of burnt onions. With vapour of water it appears to distil undecomposed, the vapour attacking the eyes strongly, and exciting violent sneezing; it has a sharp burning taste. It dissolves in very dilute *nitric acid*, crystallises again in needles on cooling; but stronger nitric acid converts it into a crystalline acid, which, according to Buff, is identical with disulphetholic or ethylene-sulphurous acid, $C^2H^6S^2O^6$.

Acids do not separate sulphocyanic acid from ethylenic sulphocyanate. The alcoholic solution does not give the reaction of sulphocyanic acid with ferric salts till it has been boiled with potash. When boiled with *baryta-water*, it yields carbonate and sulphocyanate of barium. On boiling it with *plumbic hydrate*, sulphide of lead is formed, especially on addition of potash, and the solution gives, with ferric salts, the reaction of sulphocyanic acid. The alcoholic solutions of ethylenic sulphocyanate and *mercuric chloride* yield, after a while, a white precipitate (Sonnenschein). With *ammonia* it forms an easily soluble substance, which readily gives up sulphur to mercuric oxide (Buff).—With *triethylphosphine* it acts similarly to ethylic sulphocyanate, yielding sulphide of triethylphosphine and cyanide of ethylene-hexethyl-diphosphonium (Hofmann):

$$C^2H^4.C^2N^2S^2 + 4(C^2H^5)^3P = 2(C^2H^5)^3PS + (C^2H^4)''(C^2H^5)^6P^2.C^2N^2.$$

Hexylic Sulphocyanate, $C^6H^{13}.CNS$. (Pelouze and Cahours, Ann. Ch. Phys. [4] i. 5.)—Produced by heating hexylic chloride to 100° for several hours with alcoholic sulphocyanate of potassium. It is a nearly colourless fetid liquid, of specific gravity 0·922 at 12°, boiling at 215°—220°.

Methylic Sulphocyanate, $CH^3.CNS = \left.\begin{matrix}(CS)''\\CH^3\end{matrix}\right\}N.$ (Cahours, Ann. Ch. Phys. [3] xviii. 261.)—Obtained by distilling a concentrated solution of equal parts of potassic sulphocyanate and calcic methylsulphate. It is a colourless very mobile liquid, having an alliaceous and intoxicating odour. Boils between 132° and 133°. Specific gravity of liquid, 1·115 at 16°; of vapour = 2·570—2·549. It dissolves slightly in *water*; in all proportions in *alcohol* and *ether*. Chlorine attacks it very slowly in diffused light, producing fine crystals of chloride of cyanogen, together with a heavy yellow oil, which solidifies in contact with ammonia.—*Nitric acid* of ordinary strength dissolves it when warm, and deposits it again on cooling. By continued boiling with nitric acid, it is converted into methylsulphurous acid. It is scarcely attacked by *potash* at ordinary temperatures; but alcoholic potash decomposes it when heated, ammonia and methylic disulphide being given off, while cyanide and carbonate of potassium are found in the residue. With alcoholic *sulphide of potassium*, it forms sulphocyanate of potassium and sulphide of methyl.—Aqueous *ammonia* decomposes it quickly, forming a brown substance resembling ulmin, and a small quantity of a [illegible] body.

Naphthylic Sulphocyanate, $C^{10}H^7.CNS = \left.\begin{matrix}(CS)''\\ C^{10}H^7\end{matrix}\right\}N.$ (V. Hall, Phil. Mag. [4] xvii. 304.)—This ether is produced, together with naphthylamine, by distilling dinaphthyl-sulphocarbamide (obtained by digesting crude naphthylamine with carbonic disulphide) with phosphoric anhydride:

$$\left.\begin{matrix}(CS)''\\ (C^{10}H^7)^2\\ H^2\end{matrix}\right\}N^2 = \left.\begin{matrix}C^{10}H^7\\ H^2\end{matrix}\right\}N + \left.\begin{matrix}(CS)''\\ C^{10}H^7\end{matrix}\right\}N.$$

It is a crystalline compound, having a peculiar odour, easily fusible, insoluble in water, but very soluble in alcohol and ether. With *naphthylamine*, in alcoholic solution, it reproduces naphthyl-sulphocarbamide. With *aniline*, it yields phenyl-naphthyl-sulphocarbamide, $[(CS)''.C^6H^5.C^{10}H^7.H^2]N^2$.

Phenylic Sulphocyanate, $C^6H^5.CNS = \left.\begin{matrix}(CS)''\\ C^6H^5\end{matrix}\right\}N.$ (Hofmann, Proc. Roy. Soc. ix. 274, 487; Chem. Soc. Qu. J. xiii. 309.)—Produced by distilling phenyl-sulphocarbamide, $(CS)''.C^6H^5.H^3.N^2$, with phosphoric anhydride. After rectification over the latter, it is a colourless transparent liquid, smelling like oil of mustard, having a specific gravity of 1·135 at 15°, and boiling at 220°, under a pressure of 0·762 met. It distils unaltered with water, and even with hydrochloric acid, but is very easily decomposed by alkalis. *Alcoholic potash* converts it first into diphenyl-sulphocarbamide, then into diphenyl-carbamide. With *ammonia*, it yields phenyl-sulphocarbamide:

$$C^6H^5.CS.N + NH^3 = (CS)''.C^6H^5.H^3.N^2.$$

With amines, it unites in a similar manner: with *aniline*, for example, it forms diphenyl-sulphocarbamide, and with *naphthylamine*, phenyl-naphthylsulphocarbamide, isomeric or identical with that above described.

With *triethylphosphine* it unites so energetically that the mixture often takes fire: when, however, the action is duly regulated, triethyl-phenyl-sulphocarbophosphamide, $C^{13}H^{20}NPS = (CS)''(C^2H^5)^3.C^6H^5.N.P$, is produced (iv. 616). With *trimethylphosphine*, in like manner, it forms the compound $C^{10}H^{14}NPS = (CS)''(CH^3)^3(C^6H^5).NP$, which is an oily liquid, insoluble in water, slightly soluble in ether, easily in alcohol, and forming with hydrochloric acid the crystalline salt $C^{10}H^{14}NPS.HCl$.

SULPHOCYMENIC ACID. Syn. with THYMYLSULPHUROUS ACID. (See SULPHUROUS ETHERS.)

SULPHODRACONIC ACID. A conjugated acid, produced, according to Laurent, by treating oil of anise or tarragon with a large excess of sulphuric acid.

SULPHOFLAVIC ACID. See INDIGOSULPHURIC ACIDS (iii. 262).

SULPHOFORM. An oily liquid, produced in small quantity by distilling iodoform with mercuric sulphide (Bouchardat, J. Pharm. xxiii. 12). According to Eggert, however (Chem. Centr. 1857, p. 513), this product thus obtained is nothing but carbonic disulphide.

SULPHOFULVIC ACID. See INDIGOSULPHURIC ACIDS (iii. 262).

SULPHOGLUCIC ACID. Syn. with GLUCOSOSULPHURIC ACID (ii. 872).

SULPHOGLUTINIC ACID. The name applied by Berzolius to a glutinous acid, formed, together with other products, by the action of sulphuric anhydride in excess on naphthalene. (*Gerhardt's Traité*, iii. 468.)

SULPHOGLYCERIC ACID. $C^3H^8SO^6$. Syn. with GLYCEROSULPHURIC ACID (ii. 892).

SULPHOGLYCOLLIC ACID. $C^2H^4SO^5$. Syn. with ETHYLENE-SULPHURIC ACID. (See SULPHURIC ETHERS.)

SULPHOHIPPURIC ACID. $C^9H^9NSO^6 = C^9H^9NO^3.SO^3 = \left.\begin{matrix}C^7H^5O\\ (C^2H^2O)''\\ (SO^2)''\\ H^2\end{matrix}\right\}\begin{matrix}N\\ O^2.\end{matrix}$ (Schwanert, Ann. Ch. Pharm. cxii. 59; Jahresb. 1859, p. 328.)—Formed by treating hippuric acid with sulphuric anhydride. By converting the product into a lead-salt, decomposing with sulphydric acid, &c., it is obtained as a brown, amorphous, deliquescent mass, which is decomposed by nitrous acid, yielding sulphobenzoic acid, together with an oily liquid, probably glycollic acid.

The acid is dibasic. Its neutral *barium-salt* has the composition $C^9H^7Ba''NSO^6$. By boiling the acid with *plumbic hydrate*, a salt is obtained having approximately the composition $C^9H^7Pb''NSO^6$.

SULPHO-HYDROQUINONIC ACIDS. See HYDROQUINONE (iii. 217).

SULPHOMARGARIC ACID and **SULPHOLEIC ACID.** Oily acids, produced, according to Frémy (Ann. Ch. Phys. [2] lxv. 113), together with sulphoglyceric acid, by the action of strong sulphuric acid upon olein at low temperatures. The sulpholeic acid, being insoluble in the acid liquid, separates in the form of an oil from the sulphoglyceric acid, which remains dissolved. These two acids have not been separated, and consequently their composition has not been determined. They are both soluble in water and in alcohol, so likewise are their potassium-, sodium-, and ammonium-salts; the other salts are insoluble in water, slightly soluble in alcohol.

Sulpholeic acid is decomposed by water, yielding hydroleic and meta-oleic acids (iv. 195). Sulphomargaric acid yields similar products.

SULPHOLIGNIC ACID. A syrupy acid obtained by treating cotton, linen, sawdust, and other forms of cellulose, with strong sulphuric acid. It forms soluble salts with baryta and oxide of lead. (Gerhardt, ii. 548.)

SULPHOMANNITIC ACID. $C^6H^{14}O^6.3SO^3$.—An acid produced by dissolving mannite in strong sulphuric acid. It appears to be tribasic, forms gummy deliquescent salts with the alkalis and with oxide of lead, and a crystalline salt with baryta.

SULPHOMELANURENIC ACID. $C^3N^4H^4S^2 = CyH^2N.2CyHS = \left.\begin{matrix}Cy^3\\H^4\end{matrix}\right\}\begin{matrix}N\\S^2\end{matrix}$. *Sulphomellonic acid. Sulphydromellonic acid. Hydrothiomellone.* (Jamieson, Ann. Ch. Pharm. lix. 339.)—An acid obtained as a potassium-salt by boiling persulphocyanogen with sulphydrate of potassium:

$$\begin{aligned}2C^2N^2HS^3 + 3KHS + 2H^2O = C^3N^4H^3KS^2 &+ 2CNKS + CO^2\\ &+ 3H^2S \;\; + S^2.\end{aligned}$$

The resulting liquid neutralised with acetic acid yields a copious white precipitate, consisting of sulphur and sulphomelanurenic acid, which is to be washed and treated with cold aqueous ammonia, to dissolve out the acid and leave the sulphur; and the filtered solution, after being left to evaporate in a warm place, is to be boiled with animal charcoal, till it yields a perfectly white precipitate with acids.

Sulphomelanurenic acid is nearly insoluble in cold water, alcohol, and ether, slightly soluble in boiling water, which deposits it in very small needles. It is tasteless, but reddens litmus. It begins to decompose between 140° and 150°, and is resolved at a higher temperature into mellone and sulphydric acid:

$$\underset{\text{Sulphomelanurenic acid.}}{CyH^2N.2CyHS} = \underset{\text{Mellone.}}{NCy^3} + 2H^2S.$$

When heated with hydrochloric, sulphuric, or nitric acid, it is resolved into ammonia, sulphydric acid, and cyanuric acid:

$$CyH^2N.2CyHS + 3H^2O = NH^3 + 2H^2S + Cy^3H^3O^3.$$

Sulphomelanurenic acid is monobasic. Its potassium-salt, $2C^3N^4H^3KS^2.3H^2O$, forms shining colourless prisms, very soluble in water and in alcohol.—The *sodium-salt*, $2C^3N^4H^3NaS^2.3H^2O$, crystallises in large translucent plates having a fatty aspect, or in small scales resembling cholesterin.—The *barium-salt*, $C^6N^8H^6Ba''S^4.5H^2O$, forms colourless needles, having a fine adamantine lustre, and very soluble in water.—The *strontium-salt*, $C^6N^8H^6Sr''S^4.4H^2O$, forms large plates having a waxy lustre.—The *calcium-salt*, $C^6N^8H^6Ca''S^4.2H^2O$, forms shining crystals.—The *magnesium-salt*, $C^6N^8H^6Mg''S^4.6H^2O$, crystallises in small shining needles, very soluble in water.—The *silver-salt*, $C^3N^4H^3AgS^2$, is precipitated in white flocks, quite insoluble in water, on adding nitrate of silver to an ammoniacal solution of the acid. It blackens on exposure to light, but bears a temperature of 100° without decomposition.

SULPHOMELLONIC ACID. Syn. with SULPHOMELANURENIC ACID.

SULPHOMETHYLIC ACID. Syn. with METHYLSULPHURIC ACID. (See SULPHURIC ETHERS.)

SULPHOMOLYBDATES. See MOLYBDENUM, SULPHIDES OF (iii. 1043).

SULPHOMORPHIDE. A product of the action of sulphuric acid on morphine (iii. 1055).

SULPHONAPHTHALENE. $C^{10}H^{14}SO^2 = \left.\begin{matrix}C^{10}H^7\\C^{10}H^7\end{matrix}\right\}SO^2$. (Berzelius, Ann. Ch. Phys. [2] lxv. 290.—Laurent, Rev. Scient. viii. 587.)—This compound, which may be regarded as a double molecule of naphthalene, ($C^{10}H^8$), having two of its hydrogen-atoms replaced by sulphuryl, is formed by directing the vapour of sulphuric anhydride on an excess of fused naphthalene. A red syrupy liquid is thereby formed, from which the sulphonaphthalene may be separated by treating it with boiling water, and c [illegible] residue from aqueous alcohol.

Sulphonaphthalene crystallises from alcoholic solution in tasteless inodorous nodules. It melts at 70°, and solidifies on cooling to a transparent mass, which becomes electric by friction. At a higher temperature, it decomposes, giving off sulphurous anhydride. It is slightly soluble in water, more soluble in boiling alcohol, not attacked by boiling potash-ley. Nitromuriatic acid dissolves it at the boiling heat, without formation of sulphuric acid.

SULPHONAPHTHALIC ACID. $C^{10}H^8SO^3$. Syn. with NAPHTHYLSULPHUROUS ACID. (See SULPHUROUS ETHERS.)

Disulphonaphthalic Acid, $C^{10}H^8S^2O^6$. Syn. with NAPHTHYLENE-SULPHUROUS ACID. (See SULPHUROUS ETHERS.)

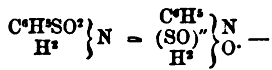
SULPHONAPHTHALIDAMIC ACID. Syn. with NAPHTHIONIC ACID (iv. 17).

SULPHONAPHTHANIC ACID. Syn. with SULPHONAPHTHALIC ACID.

SULPHONARCOTIDE. A product of the decomposition of sulphate of narcotine (iv. 28).

SULPHOPHENIC ACID. $C^6H^5.H.SO^4$. Syn. with PHENYLSULPHURIC ACID. (See SULPHURIC ETHERS.)

SULPHOPHENYLAMIDE. $C^6H^7NSO^2$ =



$\left.\begin{matrix}C^6H^5SO^2\\H^2\end{matrix}\right\}N = \left.\begin{matrix}C^6H^5\\(SO)''\\H^2\end{matrix}\right\}\begin{matrix}N\\O.\end{matrix}$ — *Sulphobenzolamide. Azoture phenylsulfureux. Azoture de sulfophenyle et d'hydrogène.* (Gerhardt and Chancel, Compt. rend. xxxv. 690.—Gerhardt and Chiozza, *ibid.* xxxv. 86; *Gerhardt's Traité*, iii. 74.)—Produced by the action of ammonia on sulphophenylic chloride. A convenient mode of preparing it is to pour the chloride on a large excess of pulverised ammonium-carbonate; the reaction commences immediately, and may be completed by gently heating the mortar in which the mixture is made, till the odour of the chloride is no longer perceptible. The product is then washed with cold water, which dissolves out the sal-ammoniac and the excess of ammonium-carbonate, and the residual sulphophenylamide is crystallised from a small quantity of boiling alcohol. It is also produced (together with sulphurous anhydride, ammonia, benzol, and a small quantity of phenylic sulphide) by heating phenylsulphite (sulphobenzolate) of ammonium. (Stenhouse, Proc. Roy. Soc. xiv. 351.)

Sulphophenylamide crystallises from alcohol in splendid nacreous scales (Gerhardt); from alcohol or water in laminæ resembling naphthalene, and melting at 153° (Stenhouse); according to Gerhardt, it is insoluble in water, very soluble in alcohol, soluble in boiling aqueous ammonia.

Sulphophenylamide contains two atoms of typic hydrogen, one or both of which may be replaced by metals or organic radicles. The following compounds have thus been obtained:—

Argentosulphophenylamide	$C^6H^6AgNSO^2$.
Benzosulphophenylamide	$C^6H^6(C^7H^5O)NSO^2$.
Argento-benzosulphophenylamide	$C^6H^5Ag(C^7H^5O)NSO^2$.
Dibenzosulphophenylamide	$C^6H^5(C^7H^5O)^2NSO^2$.
Benzacetosulphophenylamide	$C^6H^5(C^7H^5O)(C^2H^3O)NSO^2$.
Cumosulphophenylamide	$C^6H^5(C^{10}H^{11}O)NSO^2$.
Cumo-benzosulphophenylamide	$C^6H^5(C^{10}H^{11}O)(C^7H^5O)NSO^2$.
Phenylsulphophenylamide	$C^6H^6(C^6H^5)NSO^2$.
Succinosulphophenylamide	$C^6H^5(C^4H^4O^2)''NSO^2$.

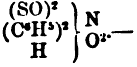
Argentosulphophenylamide, $C^6H^6AgNSO^2$, is obtained as a white crystalline precipitate on adding nitrate of silver to an alcoholic and ammoniacal solution of sulphophenylamide.

Succinosulphophenylamide, $C^{12}H^9NSO^2$, is formed by the action of succinic chloride on sulphophenylamide. The product, which is viscous at first, solidifies when treated with alcohol, and crystallises therefrom in very fine needles.

Phenylsulphophenylamide, or *Sulphophenylanilide*, $C^{12}H^{11}NSO^2$, is formed by the action of aniline on sulphophenylic chloride. The product remains viscous for a long time; but when dissolved in alcohol, it yields splendid prisms, with pyramidal faces, like small crystals of amethyst, which they also resemble in colour. They dissolve easily in alcohol and ether. (Chiozza and Biffi; *Gerhardt's Traité*, iii. 981.)

The other compounds in the preceding list have been already described under BENZAMIDE (i. 539, 540), and CUMINAMIDE (ii. 177).

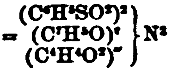
Disulphophenylamide, $C^{12}H^{11}NS^2O^4$ = $N.H.(C^6H^5SO^2)^2$ =



$\left.\begin{matrix}(\overset{''}{SO})^2\\(C^6H^5)^2\\H\end{matrix}\right\}\begin{matrix}N\\O^2.\end{matrix}$—

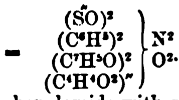
Produced by gently heating argentosulphophenylamide with sulphophenylic chloride; purified by crystallisation from ether.

Succino-dibenzo-disulphophenyldiamide, $C^{30}H^{24}N^2S^2O^8$ =



$$\left.\begin{matrix}(C^6H^5SO^2)^2\\(C^7H^5O)^2\\(C^4H^4O^2)''\end{matrix}\right\}N^2$$

=



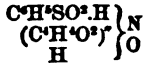
$$\left.\begin{matrix}(\overset{''}{S}O)^2\\(C^6H^5)^2\\(C^7H^5O)^2\\(C^4H^4O^2)''\end{matrix}\right\}\begin{matrix}N^2\\O^2\end{matrix}$$

.—This compound, obtained by heating argento-benzosulphophenylamide with succinic chloride, crystallises from ether in small needles.

SULPHOPHENYLIC or **PHENYLSULPHUROUS CHLORIDE.** $C^6H^5SO^2Cl$. (See SULPHUROUS ETHERS.)

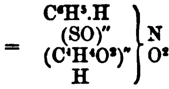
SULPHOPHENYLIC or **PHENYLSULPHUROUS HYDRIDE.** $C^6H^6SO^2$. —A compound formed by the action of reducing agents on the corresponding chloride. (See SULPHUROUS ETHERS.)

SULPHOPHENYLSUCCINAMIC ACID. $C^{10}H^{11}NSO^5$ =



$$\left.\begin{matrix}C^6H^5SO^2.H\\(C^4H^4O^2)''\\H\end{matrix}\right\}\begin{matrix}N\\O\end{matrix}$$

=



$$\left.\begin{matrix}C^6H^5.H\\(SO)''\\(C^4H^4O^2)''\\H\end{matrix}\right\}\begin{matrix}N\\O^2\end{matrix}$$

. (Gerhardt and Chiozza, Ann. Ch. Phys. [3] xlvii. 129.)—The ammonium-salt of this acid is obtained by evaporating an ammoniacal solution of succinosulphophenylamide, first at a gentle heat, then in a vacuum. A very thick syrup then remains, which alternately crystallises in concentric groups of silky fibres. This salt is very soluble in water and in alcohol, melts at 160°, giving off a large quantity of ammonia, and leaving an oil which, when dissolved in ammonia, yields crystals of sulphophenylamide. The aqueous solution of the ammonium-salt, mixed with a few drops of hydrochloric acid, deposits splendid needles, which melt between 155° and 160°, and have the composition of the original salt. The *silver-salt*, $C^{10}H^{10}AgNSO^5$, is deposited in beautiful needles on adding nitrate of silver to a solution of the ammonium-salt.

SULPHOPHLORAMIC ACID. An acid produced by heating phloramine (iv. 488) with strong sulphuric acid. On saturating the solution with carbonate of barium, decomposing the hot filtrate with sulphuric acid, and decolorising with animal charcoal, the acid is obtained in colourless needles. Its solution, even when very dilute, forms a deep violet colour with ferric chloride, like that produced by tyrosinsulphuric acid. (Hlasiwetz, Ann. Ch. Pharm. cxix. 199.)

SULPHOPHLORETIC ACID. $C^9H^{10}SO^6$.—This acid, produced by the action of sulphuric anhydride on phloretic acid, forms a very sour syrup, easily soluble in water and in alcohol. The *barium-salt*, $C^9H^8Ba''SO^6.3H^2O$, crystallises in hard apparently rhomboïdal crystals; it is insoluble in alcohol and ether, and gives off its water at 16°. The *calcium-salt*, $C^9H^8Ca''SO^6.4H^2O$, is crystalline; the *magnesium-salt*, $C^9H^8Mg''SO^6.5H^2O$, gummy. The *sodium-salt*, $C^9H^8Na^2SO^6.xH^2O$, forms hard, easily soluble, crystalline crusts, which give off their water at 260°. (Nachbaur, J. pr. Chem. lxxv. 45.)

SULPHOPHOSPHATES and **SULPHOPHOSPHITES.** See PHOSPHORUS, SULPHIDES OF (iv. 603, 604).

SULPHOPIANIC ACID. See OPIANIC ACID (iv. 206).

SULPHOPURPURIC ACID. See INDIGOSULPHURIC ACIDS (iii. 262).

SULPHOPYROMUCIC ACID. $C^5H^4SO^6$. By treating well-dried pyromucic acid with sulphuric anhydride, a yellow-brown syrup is obtained, which, by dilution, neutralisation with baryta, and evaporation, yields an indistinctly crystalline barium-salt, containing (at 150°) $C^5H^2Ba''SO^6$. (Schwanert, Ann. Ch. Pharm. cxvi. 268.)

SULPHOQUINIC ACID. Syn. with QUININE-SULPHURIC ACID (p. 26).

SULPHORETINYLIC ACID. An acid isomeric with sulphocumolic acid, obtained, according to Cahours and Gerhardt, by treating retinyl (iv. 98) with fuming sulphuric acid. Its barium-salt is less soluble than the sulphocumolate, and separates on evaporation in crystalline crusts, which have not the nacreous aspect of the sulphocumolate. (Gerhardt, iii. 388.)

SULPHORUFIC ACID. See INDIGOSULPHURIC ACIDS (iii. 262).

SULPHOSACCHARIC or **SULPHOGLUCIC ACID.** $C^{21}H^{18}SO^{27}$ =

$4C^6H^{12}O^6.SO^3$? (Peligot, Ann. Ch. Phys. [2] lxvii. 68.)—Prepared by treating glucose with 1½ pt. of strong sulphuric acid, mixing the materials by small quantities and in a cooled vessel. By saturating with carbonate of barium, and treating the filtrate with basic acetate of lead, a lead-salt is precipitated, containing (at 170°) 18·05 per cent. C, 2·5 H, 55·15 PbO, and 4·5 SO^3, agreeing approximately with the formula $C^{24}H^{40}Pb^4SO^{27}$.—By decomposing this lead-salt with sulphydric acid, sulphosaccharic acid is obtained in the form of a liquid, which reddens litmus, and has a sweet and sour taste, like that of lemonade. It does not precipitate barium-salts; in fact, nearly all its salts are soluble. It is very unstable, decomposes at ordinary temperatures in a vacuum, and quickly at the heat of the water-bath, into glucose and sulphuric acid.

SULPHOSALICYLIC ACID. $C^7H^6SO^6 = C^7H^6O^3.SO^3 = \left.\begin{array}{r}(C^7H^4O)''\\(SO)''\\H^2\end{array}\right\}O^4$.—This acid, discovered by Cahours (Ann. Ch. Phys. [3] xiii. 92), and more fully examined by Mendius (Ann. Ch. Pharm. ciii. 39; Jahresb. 1857, p. 319), is produced by exposing perfectly dry salicylic acid (prepared from wintergreen oil) to the vapour of sulphuric anhydride. The product dissolved in a small quantity of water is separated by filtration from unaltered salicylic acid; the filtrate is saturated with carbonate of barium; the resulting barium-salt, which separates partly as the filtrate cools, partly on evaporation, is decomposed by a slight excess of sulphuric acid; the filtered solution is partially saturated with carbonate of lead; the lead is precipitated by sulphydric acid; the concentrated filtrate is left over oil of vitriol till it deposits sulphosalicylic acid in crystals; and these are freed from the viscid mother-liquor by means of absolute alcohol.

Sulphosalicylic acid crystallises in long thin needles, which are dissolved in all proportions by *water*, *alcohol*, and *ether*, and absorb moisture from the air. It is a very strong and permanent acid. Its solution dissolves zinc with evolution of hydrogen, and is not decomposed by heating with nitric or hydrochloric acid, either dilute or concentrated; by boiling with a mixture of the two, however, it is resolved into sulphuric and salicylic acids, the latter being further converted into perchloroquinone (chloranil), which separates in yellow flocks. Sulphosalicylic acid melts at 120°, and decomposes at higher temperatures, giving off phenol and a sublimate of salicylic acid. (Mendius.)

Sulphosalicylates.—Sulphosalicylic acid is dibasic, forming neutral acid and double salts. They are all soluble in water (the lead and silver-salts, however, sparingly soluble), and nearly all are insoluble in alcohol and ether. With ferric salts, they produce a deep violet coloration, inclining more to red than that produced by salicylic acid. They do not give off the whole of their crystallisation-water below 180°—200°, and decompose at higher temperatures, with evolution of phenol; the acid salts also yield a sublimate of salicylic acid.

The *ammonium-salt* is difficult to obtain pure, its solution turning brown and giving off ammonia when evaporated.

Barium-salts.—The *neutral salt*, $C^7H^4Ba''SO^6.3H^2O$, prepared as above, is crystalline, easily soluble in hot, less easily in cold water.—The *acid salt*, $C^{14}H^{10}Ba''S^2O^{12}.4H^2O$, or $C^7H^4Ba''SO^6.C^7H^6SO^6.4H^2O$, crystallises in oblique, irregular, six-sided prisms.

The *calcium-salt*, $C^7H^4Ca''SO^6.H^2O$, forms hemispherical groups of silky needles.

Copper-salts.—The *neutral salt*, $C^7H^4Cu''SO^6$ (at 180°), obtained by decomposing the barium-salt with cupric sulphate, forms cauliflower-shaped masses of crystals, extremely soluble in water.—A *basic salt*, $C^7H^4Cu''SO^{10}.Cu''O.2H^2O$, is obtained as a green crystalline powder by digesting the acid with recently precipitated cupric oxide and evaporating.

The *lead-salt*, $C^7H^4Pb''SO^6$, crystallises indistinctly in small round nodules.

The *magnesium-salt*, $C^7H^4Mg''SO^6.3H^2O$, crystallises in long irregularly crossing rectangular prisms, which become opaque in the air, and dissolve very easily in water. The solution, mixed with sal-ammoniac and ammonia, is not precipitated by phosphate of sodium till boiled.

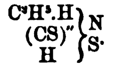
Potassium-salts.—The *neutral salt*, $C^7H^4K^2SO^6.2H^2O$, is permanent in the air, very soluble in water, less soluble in alcohol, and may be crystallised from the latter. —The *acid salt*, $C^7H^5KSO^6.2H^2O$, separates from a hot concentrated solution in spherical groups of needles.—Another *acid salt*, $C^7H^4K^2SO^6.C^7H^5KO^6.H^2O$, separates from a solution of the neutral salt mixed with a small quantity of free acid.—*Potassio-cupric* and *potassio-plumbic sulphosalicylates* have been obtained as uncrystallisable masses.

The *silver-salt*, $C^7H^4Ag^2SO^6.H^2O$, obtained by digesting recently precipitated silver-oxide in the hot aqueous acid, is sparingly soluble in cold, easily soluble in hot water.

Sodium-salts.—The *neutral salt*, $C^7H^4Na^2SO^6.3H^2O$, forms transparent, colourless, oblique, six-sided prisms, which do not give off all their water till heated to 200°; it dissolves easily in water.—A *sodio-potassic salt*, $C^7H^4KNaSO^6.4H^2O$, obtained by neutralising the acid potassium-salt with carbonate of sodium, crystallises in rectangular prisms having a silky lustre.

The *zinc-salt*, $C^7H^4Zn''SO^6.3H^2O$, resembles the magnesium-salt.

Ethylic Sulphosalicylate, $C^7H^4(C^2H^5)^2SO^6$, is formed by the action of ethylic iodide on argentic sulphosalicylate, and separates from alcoholic solution in soft, kneadable, silky crystals, which are perfectly neutral, melt at 56°, and distil unaltered with water. (Mendius.)



SULPHOSINAPIC or **ALLYL-SULPHOCARBAMIC ACID.** $C^4H^7NS^2$ $= C^3H^5CyS.H^2S = \left.\begin{matrix}C^3H^5.H\\(CS)''\\H\end{matrix}\right\}\begin{matrix}N\\S.\end{matrix}$ (Will, Ann. Ch. Pharm. lii. 30.)—This acid is not known in the free state. Its salts may be regarded as compounds of allylic sulphocyanate (oil of mustard), with metallic sulphydrates, and those which are soluble may be produced by the direct union of these constituents; also by the action of allylic sulphocyanate on the alkaline solutions of the corresponding hydrates. The insoluble salts are formed by precipitation.

The *ammonium-salt*, $C^4H^{10}N^2S^2 = (C^3H^5)CNS.(NH^4)HS$, formed as above by direct combination, solidifies to a magma of colourless laminæ; it is very unstable, decomposing spontaneously at ordinary temperatures.

The *potassium-salt*, $C^4H^6KNS^3 = (C^3H^5)CyS.KHS$, separates by slow evaporation from an alcoholic or even an aqueous solution of potassic sulphydrate, to which mustard-oil is added as long as its odour is destroyed, in large rhombic plates; by quicker evaporation in smaller crystals. It may also be prepared by slowly dropping oil of mustard into a concentrated solution of potash in absolute alcohol; decanting the solution after several hours from the crystallised potassic carbonate, diluting it with water, and evaporating the pale-yellow filtrate to a syrup: this, when set aside, deposits shining crystals of potassic sulphosinapate. The salt cannot, however, be obtained quite pure.

The crystals of potassic sulphosinapate are transparent and colourless so long as they remain in the liquid, but on exposure to the air they become opaque and yellow, lose their form, and become partly insoluble in water. The aqueous solution of the recently prepared salt may be heated without giving off the odour of mustard-oil; but on mixing the heated solution with nitrate of silver, sulphide of silver is precipitated, and the odour of mustard-oil becomes perceptible. The dried salt, when heated, gives off mustard-oil, and yields a brown liver of sulphur. When decomposed by sulphuric acid, it yields a large quantity of sulphydric acid, but no sulphur.

The *sodium-salt*, $C^4H^6NaNS^2.3H^2O$, is formed by direct combination, and separates in nacreous laminæ, which are unctuous to the touch, and when heated, first melt, and then give off a large quantity of mustard-oil; it cannot be kept without decomposing.

The *barium-salt*, $C^8H^{12}Ba''N^2S^4.4H^2O = 2C^3H^5CyS.Ba''H^2S^2.4H^2O$, is obtained: (1) by heating oil of mustard with a solution of barium-sulphydrate containing alcohol; (2) by passing sulphydric acid gas through aqueous alcohol containing hydrate of barium and oil of mustard in suspension; (3) it is deposited from the mother-liquor of the alcoholic solution of the compound of allylic sulphocyanate and sulphide of barium (p. 519). It forms crystalline laminæ resembling the sodium-salt and very soluble.

The *calcium-salt*, as obtained by the second method of preparing the barium-salt, forms a slightly yellow transparent jelly, which decomposes in drying.

The *lead-salt*, $C^8H^{12}Pb''N^2S^4$, is obtained by adding neutral acetate of lead to a very dilute solution of the potassium-salt acidulated with acetic acid, as a white precipitate, which decomposes partially, even during washing and drying in a vacuum over oil of vitriol, and quickly at 100°, yielding oil of mustard, sulphide of lead, and free sulphur.

When decomposed by sulphuric acid, it gives off abundance of sulphydric acid, without the slightest odour of mustard-oil.

The soluble sulphosinapates yield with *copper-salts* a green precipitate, and with *silver-salts* a white precipitate, both of which quickly blacken and decompose, even when immediately thrown on a filter and washed with cold water.

SULPHOSINAPISIN. The name given by Henry and Garot to sulphocyanate of sinapine. (See SINAPINE, p. 308.)

SULPHOSUCCINIC ACID. $C^4H^6SO^7 = C^4H^6O^4.SO^3 = \left.\begin{matrix}(C^4H^3O^2)''' \\ (SO)'' \\ H^3\end{matrix}\right\}O^4.$ (Fehling, Ann. Ch. Pharm. xxxviii. 285; xlix. 203.)—Produced by exposing succinic acid to the vapour of sulphuric anhydride in a vessel externally cooled, and heating the resulting viscous mass to 40° or 50° for several hours. The product is dissolved in water, the solution saturated with carbonate of lead, the lead-salt decomposed by sulphydric acid, and the filtered solution evaporated in a vacuum over oil of vitriol.

Sulphosuccinic acid thus obtained forms mammellated crystals, very soluble in water, alcohol, and ether; it has a very sour taste, and decomposes quickly when heated, leaving an abundant carbonaceous residue. The crystals absorb moisture from the air; their aqueous solution is partially decomposed by evaporation over the water-bath.

Sulphosuccinates.—The acid is tribasic, the neutral sulphosuccinates of monatomic metals having the composition $C^4H^3M^3SO^7$. The acid saturates bases completely, and even decomposes acetates.

The *neutral ammonium-salt*, $C^4H^3(NH^4)^3SO^7.H^2O$, is obtained by placing a strong solution of the acid, together with aqueous ammonia, under a bell-jar, in the form of a syrup, which ultimately becomes filled with needles having an acid reaction.

Potassium-salts.—The *neutral* or *tripotassic salt*, $2C^4H^3K^3SO^7.3H^2O$, is obtained by saturating the acid with potassic carbonate and evaporating in a vacuum, as a syrup containing a few deliquescent crystals; but on adding a small quantity of acid to the liquid, it quickly solidifies to a crystalline pulp. The salt is insoluble in absolute alcohol. It gives off a third of its water in a vacuum, the rest when heated.—The *dipotassic salt*, $C^4H^4K^2SO^7.2H^2O$, obtained by adding sulphosuccinic acid to the neutral salt, is very soluble in water, and has an acid reaction.

The *neutral sodium-salt*, obtained by decomposing the *barium-salt* with sulphate of sodium, is also very soluble in water.

The *neutral barium-salt*, $C^8H^6\overset{''}{Ba}{}^3S^2O^{14}$ (at 100°), is a white precipitate, obtained by precipitating the neutral potassium-salt with barium-chloride; it is very soluble in nitric or hydrochloric acid; dissolves also in sulphosuccinic acid, the solution, when left in a vacuum, depositing crystals which appear to consist of an acid salt.

An *acid calcium-salt*, $C^4H^4Ca''SO^7$ (at 100°), is obtained by dissolving calcic carbonate in sulphosuccinic acid and evaporating to dryness.

The *magnesium-salt* is uncrystallisable. The sulphosuccinates of *manganese*, *iron*, *cobalt*, *nickel*, and *copper* appear to be soluble, inasmuch as the potassium-salt does not precipitate the solutions of these metals.

The *neutral lead-salt*, $C^8H^6\overset{''}{Pb}{}^3S^2O^{14}.3H^2O$, is a white precipitate, obtained by adding acetate of lead to an alkaline sulphosuccinate. A *basic salt*, $C^8H^6\overset{''}{Pb}{}^3S^2O^{14}.Pb''O$ (at 100°), is formed by treating the neutral salt with ammonia.

The *silver-salt* is a white precipitate, which decomposes completely during washing, acquiring a deep-green colour.

SULPHOSULPHAMYLIC ACID. Syn. with AMYLSULPHUROUS ACID. (See SULPHUROUS ETHERS.)

SULPHOSTANNATES and **SULPHOSTANNITES.** See TIN, SULPHIDES OF.

SULPHOTELLURATES and **SUPHOTELLURITES.** See TELLURIUM, SULPHIDES OF.

SULPHOTHYMIC ACID. Syn. with THYMYLSULPHUROUS ACID. (See SULPHUROUS ETHERS.)

SULPHOTOLUOLAMIDE or **SULPHOBENZYLAMIDE.** $C^7H^9NSO^2$.—This compound, homologous with sulphophenylamide, and prepared by a similar process (p. 523), crystallises from hot water in needles or in laminæ. When heated with pentachloride of phosphorus, it is converted into a thick oil, which is decomposed by water, with reproduction of the amide; when distilled with the pentachloride, it gives off a liquid which partly dissolves in water, the solution also yielding crystals of sulphotoluolamide. (Fittig, Ann. Ch. Pharm. cvi. 277.)

SULPHOTOLUYLIC CHLORIDE. $C^7H^7SO^2Cl$. Syn. with BENZYLSULPHUROUS CHLORIDE. (See SULPHUROUS ETHERS.)

SULPHOTOLYLAMIC or **BENZYLSULPHAMIC ACID.** $C^7H^9NSO^3 = \left.\begin{matrix}C^7H^7.H \\ (SO^2)'' \\ H\end{matrix}\right\}\begin{matrix}N \\ O\end{matrix}$ (E. Sell, Ann. Ch. Pharm. cxxvi. 153; Chem. Soc. Qu. J. [2] i. 186.) —

Produced by carefully mixing 9 pts. fuming sulphuric acid with 5 pts. finely divided toluidine (benzylamine), and gently heating the syrupy mass till it gives off abundance of sulphurous anhydride. The solution is mixed with cold water, decolorised by boiling with animal charcoal, and evaporated till it assumes a reddish-yellow colour; the acid then separates in light-yellow needles, which may be purified by recrystallisation from water. The first mother-liquor yields rhomboïdal crystals, probably of benzyldisulphamic acid (p. 480).

The sulphotolylamates or benzylsulphamates are mostly very soluble in water; the barium-salt crystallises in groups of laminæ; the silver-salt, $C^7H^8AgNSO^3$, in white laminæ, which turn grey when exposed to light.

SULPHOTRIPHOSPHAMIDE. $N^3PH^6S = \left.\begin{matrix}(PS)'''\\ H^6\end{matrix}\right\}N^3$. (H. Schiff, Ann. Ch. Pharm. ci. 299.)—This compound appears to be formed by the action of ammonia-gas on phosphoric sulphochloride:

$$PSCl^3 + 3NH^3 = 3HCl + N^3PSH^6.$$

The white mass formed by the reaction is decomposed slowly by cold, immediately by warm water, with evolution of sulphydric acid. Alcohol extracts sal-ammoniac from it, and at the same time decomposes the other body contained in it, which is probably sulphotriphosphamide.

Triphenyl-sulphotriphosphamide, $\left.\begin{matrix}(PS)'''\\ (C^6H^5)^3\\ H^3\end{matrix}\right\}N^3$, appears to be contained, together with hydrochlorate of aniline, in the white mass produced by the action of phosphoric sulphochloride on aniline. (Schiff.)

SULPHOVANADATES and **SULPHOVANADITES.** See VANADIUM, SULPHIDES OF.

SULPHOVINIC ACID. Syn. with ETHYLSULPHURIC ACID. (See SULPHURIC ETHERS.)

SULPHOVIRIDIC ACID. See INDIGOSULPHURIC ACID (iii. 262).

SULPHOXALENIDE. } See CYANOGEN, SULPHYDRATES OF (ii. 285).
SULPHOXAMIDE. }

SULPHOXYBENZOIC ACID. $C^7H^6SO^6 = C^7H^6O^3.SO^3$. (Griess, Zeitschr. Ch. Pharm. 1864, p. 538.)—This acid, isomeric with sulphosalicylic acid, is produced by dissolving sulphato-diazobenzoic acid * in warm concentrated sulphuric acid:

$$C^7H^4N^2O^2.SH^2O^4 = C^7H^6O^3.SO^3 + N^2.$$

It crystallises out when the evolution of gas has ceased, and is obtained by recrystallisation from water, in white laminæ, soluble in alcohol. It is dibasic, like sulphosalicylic acid. The neutral barium-salt, $C^7H^4Ba''SO^6$, crystallises in sparingly soluble prisms. By strong nitric acid, it is resolved into sulphuric and tritro-oxybenzoic acids.

The name sulphoxybenzoic acid was formerly applied by Griess (Jahresb. 1861, p. 418) to the compound $C^7H^6SO^2$, produced by the action of sulphydric acid on the platinum-salt of chlorhydrato-diazobenzoic acid (iv. 294).

SULPHUR. *Atomic Weight*, 3; *Symbol*, S. *Vapour-density* = 32, referred to hydrogen, or 2·218, referred to air as unity.

Sulphur (*sal*, *πῦρ*), or brimstone (*brenne-stone*), has been known from the earliest times. It occurs native, either in the form of transparent amber-coloured crystals (*virgin sulphur*), or in opaque, lemon-yellow, crystalline masses (*volcanic sulphur*). It is found principally in Sicily, in beds of a blue clay formation, considered to be more recent than the chalk. The sulphur is imbedded in a matrix of rock-salt, gypsum, and celestine. Similar beds containing sulphur exist in other parts of Europe and in Mexico. It is also found occasionally in primitive rocks, granite, mica, &c. It abounds in the lava-fissures of volcanic craters, as instanced especially in the case of the Solfatara near Naples (*Forum Vulcani*), and in the volcano of Popocatepetl in Mexico. Sulphur also occurs native in combination with different metals, forming metallic sulphides, of which the principal are blende, iron-pyrites, copper-pyrites, galena, cinnabar, grey antimony, and realgar. Sulphydric acid occurs in hepatic mineral waters, and among the products of animal decomposition. Sulphurous acid is a frequent constituent of volcanic emanations, and free sulphuric acid is sometimes found in the waters of volcanic neighbourhoods. Gypsum, cœlestin, and heavy spar constitute well-known minerals; and, in addition to gypsum, the sulphates of magnesium and sodium are very common ingredients of mineral waters. Sulphur exists in the protein-compounds of animal and vegetable organisms, in the taurine of bile, in the cystin of urine, and in the alliaceous volatile oils.

---

* Obtained in needle-shaped crystals by dissolving nitrato-diazobenzoic acid (iv. 294) in sulphuric acid diluted with an equal bulk of water, then adding 3 vols. alcohol and afterwards ether. When heated somewhat above 100°, it is resolved into sulphuric acid, sulphoxybenzoic acid, and a very permanent sulpho-acid, $C^{14}H^{10}SO^8$, which is insoluble in water. (Griess.)

Extraction.—1. Native sulphur is sometimes purified by a rough process of fusion, effected on the spot where it is obtained. A heap is set fire to, whereby the heat evolved from the burning of one portion fuses the remainder. It is more usual, however, to purify it by distillation in upright earthen pots or retorts, set back to back, in two rows, in a long brick furnace. The distillate is received in somewhat similar pots, arranged in two rows outside the furnace, and furnished each with an opening near its base, through which the sulphur condensed within the pot, flows into a pail of water, in which it congeals. The sulphur thus purified by fusion or distillation is known as rough sulphur, and contains about 3 per cent. of foreign matter. It is further purified by redistillation in an iron still. The vapours are sometimes received in a large brick chamber, within which the sulphur condenses in a pulverulent state to constitute flowers of sulphur, or sublimed sulphur; or it is condensed in the liquid state in a smaller and hotter receiver, and is either cast into sticks, when it constitutes roll-sulphur, or is allowed to congeal in mass, when it constitutes refined lump-sulphur.

2. From *Pyrites.*—Sulphur may be obtained by heating disulphide of iron in close vessels, precisely as oxygen is obtained by heating dioxide of manganese under similar conditions:

$$3FeS^2 \quad = \quad Fe^3S^4 \ + \ S^2.$$

Manufactured sulphur is made principally from copper-pyrites, a double sulphide of copper and iron, as a preliminary stage in the process of copper-smelting. Upon a layer of broken pyrites is placed a layer of brushwood, and on this is constructed a huge pyramidal pile of ore, having a central wooden chimney communicating with air-passages left among the brushwood. The whole pile is covered with powdered ore, and the mass set fire to by dropping lighted faggots through the chimney. As the slow combustion of the pile proceeds, sulphur gradually trickles down, and is collected in cavities made extempore in the walls of the heap, whence it is ladled out into moulds. Such a heap, consisting of some 2,000 tons of ore, will continue burning for five or six months, and will yield about 20 tons of rough sulphur, which may be purified by fusion or distillation. Copper-pyrites is sometimes roasted for the extraction of sulphur in a tall-domed furnace, from the summit of which a horizontal flue conveys the sulphur-vapours into a chamber, within which they are condensed. The sulphur obtained from pyrites is partly expelled by heat, partly displaced by oxygen.

3. Sulphur is also prepared in this country from the decomposition, by exposure to air, of the *hydrated sulphide of iron*, resulting from the purification of crude coal-gas with ferric oxide or hydrate:

$$2FeS \ + \ H^2O \ + \ O^3 \quad = \quad 2HFe'''O^2 \ + \ S^2.$$

The hydrate of iron produced in the above reaction is again used to purify the crude gas, whereby it becomes converted into sulphide, and this sulphide is then reconverted into oxide and sulphur by exposure to air as before. These alternate processes are repeated an indefinite number of times, until the amount of sulphur in the material reaches from 40 to 50 per cent., when it is distilled off in iron retorts.

4. From *Alkali-waste.*—Alkali-makers' waste, or tank-waste, consists of sulphide of calcium, together with alkaline sulphides, chalk, lime, &c. (p. 324). This, when decomposed by hydrochloric or carbonic acid, yields a mixture of sulphydric acid and carbonic anhydride; and by introducing an additional quantity of carbonic anhydride, with some atmospheric air or sulphurous anhydride, and heating this mixture of gases to redness, the hydrogen of the sulphydric acid unites with oxygen, forming water, and the sulphur is liberated in the form of uncombined sulphur-vapour, which by cooling becomes condensed to liquid and solid sulphur. (For details of this and the other methods of preparing sulphur, see Richardson and Watts's *Chemical Technology*, vol. i. part iii. pp. 1–27.)

5. Sulphur results from a great number of other reactions, which, however, are not usually employed for its commercial preparation. Thus it may be obtained by decomposing an alkaline polysulphide with an acid; by the decomposition of the chlorides of sulphur with water; by the spontaneous decomposition of hyposulphurous acid; by the ignition of the tri-, tetra-, and penta-thionates, &c.

Properties.—At ordinary temperatures sulphur is a very brittle solid, of a lemon-yellow colour, tasteless from its insolubility in water, and almost inodorous. It is a bad conductor of heat, and a non-conductor of electricity. By friction with wool or hair, it becomes negatively electric. Its specific gravity in the native crystalline state is 2·05. It begins to melt at 114·5°, and at 120° is converted into a perfectly limpid, pale-yellow liquid, which is lighter than solid sulphur. Provided the temperature of 120° has not been much exceeded, it resolidifies suddenly at that same temperature into a transparent mass, which retains its transparency for a long time. By heating sulphur to a temperature much above 120°, its congealing-point is lowered to 111·5°, from the production of a peculiar modification of the element. Sulphur which has been congealed at this low temperature is at first transparent, but becomes opaque much more rapidly than that which has been congealed at 120°. As melted sulphur is gradually heated above 120°, it becomes darker and more viscid, until, at the temperature of 200—250°, it is so thick that the flask in which it is contained may be inverted without any outflow taking place. The temperature of maximum viscidity remains constant for some time, owing to a considerable absorption of latent heat. At from 250—300° and upwards, the sulphur again liquefies, but does not become so fluid as at 115—120° when first melted. On cooling it passes inversely through the same changes of state. Sulphur boils at 440°, and is converted entirely into an orange-coloured vapour. According to Bineau, whose statement has recently been confirmed by Deville and Troost, the density of sulphur-vapour, when taken at the temperature of 1000°, is 32 times as great as that of hydrogen at the same temperature; but its density taken at about 500° is anomalous, being three times as great as it should be theoretically. Sulphur vaporises to a slight extent at ordinary temperatures; so that a piece of silver-leaf, suspended at some distance above a stick of sulphur, becomes slowly transformed into sulphide of silver.

Sulphur is remarkable for the great number of allotropic forms in which it can exist. Of these, however, there are two principal well-characterised varieties, namely, the soluble and insoluble, and many minor modifications. Berthelot distinguishes the soluble variety by the name of electro-negative sulphur, because it is the form which appears at the positive pole of the battery during the electrolysis of sulphydric acid, and is separated from the combinations of sulphur with the electro-positive metals.

Fig. 782.

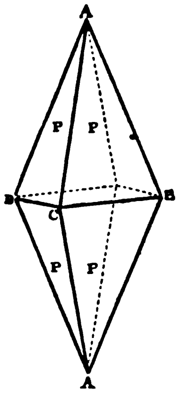


Fig. 783.

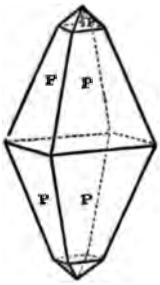

Fig. 784.

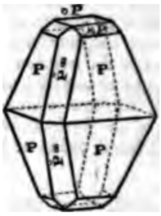


The insoluble variety he distinguishes as electro-positive sulphur, because it is the form which appears at the negative pole during the electrolysis of sulphurous acid, and separates from the compounds of sulphur with the electro-negative elements, chlorine, bromine, oxygen, &c. The following are the most important modifications of soluble sulphur:—

1. The *octahedral* variety, frequently represented by the symbol Sα, which is the most stable, and the one into which all the other varieties, soluble or insoluble, tend to change. It is the form in which native sulphur is found, and in which the crystals of sulphur, obtained by the spontaneous evaporation of its solution in carbonic disulphide, are usually deposited. Its specific gravity is 2·05, and its melting-point, according to Brodie, 114·5°. It is readily soluble in carbonic disulphide, disulphide of chlorine, benzene, turpentine, petroleum, &c.; slightly soluble in alcohol and ether. Its crystalline form is that of an elongated octahedron, belonging to the trimetric or right prismatic system (*fig.* 782), with the modifications shown in *figs.* 783, 784. Axes, $a : b : c = 0·8106 : 1 : 1·898$. Angle, P : P (brach.) = 106° 18′; P : P (macr.) = 84° 58′; P : P (basal) = 143° 17′; P̆∞ : P̆∞ (basal) = 124° 24′. Cleavage imperfect parallel to P and ∞P.

2. The *monoclinic* or *oblique prismatic* variety, often represented by the symbol Sβ, may be obtained by the slow cooling of melted sulphur, or by heating octahedral sulphur for some time to a temperature of 105—115°. If, when a few pounds of melted sulphur have been allowed to cool slowly, until a crust has formed on the surface, that superficial crust be broken, and the still liquid sulphur be poured out from the interior, the solidified walls will be seen to be lined with transparent yellowish-brown needles, crystallised in secondary forms of a monoclinic prism. Axes, $a : b : c = 1{\cdot}004 : 1 : 1{\cdot}004$. Angle $b : c = 84° 14'$; $\infty P : \infty P$ (orthod.) $= 89° 28'$; $[P\infty] : [P\infty]$ (clin.) $= 90° 18'$; $oP : \infty P = 85° 54'$. Ordinary combination $\infty P \,.\, oP$ (like *fig.* 284, ii. 152), with $-P$, $[P\infty]$ and $\infty P\infty$. Twins occur combined by the face $\infty P\infty$. The specific gravity of prismatic sulphur is 1·98. According to Brodie, when free from plastic sulphur, the presence of which lowers its melting-point to 111·5°, it melts and resolidifies at 120°. It dissolves readily in carbonic disulphide and other menstrua. In the course of a few days, this prismatic form of sulphur becomes spontaneously converted into the octahedral variety, the conversion being attended with a development of heat, which is most evident when the change is effected artificially by scratching the crystals. Opaque yellow spots first make their appearance, and then gradually spread throughout the mass. The crystals retain their prismatic shape, but on examination are found to be converted into aggregations of minute octahedrons. Conversely, a transparent crystal of octahedral sulphur, when heated to 105—115°, becomes transformed into an opaque mass of oblique prismatic crystals. When a saturated solution of sulphur in hot turpentine is allowed to cool, the crystals first deposited are of the prismatic, those last deposited (when the liquid has become comparatively cool) of the octahedral variety. Occasionally a few transparent, oblique prismatic crystals are deposited from the solution of sulphur in carbonic disulphide, but they soon break up into opaque aggregations of minute octahedrons. Roll-sulphur when first cast is of the oblique prismatic, but by keeping it changes into the octahedral variety. Its molecular condition, however, is unstable, like that of unannealed glass, whence it retains for a long time the specific gravity of the prismatic modification.

3. The *amorphous soluble* variety of sulphur is precipitated, in the form of white emulsin, on addition of acids to diluted solutions of alkaline polysulphides:

$$K^2S^5 + 2HCl = 2KCl + H^2S + S^4.$$

When examined microscopically, it is found to consist of minute granules devoid of crystalline character. It is readily soluble in carbonic disulphide and other menstrua. This form of sulphur has a greenish-white colour, and is known familiarly by the name of "milk of sulphur." By keeping, it becomes gradually converted into octahedral crystals. Sublimed sulphur appears to be allied to this form. It consists of much larger granules, neither the surface nor the fracture of which is crystalline. Sublimed sulphur always contains a minute proportion of one of the insoluble modifications of the element. Vapour of sulphur, when suddenly cooled by contact with a cold surface, condenses in the form of utricles, or of liquid drops surrounded by solid pellicles. These often retain their liquidity for a considerable time, but, when solidified, seem to have the same character as the granules of sublimed sulphur. By keeping they become crystalline in the octahedral form.

The principal modifications of insoluble sulphur are the following:—1. The *amorphous insoluble* variety, the most stable form of which is obtained as a soft magma, by decomposing disulphide of chlorine with water:

$$2S^2Cl^2 + 3H^2O = 4HCl + H^2S^2O^3 + S^2.$$

The hyposulphurous acid produced in the reaction is gradually decomposed into sulphurous acid and sulphur, thus: $H^2S^2O^3 = H^2SO^3 + S$. The sulphur, resulting in this way from the spontaneous decomposition of hyposulphurous acid, has the same characters as those formed by the original decomposition of the disulphide of chlorine. It may be obtained at once by adding dilute hydrochloric acid to the solution of a hyposulphite. If, in preparing amorphous soluble sulphur by adding an acid to the solution of an ordinary alkaline polysulphide containing some hyposulphite, any excess of acid be added, some of this insoluble variety will also be precipitated. The above form of sulphur has a yellow colour, is insoluble in carbonic disulphide or other menstruum, and is quite amorphous. Closely allied to it are the amorphous insoluble sulphur obtained by exhausting sublimed sulphur with carbonic disulphide and alcohol, and that obtained by exhausting reconverted plastic sulphur with carbonic disulphide. This last is a buff-coloured powder, slightly soluble in anhydrous alcohol. Its specific gravity is 1·95. These varieties are convertible into octahedral sulphur by fusion, or by exposure, for a greater or less length of time, to the temperature of 100°.

2. *Plastic* sulphur, frequently represented by the symbol Sγ, is obtained by heating melted sulphur to the temperature 260—300°, and then cooling it suddenly by pouring

it in a very thin stream into cold water. It is thus obtained as a soft, yellowish-brown, semitransparent mass, capable of being drawn out into fine elastic threads possessed of considerable tenacity. This sulphur has a specific gravity 1·95, and is insoluble in carbonic disulphide. When sulphur heated to 300° is suddenly cooled by a mixture of solid carbonic anhydride and ether, it solidifies into a hard perfectly transparent mass, which becomes soft and elastic at ordinary temperatures. This appears to be the solid state of plastic sulphur. Another form of plastic sulphur may be obtained by acting upon metallic sulphides with boiling nitric or nitromuriatic acid. Ordinary plastic sulphur gradually returns in the course of a few hours to its brittle state, reacquires its yellow colour, and becomes converted almost entirely into the octahedral variety, the conversion being accompanied by evolution of heat. If plastic sulphur be heated to 100°, the change takes place suddenly, and the temperature rises to 110°. According to Brodie, sulphur begins to pass into the plastic state at a temperature very little above 120°; and the gradual loss of transparency in crystallised prismatic sulphur depends upon the hardening of plastic sulphur enclosed mechanically between the crystals. Sulphur which has been converted from the plastic into the brittle state does not dissolve entirely in carbonic disulphide, but, as before observed, leaves a buff-coloured residue of insoluble sulphur, the proportion of which may, it is said, be increased by frequently causing the same sulphur to assume alternately the plastic and the brittle state.

The black and red modifications of sulphur, described by Magnus to result, the former from exhausting, with carbonic disulphide, the mass produced by the frequent alternate strong heating and sudden cooling of sulphur, and the latter from heating the black modification to a temperature of 130—150°, are considered by Mitscherlich to depend upon the presence of greasy impurities in the sulphur. When solutions of sulphydric acid and ferric chloride are mixed together, a blue precipitate is sometimes formed, which is said to be a peculiar allotropic form of sulphur.

Sulphur may be made to combine directly with the great majority of the elements. Hydrogen-gas and sulphur-vapour burn in one another, though not very readily, to form sulphydric acid, H^2S. When molted sulphur is treated with chlorine-gas, disulphide of chlorine, Cl^2S^2, is produced, and similar reactions take place with bromine and iodine. Sulphur is highly inflammable, and when heated in air or oxygen to a temperature of 250°, takes fire, and burns with a clear blue, feebly luminous flame, being converted into sulphurous oxide, SO^2. Carbonic disulphide, CS^2, results from passing sulphur-vapour over red-hot charcoal. Sulphur also unites directly with phosphorus, arsenic, silicon, and boron. Nearly all the metals combine directly with sulphur, either at ordinary or increased temperatures. Zinc, iron, copper, lead, silver, tin, &c., burn in sulphur-vapour with great brilliancy, the combustion, save of the zinc and iron, commencing spontaneously, provided the metal is in a sufficiently divided state. Moreover, mixtures of sulphur, water, and finely-divided metal—iron or copper, for instance—begin to react at ordinary temperatures, evolve a considerable amount of heat, and yield hydrated protosulphide. Sulphur, when acted on by strong nitric or nitromuriatic acid, at a gentle heat, is gradually dissolved, with production of sulphuric acid, H^2SO^4. Caustic alkalis also dissolve sulphur readily, with formation of metallic sulphydrate and hyposulphite, thus:

$$4KHO + S^4 = 2KHS + H^2O + K^2S^2O^3.$$

The two atoms of sulphydrate thus produced are capable of dissolving four additional atoms of sulphur to form a metallic pentasulphide and sulphydric acid: $2KHS + S^4 = K^2S^5 + H^2S$.

Sulphur in its chemical relations is the representative of oxygen, to which it is equivalent, atom to atom. The two elements, though very dissimilar in their ordinary physical characters, correspond very closely in the nature of the compounds which they form, and in the properties they exhibit when both are in the gaseous state. Although sulphur rarely, if ever, displaces oxygen by direct elementary substitution, yet the two elements are mutually interchangeable by double decomposition of their respective compounds; and in the great majority of instances where oxygen-compounds are obtainable by addition of oxygen, analogous sulphur-compounds are obtainable by the addition of sulphur. Thus, when cyanide of potassium, KCN, is treated with peroxides, we obtain oxycyanate of potassium, KCNO; and by treating it with sulphur, or persulphides, we obtain sulphocyanate of potassium, KCNS. Again, oxygen-gas and sulphur-vapour alike support the combustion of hydrogen, charcoal, phosphorus, and the metals, to form precisely analogous compounds. The following are a few illustrations of the number and variety of corresponding compounds to which oxygen and sulphur respectively give origin:

$$KHO,\quad CO^2,\quad C^2H^6O,\quad Cl^3PO,\quad K^3PO^4,\quad Sb^2OS^2,\quad K^2SnO^3,\quad \&c.$$
$$KHS,\quad CS^2,\quad C^2H^6S,\quad Cl^3PS,\quad K^3PO^3S,\quad Sb^2S^3,\quad K^2SnS^3,\quad \&c.$$

An atom of sulphur, being the equivalent of an atom of oxygen, is necessarily the equivalent of two atoms of hydrogen or chlorine. Thus the chloride and sulphide of triethylphosphine, Et^3PCl^2 and Et^3PS respectively, made by acting upon triethylphosphine, Et^3P, by chlorine and sulphur respectively, are the strict representatives of one another, and so in other instances. Certain sulphur-compounds, moreover, manifest a great resemblance to those of carbon. (Odling's *Manual of Chemistry.*)

SULPHUR, BROMIDES OF. Sulphur dissolves in bromine at ordinary temperatures without perceptible evolution of heat, and forms a brown-red liquid, containing, according to Löwig, the compound Br^2S^2, which is decomposed by distillation, half of the sulphur being separated, and the compound Br^2S distilling over. Neither of these compounds has, however, been obtained in definite form, as they appear to be capable of dissolving both sulphur and bromine—the latter, indeed, in all proportions. The brown-red solution of sulphur in bromine smells like disulphide of chlorine, and reacts in a similar manner with water, nitric acid, ammonia, &c. (Gm. ii. 283.)

SULPHUR, CHLORIDES OF, or **SULPHIDES OF CHLORINE.** Sulphur and chlorine unite directly even at ordinary temperatures, more quickly, however, when sulphur is sublimed in an atmosphere of chlorine. Only one compound of these elements has been obtained pure in the free state—viz. the disulphide of chlorine, Cl^2S^2, analogous to disulphide of hydrogen. — A protosulphide of chlorine, Cl^2S, analogous to sulphydric acid, is usually described as produced by treating the disulphide with excess of chlorine; but, according to the recent experiments of Carius, it is merely a mixture of the disulphide with the hemisulphide of chlorine, or tetrachloride of sulphur, Cl^4S. This last-mentioned compound is not known in the free state, but exists, according to H. Rose, in combination with several metallic chlorides.

Disulphide of Chlorine, Cl^2S^2. *Protochloride of Sulphur. Halb-Chlorschwefel. Chlorschwefel im Minimum.*—This compound was first described in 1804 by Thomson (Nicholson's Journal, vi. 96), and by Berthelot (Mém. d'Arcueil, i. 161)—the mutual action of chlorine and sulphur having been previously noticed by Hagemann, in 1781—and has been more particularly examined by H. Rose (Pogg. Ann. xxi. 431; xxiv. 303; xxvii. 107; xlii. 517, 542), Dumas (Ann. Ch. Phys. xlix. 204), Marchand (J. pr. Chem. xxii. 507), Heintz (Ann. Ch. Pharm. c. 370), and Carius (*ibid.* cvi. 291; cx. 209).

Disulphide of chlorine is prepared by passing dry chlorine-gas into a retort in which sulphur is sublimed at a gentle heat. It then distils over, and may be collected in a receiver surrounded by cold water, and freed from excess of sulphur by rectification. —It is also produced by distilling a mixture of 1 pt. sulphur with 9 pts. stannic chloride, or 8·5 pts. mercuric chloride. (Berzelius.)

Disulphide of chlorine is a mobile reddish-yellow liquid, having a peculiar, penetrating, disagreeable odour, and fuming strongly in the air. Specific gravity = 1·687. Boils at 139° (Marchand), at 136° (Chevrier, Compt. rend. lxiv. 304). Vapour-density, obs. = 4·77 (Marchand); calc. = 4·68.

It dissolves in carbonic disulphide, alcohol, and ether, not however without decomposition in the two latter. It dissolves sulphur in large quantities, especially when heated. When saturated with sulphur at ordinary temperatures, it forms a clear yellow liquid of specific gravity 1·7, and containing altogether 66·7 per cent. sulphur. The solution of disulphide of chlorine with excess of sulphur in crude benzol, is used for vulcanising or sulphurising caoutchouc.

Reactions.—1. With chlorine, bromine, and iodine.—When *chlorine-gas* is passed for several days in the dark through disulphide of chlorine, a dark brown-red liquid is formed, from which (according to Davy, Dumas, and Marchand) a certain quantity of chlorine may be expelled by gentle ebullition, leaving the protosulphide of chlorine, Cl^2S, which boils constantly at 64°. According to Carius, on the other hand, the boiling-point continually rises during the distillation, and does not become constant till it has risen to 138°, at which temperature disulphide of chlorine passes over. The brown-red liquid is also converted into the reddish-yellow disulphide by passing a stream of dry air through it. At a certain stage of the distillation, a dark brown-red liquid passes over, containing sulphur and chlorine in the proportion required by the formula Cl^2S; but it acts with metals and other bodies like a mixture of the compounds Cl^2S^2 and SCl^4. Hence Carius concludes that the so-called protosulphide of chlorine (or dichloride of sulphur) is not a definite compound, but a mixture, in atomic proportions, of the two compounds just mentioned: $Cl^2S^2 + SCl^4 = 3Cl^2S$. Carius has further shown that, by passing dry chlorine through the disulphide of chlorine at various temperatures, liquids are produced, containing various proportions of sulphur and chlorine, both above and below those required by the formula

In the first case, however, the occurrence of the sulphurous chloride, $SOCl^2$, is, for the most part, masked by the formation of secondary products, as of sulphurous anhydride—thus:

$$SOCl^2 + C^7H^5O.Na.O = NaCl + C^7H^5OCl + SO^2.$$

Acetate of sodium is decomposed by tetrachloride of sulphur in the same manner as the benzoate, but the chloride of acetyl produced acts on another portion of the sodic benzoate, forming acetic anhydride.

The compounds of tetrachloride of sulphur with metallic chlorides are obtained, for the most part, by passing chlorine-gas over the respective sulphides.—The *aluminium-compound*, $2AlCl^3.SCl^4$, is produced by gently heating chloride of aluminium with disulphide of chlorine, and passing chlorine over the resulting dark-red mass at a somewhat higher temperature. A yellow oily liquid is thus obtained, which ultimately solidifies to a crystalline mass. It is decomposed by water, with great evolution of heat, yielding free sulphur, alumina, hydrochloric, sulphuric, and hyposulphurous acids (R. Weber, Pogg. Ann. civ. 421).—The *antimony-compound*, $2SbCl^5.3SCl^4$, obtained by heating grey sulphide of antimony in a stream of chlorine, is a white amorphous powder, which melts when heated, and is resolved into disulphide of chlorine, free chlorine, and trichloride of antimony. It is oxidised and dissolved by nitric acid, and absorbs ammonia in somewhat considerable quantity (H. Rose, Pogg. Ann. xlii. 532).—The *tin-compound*, $SnCl^4.2SCl^4$, produced by the action of chlorine on stannic sulphide, forms fine large crystals, which fume strongly in the air; may be fused and sublimed without decomposition; are gradually dissolved by nitric acid, with formation of stannic oxide and sulphuric acid; form with water an acid liquid, milky from separated sulphur; and absorb ammonia-gas, with considerable evolution of heat, forming a yellow-brown mass which is decomposed by water (H. Rose, Pogg. Ann. xlii. 517).—A *titanium-compound* of uncertain composition, but apparently containing less than 2 at. SCl^4 to 1 at. $TiCl^4$, is produced by mixing titanic chloride with brown chloride of sulphur, or by passing chlorine-gas over titanic sulphide. The first process yields it in large yellow crystals; the second only as a crystalline mass. It deliquesces rapidly in contact with the air, melts when heated, solidifies in the crystalline state on cooling, and sublimes without decomposition. (H. Rose, *ibid.* p. 527.)

SULPHUR, CYANIDE OF. See SULPHOCYANIC ANHYDRIDE (p. 515).

SULPHUR, DETECTION AND ESTIMATION OF. 1. *Reactions.*—The most important compounds in which sulphur occurs are the metallic sulphides, sulphates, sulphites and hyposulphites, and certain organic compounds.

Most metallic sulphides are insoluble in water; those of the alkali-metals and alkaline earth-metals, however, dissolve in water—the former undecomposed, the latter with partial decomposition (p. 483). The solutions give with lead-salts, &c., the reactions of sulphydric acid (i. 217; iii. 204). Sulphides heated on charcoal in the oxidising blowpipe-flame give off all their sulphur as sulphurous anhydride, which may be detected by its odour; or if the sulphide be heated in an inclined glass tube open at both ends, so that a current of air may pass over it, sulphurous anhydride will also be formed, and may be detected by its odour, acid reaction, &c. (p. 540). On fusing a sulphide on charcoal with sodic carbonate or a mixture of that salt and borax, placing the piece of charcoal containing the fused mass on a plate of polished silver, and moistening it, a black or brown stain of sulphide will be formed on the metal. Metallic sulphides, acted upon by strong nitric or nitromuriatic acid, are rapidly oxidised, forming metallic oxide or chloride, sulphuric acid, and usually some free sulphur, which melts into globules very difficult to oxidise.

Metallic sulphates are, for the most part, easily soluble in water; the sulphates of strontium, calcium, lead, and mercurosum are but slightly soluble, and the barium-salt is almost insoluble in water, and likewise in hydrochloric and nitric acid. In soluble sulphates, therefore, sulphuric acid is easily detected by addition of chloride or nitrate of barium, which forms a precipitate insoluble in acids. In insoluble or sparingly soluble sulphates, the sulphuric acid is detected by boiling the salt with a concentrated solution of an alkaline carbonate, whereby an alkaline sulphate is formed, which dissolves in the water. Sulphates heated before the blowpipe on charcoal with sodic carbonate, yield sulphide of sodium, in which the sulphur may be detected in the manner above mentioned. (See SULPHATES).

The sulphites of the alkali-metals are soluble in water; the rest are insoluble or sparingly soluble, but dissolve in excess of sulphurous acid. Sulphites are easily detected by the characteristic odour of sulphurous anhydride, which they evolve when treated with hydrochloric or, better, with dilute sulphuric acid. Hyposulphites treated in the same way also give off sulphurous anhydride, but are distinguished from sulphites by likewise yielding a deposit of sulphur. (See SULPHUR, OXYGEN-ACIDS OF.)

According to W. F. Barrett (Phil. Mag. [4] xxx. 321), sulphur in the free state, and in certain states of combination, may be detected in solids, and in some liquids, by directing a flame of pure hydrogen upon a point of the surface, whereupon, if sulphur is present, even in very minute quantity, a deep blue luminous ring will be formed round the heated point. This effect is produced with free sulphur, with all metallic sulphides, with sulphuric acid, and certain sulphates, especially alum (probably in consequence of reduction), but not with sulphate of sodium and certain others. By this method sulphur has been detected in atmospheric dust.

2. *Quantitative Estimation and Separation.*—Sulphur is almost always estimated in the form of sulphuric acid. To determine the quantity of sulphur in a metallic sulphide, the compound is heated with *nitric* or *nitromuriatic acid*, or sometimes with a mixture of hydrochloric acid and potassic chlorate, till the metal is oxidised, and the sulphur converted into sulphuric acid. The solution is then treated with chloride or nitrate of barium, and the precipitated sulphate of barium is collected on a filter, washed, dried, and ignited. Before adding the baryta-solution, however, the liquid must be considerably diluted with water, because the nitrate and chloride of barium are themselves insoluble in strong nitric and hydrochloric acids. The liquid is then boiled, and afterwards left to stand till the precipitate has completely settled down; after which the clear liquid is first passed through the filter, and then the precipitate thrown upon it; if the precipitate be poured upon the filter before it has settled down, it will be sure to run through. As the oxidation of the sulphur is very slow, the metal being completely oxidised and dissolved long before it, and a portion of the sulphur separated in the free state, it is sometimes convenient to collect this portion on a small weighed filter, determine its amount by direct weighing, and afterwards estimate the dissolved portion as above. The nitric or nitromuriatic acid used for the oxidation should be strong, and the action aided by heat; otherwise, especially in treating the sulphide of manganese, the lower sulphides of iron, and the sulphides of the alkali-metals, part of the sulphur may be driven off as sulphydric acid, and thereby lost. For the same reason, on oxidising with chlorate of potassium and hydrochloric acid, the acid must not be poured at once on to the pulverised sulphide, but gradually added to the mixture of the sulphide with the chlorate of potassium. In applying these methods of oxidation to the sulphides of the alkali-metals and alkaline earth-metals, part of the sulphur is sure to escape as sulphydric acid, unless very particular precautions are taken. The only sure method of guarding against this source of error is to place the sulphide in a small test-tube enclosed in a capacious flask, pour fuming nitric acid upon it, and immediately close the vessel with a tight-fitting stopper.

Another general method of analysing metallic sulphides is, to fuse them with 3 pts. of *potassic* or *sodic nitrate*, and about the same weight of *sodic carbonate*, whereby the sulphur is converted into sulphuric acid, which unites with the alkali, and the metals are converted into oxides. The fused mass is digested with water; the filtered solution neutralised with nitric acid; the sulphur precipitated therefrom as sulphate of barium; and the residual oxides dissolved in hydrochloric or nitric acid.

By the methods just described, the metals are obtained in solution as nitrates or chlorides, and may be separated and estimated by the methods proper for each. Certain special cases may here be noticed. Native sulphide of lead (galena), if not mixed with other sulphides, is best analysed by treating the finely pulverised mass with fuming nitric acid, whereby the lead-sulphide is completely converted into sulphate, and weighing the latter. If, however, other sulphides are present, it is best to fuse the mineral with saltpetre. The use of hydrochloric acid and chlorate of potassium is not advisable, because chloride of lead would be formed as well as sulphate.—Sulphide of bismuth must be oxidised with pure nitric acid, because the presence of hydrochloric acid interferes with the quantitative estimation of bismuth.—Sulphide of silver must also be oxidised with pure nitric acid, and the silver first precipitated from the solution as chloride, then the sulphur from the filtrate as sulphate of barium.

The analysis of fahl-ores, which contain sulphide of arsenic or antimony, or both, in combination with one or more of the sulphides of copper, silver, mercury, iron, and zinc, is generally effected by the following method. The finely powdered mineral is introduced into a double bulb-tube, one end of which is bent at a right-angle, care being taken that all the mineral is contained in the bulb which is farthest from the bent end. The straight end of the tube is then connected with an apparatus for the evolution of perfectly dry chlorine; and the bent end is introduced air-tight into a receiver—which may be a large U-tube—containing a mixture of dilute hydrochloric and tartaric acids; a bent tube is connected with the other end of the U-tube, by which the excess of chlorine is conducted into methylated spirit. The bulb-tube should not be attached to the chlorine apparatus, till all the atmospheric air has been driven out of the latter. A very slow stream of chlorine is then passed through the tube, which decomposes the

In the first case, however, the occurrence of the sulphurous chloride, $SOCl^2$, is, for the most part, masked by the formation of secondary products, as of sulphurous anhydride—thus:

$$SOCl^2 + C^7H^5O.Na.O = NaCl + C^7H^5OCl + SO^2.$$

Acetate of sodium is decomposed by tetrachloride of sulphur in the same manner as the benzoate, but the chloride of acetyl produced acts on another portion of the sodic benzoate, forming acetic anhydride.

The compounds of tetrachloride of sulphur with metallic chlorides are obtained, for the most part, by passing chlorine-gas over the respective sulphides.—The *aluminium-compound*, $2AlCl^3.SCl^4$, is produced by gently heating chloride of aluminium with disulphide of chlorine, and passing chlorine over the resulting dark-red mass at a somewhat higher temperature. A yellow oily liquid is thus obtained, which ultimately solidifies to a crystalline mass. It is decomposed by water, with great evolution of heat, yielding free sulphur, alumina, hydrochloric, sulphuric, and hyposulphurous acids (R. Weber, Pogg. Ann. civ. 421).—The *antimony-compound*, $2SbCl^5.3SCl^4$, obtained by heating grey sulphide of antimony in a stream of chlorine, is a white amorphous powder, which melts when heated, and is resolved into disulphide of chlorine, free chlorine, and trichloride of antimony. It is oxidised and dissolved by nitric acid, and absorbs ammonia in somewhat considerable quantity (H. Rose, Pogg. Ann. xlii. 532).—The *tin-compound*, $SnCl^4.2SCl^4$, produced by the action of chlorine on stannic sulphide, forms fine large crystals, which fume strongly in the air; may be fused and sublimed without decomposition; are gradually dissolved by nitric acid, with formation of stannic oxide and sulphuric acid; form with water an acid liquid, milky from separated sulphur; and absorb ammonia-gas, with considerable evolution of heat, forming a yellow-brown mass which is decomposed by water (H. Rose, Pogg. Ann. xlii. 517).—A *titanium-compound* of uncertain composition, but apparently containing less than 2 at. SCl^4 to 1 at. $TiCl^4$, is produced by mixing titanic chloride with brown chloride of sulphur, or by passing chlorine-gas over titanic sulphide. The first process yields it in large yellow crystals; the second only as a crystalline mass. It deliquesces rapidly in contact with the air, melts when heated, solidifies in the crystalline state on cooling, and sublimes without decomposition. (H. Rose, *ibid.* p. 527.)

SULPHUR, CYANIDE OF. See SULPHOCYANIC ANHYDRIDE (p. 515).

SULPHUR, DETECTION AND ESTIMATION OF. 1. *Reactions.*—The most important compounds in which sulphur occurs are the metallic sulphides, sulphates, sulphites and hyposulphites, and certain organic compounds.

Most metallic sulphides are insoluble in water; those of the alkali-metals and alkaline earth-metals, however, dissolve in water—the former undecomposed, the latter with partial decomposition (p. 483). The solutions give with lead-salts, &c., the reactions of sulphydric acid (i. 217; iii. 204). Sulphides heated on charcoal in the oxidising blowpipe-flame give off all their sulphur as sulphurous anhydride, which may be detected by its odour; or if the sulphide be heated in an inclined glass tube open at both ends, so that a current of air may pass over it, sulphurous anhydride will also be formed, and may be detected by its odour, acid reaction, &c. (p. 540). On fusing a sulphide on charcoal with sodic carbonate or a mixture of that salt and borax, placing the piece of charcoal containing the fused mass on a plate of polished silver, and moistening it, a black or brown stain of sulphide will be formed on the metal. Metallic sulphides, acted upon by strong nitric or nitromuriatic acid, are rapidly oxidised, forming metallic oxide or chloride, sulphuric acid, and usually some free sulphur, which melts into globules very difficult to oxidise.

Metallic sulphates are, for the most part, easily soluble in water; the sulphates of strontium, calcium, lead, and mercurosum are but slightly soluble, and the barium-salt is almost insoluble in water, and likewise in hydrochloric and nitric acid. In soluble sulphates, therefore, sulphuric acid is easily detected by addition of chloride or nitrate of barium, which forms a precipitate insoluble in acids. In insoluble or sparingly soluble sulphates, the sulphuric acid is detected by boiling the salt with a concentrated solution of an alkaline carbonate, whereby an alkaline sulphate is formed, which dissolves in the water. Sulphates heated before the blowpipe on charcoal with sodic carbonate, yield sulphide of sodium, in which the sulphur may be detected in the manner above mentioned. (See SULPHATES).

The sulphites of the alkali-metals are soluble in water; the rest are insoluble or sparingly soluble, but dissolve in excess of sulphurous acid. Sulphites are easily detected by the characteristic odour of sulphurous anhydride, which they evolve when treated with hydrochloric or, better, with dilute sulphuric acid. Hyposulphites treated in the same way also give off sulphurous anhydride, but are distinguished from sulphites by likewise yielding a deposit of sulphur. (See SULPHUR, OXYGEN-ACIDS OF.)

According to W. F. Barrett (Phil. Mag. [4] xxx. 321), sulphur in the free state, and in certain states of combination, may be detected in solids, and in some liquids, by directing a flame of pure hydrogen upon a point of the surface, whereupon, if sulphur is present, even in very minute quantity, a deep blue luminous ring will be formed round the heated point. This effect is produced with free sulphur, with all metallic sulphides, with sulphuric acid, and certain sulphates, especially alum (probably in consequence of reduction), but not with sulphate of sodium and certain others. By this method sulphur has been detected in atmospheric dust.

2. *Quantitative Estimation and Separation.*—Sulphur is almost always estimated in the form of sulphuric acid. To determine the quantity of sulphur in a metallic sulphide, the compound is heated with *nitric* or *nitromuriatic acid*, or sometimes with a mixture of hydrochloric acid and potassic chlorate, till the metal is oxidised, and the sulphur converted into sulphuric acid. The solution is then treated with chloride or nitrate of barium, and the precipitated sulphate of barium is collected on a filter, washed, dried, and ignited. Before adding the baryta-solution, however, the liquid must be considerably diluted with water, because the nitrate and chloride of barium are themselves insoluble in strong nitric and hydrochloric acids. The liquid is then boiled, and afterwards left to stand till the precipitate has completely settled down; after which the clear liquid is first passed through the filter, and then the precipitate thrown upon it; if the precipitate be poured upon the filter before it has settled down, it will be sure to run through. As the oxidation of the sulphur is very slow, the metal being completely oxidised and dissolved long before it, and a portion of the sulphur separated in the free state, it is sometimes convenient to collect this portion on a small weighed filter, determine its amount by direct weighing, and afterwards estimate the dissolved portion as above. The nitric or nitromuriatic acid used for the oxidation should be strong, and the action aided by heat; otherwise, especially in treating the sulphide of manganese, the lower sulphides of iron, and the sulphides of the alkali-metals, part of the sulphur may be driven off as sulphydric acid, and thereby lost. For the same reason, on oxidising with chlorate of potassium and hydrochloric acid, the acid must not be poured at once on to the pulverised sulphide, but gradually added to the mixture of the sulphide with the chlorate of potassium. In applying these methods of oxidation to the sulphides of the alkali-metals and alkaline earth-metals, part of the sulphur is sure to escape as sulphydric acid, unless very particular precautions are taken. The only sure method of guarding against this source of error is to place the sulphide in a small test-tube enclosed in a capacious flask, pour fuming nitric acid upon it, and immediately close the vessel with a tight-fitting stopper.

Another general method of analysing metallic sulphides is, to fuse them with 3 pts. of *potassic* or *sodic nitrate*, and about the same weight of *sodic carbonate*, whereby the sulphur is converted into sulphuric acid, which unites with the alkali, and the metals are converted into oxides. The fused mass is digested with water; the filtered solution neutralised with nitric acid; the sulphur precipitated therefrom as sulphate of barium; and the residual oxides dissolved in hydrochloric or nitric acid.

By the methods just described, the metals are obtained in solution as nitrates or chlorides, and may be separated and estimated by the methods proper for each. Certain special cases may here be noticed. Native sulphide of lead (galena), if not mixed with other sulphides, is best analysed by treating the finely pulverised mass with fuming nitric acid, whereby the lead-sulphide is completely converted into sulphate, and weighing the latter. If, however, other sulphides are present, it is best to fuse the mineral with saltpetre. The use of hydrochloric acid and chlorate of potassium is not advisable, because chloride of lead would be formed as well as sulphate.—Sulphide of bismuth must be oxidised with pure nitric acid, because the presence of hydrochloric acid interferes with the quantitative estimation of bismuth.—Sulphide of silver must also be oxidised with pure nitric acid, and the silver first precipitated from the solution as chloride, then the sulphur from the filtrate as sulphate of barium.

The analysis of fahl-ores, which contain sulphide of arsenic or antimony, or both, in combination with one or more of the sulphides of copper, silver, mercury, iron, and zinc, is generally effected by the following method. The finely powdered mineral is introduced into a double bulb-tube, one end of which is bent at a right-angle, care being taken that all the mineral is contained in the bulb which is farthest from the bent end. The straight end of the tube is then connected with an apparatus for the evolution of perfectly dry chlorine; and the bent end is introduced air-tight into a receiver—which may be a large U-tube—containing a mixture of dilute hydrochloric and tartaric acids; a bent tube is connected with the other end of the U-tube, by which the excess of chlorine is conducted into methylated spirit. The bulb-tube should not be attached to the chlorine apparatus, till all the atmospheric air has been driven out of the latter. A very slow stream of chlorine is then passed through the tube, which decomposes the fahl-ore, with considerable evolution of heat; and when the bulb containing the mineral has cooled, it is gently heated in order to separate the volatile chlorides, which must be driven beyond the space between the two bulbs. Those elements which are volatilised as chlorides are *sulphur*, *arsenic*, *antimony*, *mercury*, part of the *iron*, (and, if too strong a heat has been applied, some of the *zinc*): those which remain in the bulb as non-volatile chlorides, are *copper*, *silver*, *zinc*, and the greater part of the *iron*.

For the analysis of the volatile chlorides, the bulb-tube is divided between the two bulbs, and the portion containing the sublimate is covered with a wide tube, closed at one end, and moistened on the inside with water, in which position it is left for 24 hours. The sublimate thus absorbs water gradually, and may then be dissolved out by water, without the evolution of heat and probable loss which would ensue if this precaution were neglected. The tube being thoroughly rinsed out, the solution is added to the liquid in the receiver, any sulphur that separates is filtered off, and any antimony that separates is dissolved by heat. The acid solution is then saturated with sulphydric acid, the washed precipitate digested with sulphide of ammonium, and the undissolved sulphide of mercury collected on a filter, dried at 100°, and weighed ($Hg''S : Hg = 29 : 25$). The sulphides of antimony and arsenic are precipitated from the sulphide of ammonium solution by dilute sulphuric acid, and the metals separated in the manner described under ARSENIC (i. 368). The filtrate (containing tartaric acid) is neutralised with ammonia; sulphide of ammonium added; the precipitated sulphide of iron filtered off, washed with water containing sulphydric acid, and dissolved in hydrochloric acid; the solution heated with nitric acid; and the iron precipitated by ammonia.

The bulb containing the non-volatile chlorides is digested with dilute hydrochloric acid, till only chloride of silver remains undissolved; this is weighed as described at p. 298. From the solution the copper is precipitated by sulphydric acid; and the iron and zinc are separated as described under IRON (iii. 386).

The sulphur is best estimated, in a separate portion of the ore, by fusion with 8 pts. chlorate of potassium and 3 pts. carbonate of sodium.

This mode of analysis is applicable to bournonite (sulphides of antimony, lead, and copper), red silver-ore (sulphides of antimony or arsenic and silver), and other minerals resembling fahl-ores in composition. When *lead* is present, the chlorides must be distilled at a very gentle heat, so that the lead may remain with the non-volatile chlorides; and when these chlorides are treated with dilute hydrochloric acid, a large quantity of water must be added, to insure the complete solution of the plumbic chloride. (Conington's *Handbook of Chemical Analysis*, p. 218.)

The sulphides of the alkali-metals and alkaline earth-metals are sometimes analysed by decomposing them with hydrochloric acid, receiving the evolved sulphydric acid in a solution of acetate of lead, oxidising the precipitated sulphide of lead with fuming nitric acid, weighing the sulphate of lead thus produced, and thence calculating the quantity of sulphur. In the sulphides of gold and platinum, from which the sulphur is completely expelled by ignition, its amount may be determined by weighing the residual metal.

From all non-metallic elements, except selenium and tellurium, sulphur may be separated in the same way as from the metals, viz., by oxidation to sulphuric acid, and precipitation as barium-sulphate. The methods of separating it from selenium and tellurium are given under SELENIUM (p. 225).

The sulphur in organic compounds may likewise be estimated by oxidising the compound with fuming nitric acid, and precipitating the resulting sulphuric acid with a baryta-solution (i. 247). Another method, given by W. J. Russell (Chem. Soc. Qu. J. vii. 212), is to burn the substance in a combustion-tube with oxide of mercury, carbonate of sodium being added to take up the sulphuric acid produced, and a small bent tube dipping under water fitted into the open end of the combustion-tube, so that any acid vapours that escape may be condensed in the water. At the end of the combustion, this liquid is acidulated with hydrochloric acid, the tube washed out with the acid solution, the liquid filtered, and the sulphuric acid precipitated by chloride of barium.

The quantity of sulphuric acid in a soluble sulphate is estimated by precipitating the aqueous solution with chloride of barium. Some sulphates which are insoluble in water, may be dissolved in hydrochloric or nitric acid, and the baryta-solution then added. The sulphates of calcium, strontium, and lead may be decomposed by boiling with a solution of sodic carbonate, and the sulphuric acid precipitated by chloride of barium from the filtered solution previously acidulated with nitric or hydrochloric acid. Sulphate of barium may be analysed by fusing it in a platinum crucible with three times its weight of sodic carbonate; the fused mass digested in water; the filtered soda-solution acidulated; and the sulphuric acid precipitated as above.

Sulphurous and hyposulphurous acid may be estimated by oxidation with nitric acid, whereby they are converted into sulphuric acid; or by Bunsen's iodometric method (i. 265).

3. *Atomic Weight of Sulphur.*—**Berzelius** in 1818 (*Lehrbuch*, v. 1187), determined the atomic weight of sulphur from the quantity of plumbic sulphate ($Pb''SO^4$) produced by treating a known weight of pure lead with nitric and sulphuric acids. 100 pts. of lead yielded from 146·380 to 146·458, or on the average, 146·419 $PbSO^3$: whence (for Pb = 207) S = 32·18. Subsequently (1845), Berzelius obtained nearly the same result by determining the quantity of silver-sulphide produced by decomposing a known weight of the chloride with dry sulphydric acid gas. In four experiments he found (for Ag = 108 and Cl = 35·46), S = 32·1. The same number was found by **Svanberg** and **Struve** (J. pr. Chem. xliv.) from a single experiment made in the same manner. **Erdmann** and **Marchand** in 1844 (J. pr. Chem. xxxi. 396), by heating pure cinnabar in hydrogen gas, obtained from 100 pts. of the sulphide, in four experiments, 86·205 to 86·222 pts., mean 86·211 pts. of mercury: hence (for Hg = 200), S = 32·005. **Struve** in 1852 (Ann. Ch. Pharm. lxxx. 203) by reducing argentic sulphate with hydrogen, obtained, as a mean of six experiments, S = 32. **Dumas** in 1859 (Ann. Ch. Pharm. cxiii. 20), by converting a known weight of silver into sulphide, Ag^2S, obtained S = 32·01; and lastly, **Stas** in 1860 (*Recherches sur les rapports réciproques des poids atomiques*) by heating silver in a stream of pure sulphur-vapour or pure sulphydric acid gas, obtained as a mean of five experiments, from 100 pts. silver, 114·8522 argentic sulphide: whence S = 32·07.

All these results come so near to the whole number 32, that this number may be used in calculation without sensible error.

SULPHUR, FLUORIDE OF. According to Davy and Dumas, a compound of fluorine and sulphur is obtained by distilling fluoride of lead or fluoride of mercury with sulphur.

SULPHUR, IODIDES OF. Iodine and sulphur combine when heated together even under water. The resulting compound, I^2S^2, is a blackish-grey radio-crystalline mass, resembling native sulphide of antimony. It decomposes at higher temperatures, gives off iodine on exposure to the air, and is insoluble in water.—By heating 2 at. iodine with 1 at. sulphur, a compound is obtained which smells like iodine, and is said to be a powerful remedy in skin diseases.—A cinnabar-red iodide of sulphur is obtained, according to Grosourdi, by precipitating trichloride of iodine with sulphydric acid.

SULPHUR, OXIDES AND OXYGEN-ACIDS OF. Sulphur forms two oxides, viz. **sulphurous oxide or anhydride**, SO^2, and **sulphuric oxide or anhydride**, SO^3. Sulphurous oxide is produced by the combustion of sulphur in air or oxygen-gas: and sulphuric oxide may be formed by passing a mixture of dry sulphurous oxide and oxygen or air over heated spongy platinum. Each of these oxides unites with 1 at. water, forming respectively **sulphurous acid**, $H^2O.SO^2 = H^2SO^3$, and **sulphuric acid**, $H^2O.SO^3 = H^2SO^4$.

These two acids may be regarded as oxides of sulphydric acid, H^2S. A complete series of oxidised compounds of sulphydric acid would comprise the following members, corresponding to the oxides of hydrochloric acid (i. 907):

Sulphydric acid,	H^2S.	Hydrochloric acid,	HCl.
————	H^2SO.	Hypochlorous acid,	HClO.
————	H^2SO^2.	Chlorous acid,	$HClO^2$.
Sulphurous acid,	H^2SO^3.	Chloric acid,	$HClO^3$.
Sulphuric acid,	H^2SO^4.	Perchloric acid,	$HClO^4$.

The first and second members of the sulphur series of oxygen-compounds are at present unknown, but we are acquainted with their chloro-derivatives, **sulphurous chloride, or chloride of thionyl**, Cl^2SO, and **sulphuric chloride, or chloride of sulphuryl**, Cl^2SO^2.

The chlorine acids are monobasic, or contain but one atom of replaceable hydrogen; but the sulphur-acids are dibasic, or contain two atoms of hydrogen replaceable by metals; both sulphurous and sulphuric acids are accordingly capable of forming neutral, acid, and double salts.

Sulphurous and sulphuric acids can be formed from the anhydrides by direct hydration, and the anhydrides from the acids by direct dehydration.

Sulphurous and sulphuric acids can both be obtained by the direct oxidation of sulphydric acid; and conversely, metallic sulphides can be formed by the deoxidation of sulphites and sulphates. Sulphurous acid, moreover, very readily affords sulphydric acid by deoxidation.

Sulphurous and sulphuric acids are convertible into one another by oxidation and deoxidation respectively.

Sulphurous and sulphuric chlorides, $SOCl^2$ and SO^2Cl^2, yield sulphurous and sulphuric acids respectively by treatment with water [replacement of Cl^2 by $(HO)^2$], and may be reproduced from those acids by the action of pentachloride of phosphorus. They may also be produced from the chlorides of sulphur (p. 534).

Allied to the sulphates there is a group of salts called thiosulphates or more frequently hyposulphites. Their composition is that of sulphates (M^2SO^4), in which 1 at. oxygen is replaced by sulphur, their general formula being $M^2S^2O^3$. When a sulphite, such as Na^2SO^3, is acted upon by oxygen or a peroxidised substance, it becomes an oxysulphate, Na^2SO^4; when acted upon by sulphur or a persulphuretted substance, it becomes a thiosulphate, $Na^2S^2O^3$.

There is also a remarkable series of acids called polythionic acids containing six atoms of oxygen and two or more atoms of sulphur, viz.:

$H^2S^2O^6$ Dithionic acid.
$H^2S^3O^6$ Trithionic acid.
$H^2S^4O^6$ Tetrathionic acid.
$H^2S^5O^6$ Pentathionic acid.

The corresponding anhydrides are not known.

The dithionates (also called *hyposulphates*) are formed directly from sulphurous anhydride and a metallic peroxide, thus: $MnO^2 + 2SO^2 = Mn''S^2O^6$. When heated they break up into a sulphate and sulphurous anhydride, *e.g.* $Mn''S^2O^6 = Mn''SO^4 + SO^2$. The tri-, tetra-, and penta-thionates undergo a similar decomposition when heated, but yield sulphur in addition.

Sulphurous Compounds.

DIOXIDE OF SULPHUR, SULPHUROUS OXIDE, OR SULPHUROUS ANHYDRIDE, SO^2.—This compound occurs as gas in volcanic neighbourhoods, in the gaseous state and dissolved in the water of the springs. It is formed artificially either by oxidation of sulphur or by deoxidation of sulphuric acid:—(α) By burning sulphur in air or oxygen, by roasting metallic sulphides, or by heating sulphur with metallic oxides, those of copper and manganese for instance; (β) By heating sulphuric acid with copper, mercury, or other metals, or with charcoal, sulphur, or organic bodies. It also results from the decomposition of thiosulphuric and dithionic acids.

Preparation.—Sulphurous oxide is usually prepared by the deoxidation of sulphuric acid. For preparation on the laboratory scale, strong sulphuric acid is heated with copper or mercury:

$$Hg + 2H^2SO^4 = Hg''SO^4 + 2H^2O + SO^2.$$
$$Cu^2 + 2H^2SO^4 = Cu^2SO^4 + 2H^2O + SO^2.$$

The sulphurous oxide then passes off as gas, and the residue consists, in the case of mercury, of mercuric sulphate, in the case of copper, of cuprous sulphate, mixed, according to Maumené, with cuprous and cupric sulphides. The gas may be passed through a small quantity of water to wash it, and then dried over chloride of calcium. In the manufactory, charcoal, straw, sawdust, &c., are substituted for the metals, but the sulphurous oxide obtained by means of these substances is always contaminated with about half its bulk of carbonic dioxide. Wach (Schw. J. l. 26) recommends a laboratory process for making sulphurous oxide, by heating sulphur and sulphuric oxide together in sealed U-tubes, whereby the sulphurous oxide is obtained in the liquid state, at the cooled extremity.

Properties.—At common temperatures, sulphurous oxide is a gas, but it may very readily be condensed into the liquid state by a pressure of three atmospheres, or by a freezing mixture of ice and salt. The liquid oxide may be obtained in large quantities by heating copper turnings with sulphuric acid, and passing the evolved gas first through a little water to wash it, then through an empty U-tube surrounded by ice to cool the gas and condense its moisture, then through a chloride of calcium tube to render it perfectly dry, and lastly into a suitable receiver immersed in a freezing mixture of salt and ice. The product thus obtained may be preserved in sealed tubes, or in soda-water bottles firmly corked and wired, or preferably closed with a vulcanised caoutchouc pad retained by a screw-clamp. When the liquid oxide is evaporated rapidly under the air-pump, or when it is cooled by a mixture of solid carbonic dioxide and ether, it solidifies in white semicrystalline flakes. Solid sulphurous oxide is heavier than the liquid. It melts at about −79°. The liquid oxide is a colourless, transparent, mobile fluid. Its specific gravity is 1·45. It boils at −10°. Respecting the tension of its vapour, as determined by Regnault, see HEAT (iii. 94).

By its evaporation it produces intense cold, sometimes even sufficient to freeze itself, and readily to freeze water on which it is poured.

Sulphurous oxide in the gaseous state is colourless, irrespirable, and incombustible. It is more than twice as heavy as atmospheric air, and may consequently be collected by displacement. It may also be collected over mercury, but not over water, in which it is very soluble. It has a peculiar suffocating sulphurous odour. When perfectly dry it does not redden litmus-paper, at any rate not for some time. It temporarily bleaches many vegetable colours. The oxide or acid is largely used for bleaching wool, straw, &c., and for preserving certain animal tissues, such as vellum and catgut. The moist substances are placed in close chambers in which sulphur is burnt. The colouring-matters seem merely to enter into combination with the acid or anhydride, and may be reproduced by the addition of an alkali to neutralise, or of a stronger acid to expel the sulphurous acid. The fume of burning sulphur has also been employed as a disinfecting agent.

When heated to 1200° or upwards, or subjected to the action of a powerful induction-spark, it is resolved into free sulphur and oxygen, which oxidises part of the sulphurous oxide to sulphuric oxide. It rapidly extinguishes the flame of burning bodies.—Nevertheless *potassium* burns brightly in it, forming a polysulphide of potassium together with sulphate and thiosulphate.—Finely divided *tin* heated in the gas also burns brightly, forming stannic oxide and sulphide.—*Arsenic* acts upon it only in the form of vapour, forming arsenious oxide and sulphide.—*Antimony* is slowly attacked by it, forming the red trisulphide.—Precipitated *lead* is slowly converted into sulphide.—*Iron* (finely divided) glows when heated in the gas, forming sulphide of iron and ferrous sulphate.—*Manganic peroxide*, gently heated in the gas, is converted into manganous sulphate: *lead-oxide* or *carbonate*, chiefly into sulphide.—*Cupric oxide* is two-thirds reduced to cuprous oxide, the remainder being converted into cupric sulphide. (Schiff, Ann. Ch. Pharm. cxvii. 92.)

Sulphurous Acid, $H^2SO^3 = H^2O.SO^2 = \left.\begin{matrix}(SO)''\\ H^2\end{matrix}\right\}O^2$.—*a.* This acid may be obtained by burning sulphydric acid in excess of air or oxygen; or by liberating it from its salts, the sulphites, by the addition of a stronger acid, such as the sulphuric, hydrochloric, oxalic, &c.—In practice it is always made by passing sulphurous oxide into water. When liquid sulphurous oxide is added to ice-cold water, or even to ice, combination attended by violent ebullition takes place, while a solid hydrated acid remains, mixed with an excess of ice, whether used as such or frozen during the reaction. The solid hydrated acid, in the form of white laminated crystals, may also be made by passing moist sulphurous oxide gas through a freezing mixture. Pierre (Ann. Ch. Pharm. lxviii. 228) obtained nitre-like crystals of sulphurous acid, having the formula $H^2SO^3.8H^2O$, by cooling to $-6°$ a saturated solution of sulphurous acid through which a current of the gas was being transmitted. The crystals fused at $+4°$. Döpping (J. pr. Chem. xliv. 255) succeeded in procuring the pure acid, H^2SO^3, in the form of cubical crystals, by cooling to zero a saturated aqueous solution of sulphurous acid.

The solution of sulphurous acid is made commercially by condensing the vapour from burning sulphur in a coke scrubber, through which water is kept trickling. In the laboratory the gaseous oxide is passed into distilled water, which at 15° absorbs about 45 times its volume of the gas (ii. 798). The combination is attended by a slight elevation of temperature. The resulting liquid has a specific gravity of 1·04. It is colourless, has the smell of burning sulphur, and reacts strongly acid to test-paper. When boiled it gives off sulphurous acid or oxide, but very prolonged ebullition is required to drive off the whole of the gas. By exposure to air, the solution slowly oxidises into sulphuric acid. When mixed with hydrochloric acid and metallic zinc or stannous chloride, it is reduced to the state of sulphydric acid, which in the case of zinc may be recognised by its reaction on lead-paper. With stannous chloride a precipitate of brown stannous sulphide is formed.

Sulphurous oxide and sulphurous acid act as powerful reducing agents. They liberate iodine from iodic acid, and, in presence of water, finally convert it into hydriodic acid. The smallest trace of free sulphurous acid in a gaseous mixture, or in a solution, may be detected by means of strips of paper steeped in starch-paste to which a small quantity of iodic acid or potassic iodate has been added. The sulphurous acid sets free the iodine, which forms the well-known blue compound with the starch (Persoz, Ann. Ch. Pharm. lxiv. 408). Starch-paper, containing iodide of potassium, which has been turned blue by the action of chlorine, is decolorised by sulphurous acid. (Schönbein, Pogg. Ann. lxx. 88.)

Sulphurous acid and iodine, in presence of a large quantity of water, yield hydriodic and sulphuric acids: $H^2SO^3 + I^2 + H^2O = 2HI + H^2SO^4$. Bunsen's method of volumetric analysis is based upon this reaction.

Sulphurous acid and oxide reduce the arsenic, chromic, and permanganic acids, and precipitate metallic gold from its chloride. They also precipitate tellurium and selenium from tellurious and selenious acids respectively, and sulphur from sulphydric acid.

For the detection of sulphurous oxide in gaseous mixture, Schiff (Ann. Ch. Pharm. cxviii. 91) recommends the use of paper moistened with solution of mercurous nitrate, which becomes grey from precipitation of metallic mercury. Bright metallic copper heated with hydrochloric acid containing sulphurous acid immediately becomes dull, then grey and brown, or brown-black, from formation of sulphide. The deposit thus formed is distinguished from that produced by arsenic under similar circumstances by not adhering closely to the metal, by not disappearing when heated in a tube, and by not dissolving, with evolution of hydrogen, when boiled with moderately dilute hydrochloric acid. Reinsch (Zeitschr. anal. Chem. i. 220) recommends this reaction as a very delicate test for sulphurous acid; but according to Fresenius (*ibid.* i. 221), it is not nearly so delicate as that with iodate of potassium and starch.

SULPHUROUS CHLORIDE, $SOCl^2$. *Chloride of Thionyl. Sulphurous Chloraldehyde.*—This compound, derived from sulphurous acid, SO.HO.HO, by the substitution of 2 at. chlorine for 2 at. hydroxyl, is formed by the action of water alcohols, acids, &c. on the sulphides of chlorine (pp. 534, 535); but is more easily prepared by the action of phosphoric pentachloride on sulphurous oxide (Schiff, Ann. Ch. Pharm. cii. 111), or by that of phosphoric oxychloride on sulphite of calcium (Carius, *ibid.* lxx. 297):

$$SO^2 + PCl^5 = POCl^3 + SOCl^2.$$

$$3CaSO^3 + 2POCl^3 = Ca^3P^2O^8 + 3SOCl^2.$$

It is separated by fractional distillation from the fixed calcic phosphate produced simultaneously in the second, and by fractional distillation from the phosphoric oxychloride produced in the first reaction.

Sulphurous chloride is a colourless, strongly refracting liquid, which boils at 82°. It is decomposed by water, yielding hydrochloric and sulphurous acids; by alcohols with formation of hydrochloric acid and alcoholic chlorides and sulphites (p. 535), and by ammonia, with formation of thionamide: $Cl^2SO^2 + 2NH^3 = H^2O + (NH^2)^2SO$.

METALLIC SULPHITES.—Sulphurous acid, as already observed, is dibasic, forming normal or neutral, and acid salts represented by the formulæ M^2SO^3 and $MHSO^3$ for monatomic metals; and by corresponding formulæ for polyatomic metals; also double salts. The sulphites have been examined chiefly by Muspratt (Ann. Ch. Pharm. l. 259; lxiv. 240) and Rammelsberg (Pogg. Ann. lxvii. 245, 391).

Sulphites are usually made by transmitting gaseous sulphurous oxide through water in which metallic hydrates or carbonates are dissolved or suspended. The acid sulphites of barium, strontium, calcium, and magnesium, and the neutral and acid sulphites of lithium, sodium, and potassium, are soluble in water. Most other sulphites are insoluble, and may be prepared by precipitation with a sulphite of alkali-metal. The sulphites M^2SO^3 and $MHSO^3$, present a great analogy to, and are for the most part isomorphous with, the carbonates, M^2CO^3 and $MHCO^3$ respectively. Both acid and neutral sulphites form well-defined crystals, sometimes hydrated, but more generally anhydrous. The sulphites are decomposed at a red heat, either into sulphate and sulphide, or into sulphurous anhydride and metallic oxide. When heated with charcoal, they are completely reduced to the state of sulphides, or in some cases to that of oxides. They are also readily reduced in the moist way by stannous chloride, or by nascent hydrogen evolved from hydrochloric acid and zinc, with formation of metallic sulphide or of sulphydric acid. The sulphites, particularly if in solution, become converted into sulphates by exposure to air, or by treatment with oxidising agents, such as nitrous acid, hypochlorous acid, chlorine, &c. The solutions also, when acted on by sulphur, sulphydric acid, or alkaline sulphydrate, form thiosulphates (hyposulphites). The sulphites are decomposed by nearly all acids, save the carbonic and boric, with liberation of sulphurous acid. The acidified solutions of the salts act like sulphurous acid as powerful reducing agents, and are frequently employed as such in analysis. Acid sulphite of sodium was at one time much used as an *antichlore* (i. 310).

Sulphite of Aluminium.—A basic sulphite, $Al^2O^3.SO^2.4H^2O$ or $Al^2(SO^3)^3.4AlH^3O^3.6H^2O$, is obtained, according to Gougginsperg, by dissolving recently precipitated aluminic hydrate in cold aqueous sulphurous acid, or passing sulphurous gas into water in which the hydrate is suspended. On heating the resulting solution, the salt separates as a white earthy powder, which must be collected on a filter while hot, as it redissolves on cooling. It is insoluble in pure water, and on exposure to the air is gradually converted into sulphate.

Sulphites of Ammonium.—The *neutral salt*, $(NH^4)^2SO^3.H^2O$, is prepared by passing sulphurous oxide and ammonia-gases, both moist, into absolute alcohol; the liquid then becomes filled with white silky crystals of the salt, which must be dried between filter-paper. It has a strong alkaline reaction, an unpleasant caustic taste, and dissolves very slowly in water. The crystals, when exposed to the air, first become moist, but afterwards dry, being converted by oxidation into sulphate of ammonium. (Muspratt.)

The neutral sulphite, when heated, gives off water and ammonia, and is converted, according to Muspratt, into the *anhydrosulphite*, $(NH^4)^2O.2SO^2$ or $(NH^4)^2SO^3.SO^2$. [It might rather be expected to yield the *acid sulphite*, $NH^4.H.SO^3 = (NH^4)^2SO^3 - NH^3$]. This salt is neutral to vegetable colours, gives off a considerable quantity of sulphurous oxide on exposure to the air, and is gradually but completely converted into sulphate of ammonium. It dissolves easily in water and in alcohol. When heated in a tube it gives off sulphurous oxide, and yields a sublimate perhaps consisting of $2NH^3.SO^2.\frac{1}{2}H^2O$ or $\left.\begin{matrix}H^2\\(SO)''\\H\end{matrix}\right\}\begin{matrix}N\\O\end{matrix}.\frac{1}{2}H^2O$. When sulphurous oxide is passed into aqueous ammonia till the odour is entirely destroyed, and absolute alcohol is then added, a white alkaline crystalline mass separates, containing $(NH^4)^2SO^3.NH^3.\frac{3}{2}H^2O$. (Muspratt.)

Sulphite of Antimony, $Sb^2O^3.3SO^2 = \overset{'''}{Sb}{}^2(SO^3)^3$, is obtained, according to Berzelius, by digesting antimonious oxide in sulphurous acid, or by passing sulphurous oxide into antimonious chloride. It is a white insoluble powder.

Sulphite of Barium, $Ba''SO^3$, is obtained by precipitation as a white powder, and crystallises from solution in warm aqueous sulphurous acid in permanent six-sided prisms. When heated in a close vessel, it is resolved, according to Rammelsberg, into sulphide and sulphate of barium: $4BaSO^3 = BaS + 3BaSO^4$.

Sulphite of Bismuth, $Bi^2O^3.SO^2 = 2Bi^2O^3.Bi^2(SO^3)^3$, is deposited, according to Danson, from a solution of bismuth-oxide in the aqueous acid, left to stand in a close vessel, as a straw-yellow precipitate, becoming white when dry. According to Muspratt, it is likewise produced by passing sulphurous oxide through the nitrate.

Sulphite of Cadmium, $Cd''SO^3$.—The anhydrous salt separates from the aqueous solution by evaporation, in indistinct crystalline forms (Rammelsberg). On adding alcohol to the solution, the same salt separates as a precipitate resembling alumina, which, if left to stand in the liquid, changes into fine silvery crystals of the hydrated salt, $Cd(SO^3)^3.H^2O$. these crystals dissolve sparingly in water, easily in dilute acids (Muspratt). The salt oxidises slowly in the air, and when heated, gives off sulphurous oxide, leaving a yellow residue of cadmic oxide, sulphide, and sulphate. Sulphate of cadmium is also formed, together with the sulphide, on dissolving cadmium in sulphurous acid. (Fordos and Gélis.)

Ammonio-cadmic sulphite, $(NH^4)^2Cd''(SO^3)^2$, is obtained, according to Schüler, by passing sulphurous oxide to saturation into the solution obtained by adding ammonia in slight excess to chloride of cadmium. It then separates as a white precipitate consisting of microscopic rhombic prisms, nearly insoluble in water, even on boiling. When heated, it gives off sulphite of ammonium, leaving a mixture of cadmic oxide and sulphate.—*Acid sulphite of Cadmammonium*, $(NH^2Cd'')HSO^3$, is formed by dissolving cadmic sulphite in aqueous ammonia, and separates on cooling as a crystalline powder, or in small shining prisms which smell of ammonia and are decomposed by water. (Rammelsberg.)

Sulphite of Calcium, $Ca''SO^3$, is obtained in the anhydrous state by precipitation. On suspending the precipitate in water, passing sulphurous oxide through the liquid, and leaving the resulting solution for several days over oil of vitriol, a hydrated salt separates in six-sided prisms containing $Ca''SO^3.2H^2O$ (Muspratt), $2Ca''SO^3.H^2O$ (Rammelsberg). Sulphite of calcium has an astringent sulphurous taste, and becomes covered, on exposure to the air, with silky efflorescences of calcic sulphate. When heated, it gives off water, sulphurous oxide, and sulphur, and leaves a residue of calcic sulphide and sulphate (Muspratt, Rammelsberg). Respecting the preparation of this salt on the large scale, and its use in bleaching, and in protecting organic substances from decay, see Anthon. (Dingl. pol. J. clix. 137.)

A compound of *calcic sulphite* and *sulphide*, $CaSO^3.2CaS.6H^2O$, is found, according to Kuhlmann (Compt. rend. lii. 1169), lining the cavities of soda-residues which have been lixiviated, and afterwards exposed to the air for several years.

Sulphite of Cerium, $Ce''SO^3$, crystallises in needles. (Klaproth.)

Sulphite of Chromium, $2Cr^2O^3.3SO^2.16H^2O$, separates from solution as a yellow powder (Danson), on addition of alcohol, or on heating, as a greenish-white powder which gives off sulphurous oxide when heated (Muspratt). According to Berthier, sulphurous oxide passed into a solution of potassic chromate forms a brown precipitate, gradually turning green, and dissolving to a green liquid, which deposits a basic salt on cooling.

Sulphites of Cobalt.—*a. Cobaltous Sulphite*, $Co''SO^3$, separates on addition of alcohol to the solution of cobaltous carbonate in sulphurous acid, as a flocculent precipitate probably containing 1 at. water. From a solution freed from air by boiling and left to cool in a closed vessel, red granular crystals separate containing 5 at. water (Muspratt). The same solution evaporated down in an atmosphere of hydrogen, gives off sulphurous oxide, and deposits peachblossom-coloured crystals of a salt containing 3 at. water. The mother-liquor on cooling deposits a light rose-coloured powder, probably a basic salt. Ammonia partially dissolves the trihydrated salt with red-brown colour, and alcohol added to the solution throws down a yellow crystalline powder containing ammonia, sulphurous oxide, and probably cobaltic oxide, Co^2O^3. (Rammelsberg.)

Potassio-cobaltous sulphite, $K^2O.Co''O.2SO^2 = K^2Co''(SO^3)^2$, is obtained, as a pale-red crystalline or amorphous precipitate, by heating cobaltous sulphite or chloride with neutral sulphite of potassium, or by boiling cobaltic hydrate with a sufficient quantity of the alkaline sulphate.—A *sodium-salt* containing $Na^2O.3Co''O.3SO^2$ or $Na^2\overset{''}{Co}{}^2(SO^3)^3.Co''O$, is prepared in like manner. Both salts oxidise on exposure to the air. (W. Schultze, Zeitschr. Ch. Pharm. 1865, p. 89; Jahresb. 1865, p. 270.)

β. Cobaltic Sulphites.—A warm solution of ammonium-sulphite dissolves recently precipitated cobaltic hydrate, with evolution of ammonia, forming a dark alkaline liquid; and this, if strongly saturated, deposits after a while, a reddish-yellow powder which redissolves on washing with water, the solution then gradually depositing yellow-brown crystals, and afterwards a yellow powder containing $2(Co^2O^3.3SO^2).10NH^3.9H^2O$, and apparently identical with the purpureo-cobaltic sulphite described by Künzel (i. 1049). The mother-liquor deposits brown crystals which are decomposed by water, yielding a yellow salt probably identical with Künzel's triammonio-cobaltic sulphite (i. 1051). (Geuther, Ann. Ch. Pharm. cxxviii. 157; Jahresb. 1863, p. 267.)

Potassio-cobaltic sulphite, $K^2O.Co^2O^3.4SO^2 = KCo'''(SO^3)^2$, is formed, by heating cobaltic hydrate for some time with a frequently renewed, concentrated, neutral, or slightly alkaline solution of potassic sulphite, as an amorphous powder which dissolves slightly in sulphurous or hydrochloric acid, and decomposes in drying.—A *sodium-salt*, having the composition $Na^2O.Co^2O^3.3SO^2$, is obtained in a similar manner. (Geuther, Schultze.)

Sulphites of Copper.—*a.* A basic *cupric sulphite*, $4Cu''O.SO^2.7H^2O$ or $Cu''SO^3.3Cu''H^2O^2.4H^2O$, is obtained by adding cupric hydrate to absolute alcohol saturated with sulphurous oxide, as a green precipitate, insoluble in water, and not decomposed by washing therewith.

β. Cuprous sulphite, Cu^2SO^3.—The anhydrous salt, which has a brown-red colour, is obtained, according to Böttger, by treating cuprous hydrate with aqueous sulphurous acid. The same salt is obtained pure and as a hydrate, by passing sulphurous oxide through water in which ammonio-cuprous sulphite is suspended. The latter is thus converted into an insoluble red powder, which on boiling the liquid, is converted into a mass of microscopic crystals consisting of $Cu^2SO^3.H^2O$, resembling the red double salt in general appearance, but lighter-coloured, and exhibiting under the microscope, distinct quadratic prisms or octahedrons, whereas the double salt crystallises in oblique prisms. Cuprous sulphite is converted by hydrochloric acid into cuprous chloride, and dissolved by ammonia to a colourless liquid which does not turn blue. (Rogojski, J. pr. Chem. liii. 408.)

Ammonio-cuprous sulphite, $(NH^4)CuSO^3$, is obtained in colourless laminæ by decomposing cupric sulphate with excess of ammonium-sulphite, and passing sulphurous oxide through the brown liquid till it becomes colourless; or by passing the sulphurous gas (not too long) through an ammoniacal solution of cupric sulphate (Rogojski); or by adding sulphite of ammonium at the boiling heat to a solution of cupric sulphate or nitrate strongly supersaturated with ammonia, till it becomes colourless; the resulting solution mixed with excess of nitric acid and exposed to the air, deposits the double salt in nacreous six-sided tables (H. Vohl, J. pr. Chem. xcv. 218). It is insoluble in cold water, and is decomposed by boiling water into sulphurous oxide and cuprous oxide; also by sulphuric acid into metallic copper and cupric sulphate. In a solution of cupric sulphate it is immediately converted into red cuproso-cupric sulphite (Rogojski).—Another double salt, containing $Cu^2SO^3.7(NH^4)^2SO^3.10H^2O$ or $(NH^4)^7Cu(SO^3)^4.5H^2O$, is produced, according to Péan-de-Saint-Gilles (Ann.

Ch. Pharm. lxxxviii. 165; Jahresb. 1853, p. 372), by treating cuprous chloride with sulphite of ammonium. It crystallises in needles, and is converted into the preceding salt by saturating its solution with sulphurous acid.

Potassio-cuprous Sulphites.—The salt, $Cu^2SO^3.2K^2SO^3$, is produced, according to Chevreul and Muspratt, by adding sulphite of potassium to a moderately concentrated solution of cupric sulphate or nitrate, or according to Vohl by passing sulphurous oxide into a solution of a cupric salt mixed with excess of potash. It is a yellow precipitate which by boiling with water is converted into the salt $3Cu^2SO^3.3Cu''SO^3.2K^2SO^3$. Rammelsberg, by mixing a cupric salt in the cold with sulphite of potassium, and digesting the resulting yellow-brown precipitate with a strong solution of potassic sulphite, obtained a salt containing apparently $Cu^2SO^3.8K^2SO^3.16H^2O$; but its composition is uncertain, as it was perhaps mixed with uncombined potassic sulphite.

Sodio-cuprous sulphite, $Cu^2SO^3.5Na^2SO^3.38H^2O$, is formed, according to Muspratt, by adding alcohol to a mixture of the solution of sodic and cupric sulphites; on leaving the liquid thereby separated in a vacuum, the double salt is deposited in fine yellow crystals.

A *sodio-ferroso-ferrico-cuprous sulphite*, $\left.\begin{matrix}Na^2O.SO^2\\2(Fe''O.SO^2)\\Fe^2O^3.2SO^2\\Cu^2O.SO^2\end{matrix}\right\}.16H^2O$, is said to be obtained by adding neutral sulphite of sodium to a solution of 2·49 grms. (2 at.) cupric sulphate and 5·56 grms. (4 at.) ferrous sulphate in 100 c.c. water. The precipitate formed at first redissolves to a dark purple-red liquid, which after some hours deposits the complex salt in small black crystals, appearing dark purple-red by transmitted light. (A. Stromeyer, Ann. Ch. Pharm. cix. 237.)

Cuproso-cupric Sulphite, $\left.\begin{matrix}Cu^2\\Cu''\end{matrix}\right\}S^2O^6.2H^2O = Cu^2SO^3.Cu''SO^3.2H^2O$. (Rammelsberg and Rogojski.)—Prepared by treating hydrate or carbonate of copper with aqueous sulphurous acid, or by passing sulphurous oxide through water in which either of these compounds is suspended (Muspratt), or by adding a concentrated solution of acid potassic sulphite to a solution of cupric sulphate, and gently warming the filtered liquid (Bourson). It forms red crystals or a crystalline powder, which dissolves in hydrochloric acid with brown colour, becoming green on dilution, with separation of white cuprous chloride. The same salt is obtained combined with 5 at. water, by slowly passing sulphurous oxide through a solution of cupric acetate, or by adding an alkaline sulphate to a cupric salt in excess. It then separates as a yellow flocculent precipitate, which remains unaltered in dry air, is insoluble in water, but dissolves without decomposition in acetic or sulphurous acid. On evaporating its solution the red dihydrate separates out. (Péan-de-St-Gilles.)

Ammonio-cuproso-cupric sulphite, $(NH^4)^2Cu^2Cu''(SO^3)^3.5H^2O$, separates in light-green crystals on mixing a saturated solution of ammonium-sulphite with cupric sulphate (Péan-de-St-Gilles).—A *potassio-cuproso-cupric sulphite*, $K^4Cu^6\overset{''}{Cu}{}^2(SO^3)^6$, is obtained as a red precipitate on heating a solution of cupric sulphate with potassic sulphite. (Rogojski.)

Sulphite of Didymium, $Di''SO^3.H^2O$.—Produced by passing sulphurous oxide through water in which strongly-ignited oxide of didymium is suspended. The rose-coloured solution becomes turbid when heated, and deposits the salt as a light bulky precipitate, which redissolves on cooling. If, however, the excess of sulphurous acid be expelled by boiling, the precipitate becomes reddish-white and pulverulent, and no longer redissolves on boiling. (Marignac.)

Sulphite of Glucinum, $G''SO^3$, is very soluble in water, and is not decomposed by boiling.

Sulphites of Gold.—Neither auric nor aurous sulphite is known in the separate state.—*Potassio-auric sulphite*, $5K^2SO^3.\overset{'''}{Au}{}^2(SO^3)^3.5H^2O$, or $2(KAu'''O^2.4KHSO^3).H^2O$, is obtained by dropping a solution of potassic sulphite into a slightly alkaline solution of potassic aurate, in yellow needles insoluble in the alkaline liquid, but dissolving in water, with evolution of sulphurous acid and separation of gold. Acids likewise decompose it. When heated, it leaves metallic gold and sulphate of potassium. (Frémy.)

Sodio-aurous sulphite, $2Na^3Au(SO^3)^2.5H^2O$, or $3Na^2SO^3.Au^2SO^3.5H^2O$, forms a colourless solution, which is precipitated by alcohol, appears yellow by reflected light (like fulminating gold), purple by transmitted light (like purple of Cassius). Its solution gives with nitrate of silver a precipitate of the colour of lead-chromate, and forms with lead-salts a red insoluble compound. (Heintz.)

Sulphites of Iridium. (Birnbaum, Ann. Ch. Pharm. cxxxvi. 177; Jahresb. 1865, p. 283.)—*a. Iridic Sulphite,* $IrO^2.SO^2.4H^2O = \left.\begin{matrix}(SO)''\\(IrO)''\end{matrix}\right\}O^2$.—On passing sulphurous oxide into water in which iridic oxide (iii. 322) is suspended, part of the oxide dissolves with light olive-green colour, while the rest remains undissolved as brownish-green iridic sulphite. This salt, when dry, forms a black-brown amorphous mass; which, when heated, gives off water, sulphurous acid and sulphuric acid, and leaves black oxide of iridium. Hydrochloric and sulphuric acids dissolve it with green colour and evolution of sulphurous oxide; nitric acid and potash separate blue iridic oxide.

β. Iridious Sulphite, $\overset{'''}{Ir}{}^2(SO^3)^3.6H^2O = \left.\begin{matrix}(\overset{''}{SO})^3\\(Ir''')^2\end{matrix}\right\}O^6.6H^2O$.—This salt is contained in the light olive-green solution above mentioned, and separates by gradual evaporation as a brown amorphous mass. It dissolves easily and with grey colour in acids, and when heated with potash, becomes first brown, then green and blue.

The following double salts of iridious sulphite are obtained by mixing the olive-green liquid filtered from iridic sulphite with the corresponding alkaline carbonates, in quantity not sufficient to form a precipitate. The solutions, when left to themselves, deposit the double salts as dark crystalline precipitates:

Ammonio-iridious sulphite,	$(NH^4)^3Ir'''(SO^3)^3.3H^2O$.
Potassio-iridious sulphite,	$K^3Ir'''(SO^3)^3.3H^2O$.
Sodio-iridious sulphite,	$Na^3Ir'''(SO^3)^3.4H^2O$.

Respecting other double sulphites of iridium, see vol. iii. p. 322.

Sulphites of Iron.—*a. Ferric salts.*—The *neutral salt,* $Fe^2O^3.3SO^2 = Fe^2(SO^3)^3 = \left.\begin{matrix}(\overset{''}{SO})^3\\(Fe''')^2\end{matrix}\right\}O^6$, is not known in the solid form. The red solution formed by dissolving ferric hydrate in sulphurous acid, or adding an alkaline sulphite to a ferric salt, quickly becomes converted into ferrous sulphate.—The *dibasic salt,* $2Fe^2O^3.3SO^2 = Fe^2O^3.Fe^2(SO^3)^3 = \left.\begin{matrix}(\overset{''}{SO})^3\\(Fe''')^4\end{matrix}\right\}O^9$, is thrown down by alcohol from the red solution above mentioned, as a yellow-brown hydrated precipitate, which oxidises in the air to soluble ferric sulphate.—The *tribasic salt,* $Fe^2O^3.SO^2.6H^2O = 2Fe^2O^3.Fe^2(SO^3)^3.18H^2O = \left.\begin{matrix}(SO)''\\(Fe''')^2\end{matrix}\right\}O^4.6H^2O$, is produced by treating the dibasic salt with water. A solution of ferric oxide in sulphurous acid, exposed to the air for several days, deposits the tribasic salt as a red-brown precipitate containing 7 at. water (Muspratt, Koene). If, on the other hand, the same solution is heated, it deposits a straw-yellow ochry precipitate, which contains, according to Koene, $3Fe^2O^3.SO^2.7H^2O$, and suffers no alteration on exposure to the air.

Potassio-ferric Sulphites.—The blood-red solution obtained by passing sulphurous gas through water in which ferric hydrate is suspended, yields, on addition of caustic potash, a double salt containing $(Fe^2O^3.SO^2).2(K^2O.SO^2).5H^2O = \left.\begin{matrix}(S''O)^3\\(Fe''')^2K^4\end{matrix}\right\}O^8.5H^2O$ (Muspratt).—Another double salt, $(Fe^2O^3.SO^2).K^2O.2SO^2$, is formed, according to Koene, as a deep-yellow precipitate on adding dilute potash-ley to the alcoholic filtrate obtained in the preparation of dibasic ferric sulphite.

β. Ferrous sulphite, $Fe''SO^3.3H^2O$, is obtained, together with an equivalent quantity of the hyposulphite, by dissolving clean iron-wire in aqueous sulphurous acid (Fordos and Gélis). On leaving this solution to evaporate in a vacuum, the sulphite separates out first in pale-green crystals; or it may be precipitated as a white powder by adding alcohol to the solution. It is also produced by dissolving recently precipitated ferrous carbonate in sulphurous acid. The nearly colourless crystals dissolve sparingly in water, but abundantly in aqueous sulphurous acid, and are converted slowly in dry, quickly in moist air, into sulphate. (Muspratt.)

Sulphite of Lead, $Pb''SO^3$, prepared by double decomposition, or by passing sulphurous oxide into a solution of neutral plumbic acetate, is a white, insoluble, anhydrous powder, which when heated gives off sulphurous oxide, and leaves a mixture of sulphate and sulphide. It has been proposed as a substitute for white lead.

Sulphite of Lithium, $Li^2SO^3.6H^2O$, separates from its aqueous solution on boiling, or on addition of alcohol, in white feathery crystals, which turn light-yellow on exposure to the air. (Danson.)

Sulphite of Magnesium, $Mg''SO^3.6H^2O$, forms small shining crystals, belonging to the rhombohedral system, which dissolve in 20 pts. of cold water, and are gradually converted into sulphate on exposure to the air. It gives off part of its water at 100°, the rest, together with sulphurous oxide, at 200° (Rammelsberg).—Muspratt obtained a salt with 3 at. water, crystallising in oblique rhombic prisms.

Ammonio-magnesic sulphite, $(NH^4)^2\overset{''}{Mg}{}^3(SO^3)^4.5H^2O$, is obtained, according to Rammelsberg, by mixing a solution of magnesia in sulphurous acid, with excess of ammonia, dissolving the resulting precipitate in sulphurous acid, and leaving the solution to crystallise. Sulphite of magnesium then separates out first, and afterwards the much more soluble double salt.—Another hydrate, containing $(NH^4)^2\overset{''}{Mg}{}^3(SO^3)^4.18H^2O$, is obtained in monoclinic crystals from the mixed solution of the component salts (Rammelsberg).—The potassic double salt is difficult to obtain pure, because it is about as soluble as the simple magnesic sulphite formed at the same time.

Sulphite of Manganese, $Mn''SO^3.2H^2O$ or (according to Rammelsberg) $2Mn''SO^3.5H^2O$, is a reddish-white crystalline powder, tasteless at first, but leaving a nauseous metallic aftertaste. It is insoluble in water, alcohol, and ether, and permanent in the air (Muspratt, John). When heated in a small retort, it gives off water and sulphurous oxide, and leaves a greenish-brown pulverulent residue of manganic oxide, manganous sulphate, and sulphide of manganese. (Rammelsberg.)

Sulphites of Mercury.—*a. Mercuric salts.*—When a syrupy solution of basic mercuric nitrate is mixed with a dilute solution of alkaline sulphite, a heavy white curdy precipitate is formed, varying in composition between the neutral salt, $Hg''O.SO^2$, or $Hg''SO^3$, and the basic salt, $2Hg''O.SO^2$ or $Hg''O.Hg''SO^3$, according as the mercuric salt used in the preparation contained less or more of base.—The *neutral salt*, $Hg''SO^3$, is very unstable, and is converted by boiling with water into a mixture of mercurous sulphate and metallic mercury.—The *basic salt*, $Hg''O.Hg''SO^3$, when gently heated in the dry state, or boiled with water, is converted, without alteration of percentage composition, into neutral mercurous sulphate, Hg^2SO^4 (Péan-de-St-Gilles, Ann. Ch. Phys. [3], **xxxvi.** 80).—The nitrate is the only mercuric salt from which mercuric sulphite can be prepared, all others being reduced or dissolved by alkaline sulphites.

Acid mercuric sulphite, $Hg''H^2(SO^3)^2$, is formed, according to Wicke, by treating solid mercuric chloride with a solution of acid sulphite of sodium, and separates as a white crystalline powder consisting of microscopic cubes. It is moderately soluble in water. The solution deposits metallic mercury when heated; it is decomposed by potash in the cold, by ammonia only when heated, with formation of a white precipitate; it is not precipitated by alkalis.

Ammonio-mercuric Sulphite, $(NH^4)^2Hg''(SO^3)^2$.—A solution of acid ammonium-sulphite, saturated at the boiling heat with mercuric oxide, and then left to evaporate at a gentle heat, deposits this double salt in large, transparent, colourless, soft, tabular crystals. It decomposes when exposed to light, with separation of mercury-globules; slowly also even when kept in the dark and in well-closed vessels. The aqueous solution decomposes in the same way, slowly in the cold, immediately on boiling. With potash it yields a white precipitate, consisting of $2Hg''SO^3.N^2\overline{Hg}{}^3.2H^2O$. (Hirzel.)

Potassio-mercuric sulphite, $K^2Hg''(SO^3)^2.H^2O$, separates from a mixture of the saturated solutions of potassic sulphite and mercuric chloride, in tufts of small white needles. It dissolves slightly in cold water, forming a neutral solution. (Péan-de-St-Gilles.)

Sodio-mercuric sulphite, $Na^2Hg''(SO^3)^2.H^2O$, is obtained by adding mercuric chloride to excess of sodic sulphite. On evaporating the liquid, the salt crystallises in small rhombohedral plates, whose solution has a neutral reaction, and is not precipitated by iodide of potassium (Péan de St-Gilles).—Another double salt, containing $Na^2Hg^2(SO^3)^3.H^2O$, is produced, with separation of a small quantity of calomel, on mixing the hot saturated solutions of sodic sulphite and mercuric chloride, the latter being in excess. The liquid, filtered hot, deposits the double salt on cooling as a compact mass of indistinct needle-shaped crystals. It is more soluble than the preceding. The solution has an alkaline reaction, and iodide of potassium separates half the mercury from it. Potash heated with it separates one-fourth of the mercury. (Péan-de-St-Gilles.)

A compound of *ammonium-sulphite* with *mercuric chloride*, $2(NH^4)^2SO^3.3Hg''Cl^2$, separates in nacreous crystalline laminæ, on mixing the solutions of the component salts. When heated to boiling with water, it gives off sulphurous oxide, and deposits mercurous chloride.

β. Mercurous Sulphite.—The neutral salt is not known. An *anhydrosulphite*, $2Hg^2O.3SO^2 = 2Hg^2SO^3.SO^2$, or $3Hg^2O.4SO^2 = 3Hg^2SO^3.SO^2$, is produced by passing sulphurous oxide through water in which recently precipitated mercuric oxide is suspended. It is a white, very easily decomposible salt, being quickly oxidised to sulphate, with separation of metallic mercury. When heated in a test-tube, it melts, gives off a large quantity of sulphurous oxide, and yields a sublimate of mercurous sulphite and metallic mercury. It is also quickly decomposed by boiling with water, mercury being separated, and free sulphuric acid remaining in solution. Warm nitric acid dissolves it easily, with evolution of nitrous acid. Hydrochloric acid converts it into mercurous chloride. When it is digested with caustic potash, the filtrate which runs away from the black mercurous oxide, contains but little sulphite of potassium. (Rammelsberg.)

Sulphite of Nickel, $Ni''SO^3.6H^2O$, separates by spontaneous evaporation from its aqueous solution, in fine tetrahedrons. It is insoluble in pure water, soluble in water containing sulphurous acid, and becomes opaque when heated with water, probably in consequence of conversion into the anhydrous salt, or of another hydrate (Muspratt). —The *tetrahydrated salt*, $Ni''SO^3.4H^2O$, is obtained, according to Muspratt, by boiling the solution of nickel-hydrate in sulphurous acid; it then separates in small green crystals, nearly insoluble in water. .Metallic nickel is dissolved by aqueous sulphurous acid, with formation of sulphite and hyposulphite of nickel; on evaporating the solution, the sulphite crystallises out with 6 at. water. (Fordos and Gélis.)

An *ammonio-sulphite of nickel*, $Ni''SO^3.3NH^3.3H^2O$, is thrown down by alcohol from a solution of nickel-sulphite in ammonia, as a light-blue crystalline precipitate, which dissolves in a small quantity of water to a light-blue liquid, becoming turbid when mixed with more water, or when heated. (Rammelsberg.)

Sulphites of Osmium.—*Osmious Sulphite*, $Os''SO^3$, is formed by treating aqueous osmic acid with sulphurous acid, and separates on mixing the solution with sulphate or carbonate of sodium, and leaving it to evaporate, or warming it, as a blue jelly, which, while moist, oxidises readily, with formation of sulphuric acid, but, after drying, forms an almost unalterable powder of a dull black-blue colour. It is insoluble in water, but dissolves easily in hydrochloric acid, forming an indigo-coloured solution without evolution of sulphurous oxide. It is decomposed by potash at the boiling heat, and when heated by itself is resolved into sulphide of osmium, osmic tetroxide, and sulphurous anhydride. (Claus, J. pr. Chem. xc. 65; Jahresb. 1863, p. 295.)

The salt, $OsO.2SO^2.6KCl$, is obtained by treating the following compound with hydrochloric acid: it forms a brown-red crystalline salt, having a sharp taste, and very soluble in water. (Claus, Ann. Ch. Pharm. lxvii. 375.)

Osmio-potassic Sulphite, $Os''H^2(SO^3)^2.3K^2SO^3.4H^2O$, or $Os''K^6H^2(SO^3)^5.4H^2O$, is formed by heating osmio-potassic chloride with a solution of potassic sulphite. It is a light, white, or faintly rose-red powder, consisting of small, soft, crystalline scales. It is very slightly soluble in water, and decomposes at 180°. (Claus, Ann. Ch. Pharm. lxiii. 355.)

Sulphites of Platinum.—*a. Platinic Sulphite*, $Pt^{iv}(SO^3)^2$, obtained by dissolving platinic oxide in sulphurous acid, and gradual evaporation, is a white gummy mass, soluble in water and in alcohol, and having a strong acid reaction. When heated it is resolved into metallic platinum and sulphuric anhydride. From a solution of auric chloride it throws down metallic gold, the solution then containing platinic chloride and sulphuric acid. It is not decomposed by sulphuric or by hydrochloric acid. It forms double salts with sulphites of alkali-metal. (Döbereiner.)

β. Platinous Sulphite, $Pt''SO^3$, is obtained by passing sulphurous oxide through water in which platinous oxide is suspended. On leaving the liquid to itself with the vessel closed airtight, the oxide gradually dissolves, forming a brown-green solution. It forms colourless double salts with sulphites of alkali-metals.

Ammonio-platinous Sulphite, $(NH^4)^2Pt''(SO^3)^2.H^2O$, discovered by Liebig and analysed by Böckmann, is prepared by reducing a solution of platinic chloride to platinous chloride with sulphurous acid, neutralising with ammonia, precipitating with alcohol, and crystallising from water. Forms long, flat, white needles, easily soluble in water. —Another ammonio-platinous sulphite, containing $(NH^4)^6Pt''(SO^1)^4$, is formed, as a white, bulky, crystalline precipitate, on mixing a moderately concentrated solution of ammonio-platinous chloride with neutral sulphite of ammonium. (J. Lang, J. pr. Chem. lxxxiii. 415.)

Potassio-platinous Sulphite, $2K^6Pt''(SO^3)^4.3H^2O$, produced by heating potassio-platinous chloride with acid sulphite of potassium, crystallises in microscopic six-sided prisms, having a faint straw-yellow colour, sparingly soluble in cold, easily in warm water. The neutral solution is decomposed by hydrochloric acid, only when heated; hydrate and carbonate of potassium do not alter it, even with aid of heat; carbonate of sodium throws down a white precipitate of the sodium double salt; carbonate of ammonium and sulphydric acid do not act upon it (Lang). Claus, by decomposing platinic chloride with sulphite of potassium, obtained the salt $K^6Pt''H^2.(SO^3)^5.H^2O$, analogous to the osmium-salt above described. Lang was not able to prepare this salt.

Sodio-platinous Sulphite, $Na^6Pt''(SO^3)^4.3H^2O$, prepared by reducing platinic chloride to platinous chloride with sulphurous acid, saturating the liquid with sulphurous acid. and exactly neutralising with sodic carbonate, is a bulky nearly colourless precipitate, which dries up to a white amorphous powder, acquiring a tinge of yellow when moistened. It is sparingly soluble in cold, more soluble in warm water, insoluble in alcohol. From the aqueous solution it is precipitated unaltered by the chlorides of sodium, ammonium, and barium, and by nitrate of silver. It gives off its water of crystallisation between 180° and 200°, and may then be heated to 240° without alteration; but at higher temperatures it becomes darker, and is completely decomposed at a red heat. The platinum in this salt cannot be detected by the ordinary reagents; but strong acids decompose the salt, eliminating sulphurous oxide, and converting it into the following compound. By cyanide of potassium it is dissolved and converted into potassio-platinous cyanide. (Litton and Schnedermann, Ann. Ch. Pharm. xliii. 316.—Lang.)

Another sodio-platinous sulphite, $Na^2Pt''(SO^2)^2.H^2O$, is obtained by dissolving the preceding in dilute hydrochloric or sulphuric acid, and leaving the solution to evaporate. It is then deposited as a yellow powder, moderately soluble in water, and forming a slightly acid solution, from which it is precipitated by common salt. In other respects it resembles the preceding compound. (Litten and Schnedermann.)

Argento-platinous Sulphite, $Ag^6Pt''(SO^3)^4$, produced by mixing the corresponding potassium-salt with nitrate of silver, is a white precipitate, insoluble in water, easily soluble in ammonia. (Lang.)

Sulphites of Potassium.—The *neutral salt*, $K^2SO^3.2H^2O$, is obtained by saturating a solution of the carbonate with sulphurous acid, and evaporating over oil of vitriol, in large monoclinic octahedrons, somewhat deliquescent, very soluble in water, slightly soluble in alcohol, having a strong alkaline reaction and bitter taste. When heated, it swells up, gives off sulphurous oxide, and leaves sulphate of potassium mixed with sulphide and hydrate. (Muspratt.)

The *acid salt*, $KHSO^3$, is produced by supersaturating a warm and moderately concentrated solution of the carbonate with sulphurous acid, and separates on cooling, or on addition of absolute alcohol, as a white mass of crystalline needles. The solution, if left for several weeks in a stoppered bottle, deposits the salt in large rhombic prisms. It has a disagreeable sulphurous aftertaste, a neutral reaction, gives off sulphurous oxide continually on exposure to the air, and is finally converted into sulphate. Its solution, when evaporated, gives off sulphurous acid, leaving a mixture of acid and neutral salt, and after prolonged boiling, only the neutral salt remains. (Muspratt, Rammelsberg.)

An *anhydrosulphite*, $K^2O.2SO^2$, or $K^2SO^3.SO^2$, is formed by passing sulphurous oxide through a warm concentrated solution of the carbonate, till the effervescence ceases and the liquid assumes a greenish colour. It is then deposited on cooling, in hard granular crystals, which must be collected on a filter, washed with alcohol, and dried between filter-paper. It dissolves very slowly in water, very slightly in alcohol, and not at all in ether, has a disagreeable saline taste, and is permanent in the air. When heated, it gives off sulphurous oxide and sulphur, leaving a residue of potassic sulphate. (Muspratt.)

Sulphite of Rhodium. See RHODIUM (p. 105).

Sulphite of Ruthenium and Potassium, $K^2Ru''(SO^3)^2$, is produced, according to Claus, as a cream-coloured pulverulent precipitate, by boiling potassio-ruthenious chloride with sulphite of potassium. By repeated solution and evaporation it may be obtained nearly white. (Claus.)

Sulphite of Silver, Ag^2SO^3, is prepared by dissolving silver-oxide in sulphurous acid, or by precipitating a silver-salt with an alkaline sulphite or sulphurous acid; and is deposited, according to the mode of preparation, in small white shining needles, or as a white precipitate resembling chloride of silver. The salt is very slightly soluble in water, has a disagreeable taste, and, according to Muspratt, acquires, on exposure to the air, a dark purple and ultimately black colour. According to Fourcroy, the crystals are unalterable even in sunlight. It forms double salts with alkaline sulphites.

Sulphites of Sodium.—The *neutral salt*, Na^2SO^3, is easily prepared by saturating a solution of the carbonate with sulphurous acid, and adding to it, while warm, as much sodic carbonate as it originally contained. The salt then separates on cooling in monoclinic crystals containing $Na^2SO^3.7H^2O$. It is very soluble in water; the solution has an alkaline reaction, and, when heated, deposits a salt (probably anhydrous), which disappears again on cooling. It dissolves slightly in aqueous alcohol. At 150° it gives off the whole of its water, becoming white and enamel-like, and at a higher temperature melts to a yellowish-red mass, from which alcohol extracts sulphide of sodium, leaving sulphate (Rammelsberg).—Another hydrate, containing $Na^2SO^3.10H^2O$, is produced, according to Muspratt, by saturating a solution of sodic carbonate with sulphurous acid till it acquires an acid reaction, and leaving it over oil of vitriol. It then separates in large oblique prisms, which, on exposure to the air, quickly effloresce, and are gradually converted into sulphate. It has a faint alkaline reaction and cooling sulphurous taste (Muspratt). Specific gravity of the decahydrated crystals = 1·561 (Buignet, Jahresb. 1861, p. 15).—Vauquelin obtained the neutral sulphite with 8 at. water.

Acid sulphite, $NaHSO^3$.—A solution of sodic carbonate, supersaturated, while warm, with sulphurous acid, deposits this salt on cooling in small shining prisms. Alcohol precipitates it in the granular form. It smells of sulphurous acid, has an acid reaction, an unpleasant sulphurous taste, effloresces very easily in the air, and is finally converted into sulphate (Muspratt). Clark obtained an acid salt with 9 at. water.

Sodio-ammonic sulphite, $Na^2(NH^4)H(SO^3)^2.8H^2O$, crystallises, according to Marignac, in thin monoclinic tablets.

Sulphite of Strontium, $Sr''SO^3$, is obtained by double decomposition, as a white tasteless powder, and in crystalline grains by dissolving the precipitate in aqueous sulphurous acid, or by passing sulphurous oxide through water in which carbonate of strontium is suspended (Muspratt). The crystals are flat rectangular plates, acuminated with two faces (Rammelsberg). The salt is gradually converted into sulphate by exposure to the air.

Sulphite of Titanium is precipitated, according to Berthier, on boiling a solution of titanic hydrate in sulphurous acid.

Sulphites of Uranium. *Uranic Sulphite*, or *Sulphite of Uranyl*, $Ur^2O^3.SO^2.3H^2O = (Ur^2O^2)''SO^3.3H^2O$, separates as a flocculent precipitate, of a fine light-yellow colour, on mixing the nitrate with sulphite of ammonium, or on passing sulphurous oxide through water in which uranic hydrate is suspended. It is permanent in the air at ordinary temperatures, but decomposes when heated, giving off sulphurous oxide, and leaving a brown residue, probably of uranoso-uranic oxide (Muspratt). According to Reinele (Pogg. Ann. cxxv. 238), a solution of uranic nitrate mixed with sulphite of ammonium yields a lemon-yellow or sulphur-yellow precipitate, consisting of $(U^2O^2)''SO^3.2H^2O$, mixed with variable quantities of uranate of ammonium; it is soluble in excess of ammonium-sulphite, and somewhat soluble even in water. According to Girard (Compt. rend. xxxiv. 22; Jahresb. 1852, p. 376), the salt obtained by passing sulphurous oxide through water in which uranic oxide is suspended, and leaving the solution to evaporate, contains $(U^2O^2)''SO^3.4H^2O$.

Uranous Sulphite.—A basic salt, $Ur''SO^3.Ur''H^2O^2.H^2O$, is precipitated, with evolution of sulphurous oxide, on mixing a solution of uranous chloride with sulphite of sodium. It has a grey-green colour, dissolves easily in acids, and, when heated, gives off sulphurous oxide and leaves uranoso-uranic oxide.

Sulphite of Yttrium, $Y''SO^3$, is a white powder, insoluble in water, slightly soluble in sulphurous acid. Its solution, when evaporated, yields crystals of yttric sulphate. (Berlin, Pogg. Ann. xliii. 105.)

Sulphite of Zinc, $Zn''SO^3.2H^2O$ (according to Fórdos and Gélis), or $2Zn''SO^3.5H^2O$ (according to Rammelsberg), crystallises, on evaporating a solution of zinc-carbonate in sulphurous acid, in small sparingly soluble prisms having an unpleasant astringent taste. It is precipitated from the aqueous solution by alcohol or ether in needle-shaped crystals. On exposure to the air, it is quickly converted into sulphate, and, when heated, gives off water and sulphurous oxide, leaving a residue of sulphate, sulphide, and oxide of zinc.

An *acid sulphite of zinc-ammonium*, $\left.\begin{matrix} NZn''H^3 \\ H \end{matrix}\right\} SO^3$, is obtained in crystalline crusts by dissolving zinc-sulphite in warm aqueous ammonia, and evaporating at a gentle heat. It smells of ammonia, and is decomposed by water, which dissolves out sulphite of ammonium. (Rammelsberg.)

Sulphite of Zirconium is a white powder, insoluble in water, somewhat soluble in sulphurous acid, and precipitated from the solution by boiling. (Berthier.)

Alcoholic Sulphites. Sulphurous Ethers.

The two atoms of hydrogen in the molecule of sulphurous acid, $\left.\begin{matrix}(SO)''\\H^2\end{matrix}\right\}O^2$, may be partly or wholly replaced by monatomic alcohol-radicles, giving rise to acid and neutral sulphurous ethers, represented by the general formulæ:

$$\underset{\text{Acid.}}{\left.\begin{matrix}(SO)''\\R.H\end{matrix}\right\}O^2} \text{ and } \underset{\text{Neutral.}}{\left.\begin{matrix}(SO)''\\R^2\end{matrix}\right\}O^2}.$$

The acid ethers may also be regarded as compounds of sulphuric anhydride with hydrocarbons containing even numbers of hydrogen-atoms, and are sometimes designated as sulpho-acids, *e.g.*:

$$\text{Phenylsulphurous acid, } \left.\begin{matrix}(SO)''\\C^6H^5.H\end{matrix}\right\}O^2 \quad = \quad C^6H^6.SO^3, \quad \text{Sulphobenzolic acid.}$$

No neutral sulphurous ethers are at present known of the form $\left.\begin{matrix}(SO)''\\R''\end{matrix}\right\}O^2$, but there is a group of acid ethers, $\left.\begin{matrix}(SO)^2\\R''H^2\end{matrix}\right\}O^4$, derived from a double molecule of sulphurous acid, $H^4S^2O^6$, by substitution of a diatomic alcohol-radicle for half the hydrogen. These are the so-called disulpho-acids, which may also be formulated as compounds of hydrocarbon with 2 at. SO^3, *e.g.*:

$$\text{Phenylene-sulphurous acid, } \left.\begin{matrix}(SO)^2\\(C^6H^4)''\\H^2\end{matrix}\right\}O^4 \quad = \quad C^6H^6.2SO^3, \quad \text{Disulphobenzolic acid.}$$

The acid sulphurous ethers of the monatomic alcohol-radicles, C^nH^{2n+1}, homologous with ethyl, are produced by the action of oxidising agents, especially of nitric acid, on the sulphides, sulphydrates, and sulphocyanates of the corresponding radicles; methylsulphurous acid also, by electrolytic reduction of its chlorinated derivatives (p. 555); these ethers do not appear to be formed by the action of sulphurous acid on the corresponding alcohols.

The acid sulphurous ethers of other alcohol-radicles (phenyl, naphthyl, &c.) are produced by the action of strong sulphuric acid on the corresponding hydrocarbons containing even numbers of hydrogen-atoms, *e.g.*:

$$\underset{\text{Benzene.}}{C^6H^6} + H^2SO^4 = H^2O + \underset{\text{Phenylsulphurous acid.}}{(C^6H^5)HSO^3}.$$

All these ethers are monobasic acids, forming well-defined crystalline salts. The potassium-salts of phenylsulphurous and benzylsulphurous acid are decomposed by fusion with excess of *potassic hydrate*, yielding sulphate of potassium and the corresponding alcohols, phenol and cresol, *e.g.*:

$$\underset{\text{Benzylsulphite of potassium.}}{(C^7H^7)KSO^3} + KHO = K^2SO^3 + \underset{\text{Cresol.}}{(C^7H^7)HO}.$$

The salts of all the acid sulphurous ethers are converted by pentachloride of phosphorus into chlorides derived from the acid ethers by substitution of chlorine for hydroxyl, *e.g.*:

Ethylsulphurous acid . . . . . $SO.C^2H^5O.HO$.
Ethylsulphurous chloride . . . . . $SO.C^2H^5O.Cl$.

These chlorine-compounds, when enclosed in sealed tubes, gradually resolve themselves into a chloride of the alcohol-radicle, RCl, and sulphurous oxide, SO^2; when heated with pentachloride of phosphorus, they are decomposed according to the general equation:

$$RClSO^2 + PCl^5 = SOCl^2 + RCl + POCl^3.$$

They are converted by caustic potash into the original acid ethers; by ammonia into amides; by alcohols into the corresponding neutral ethers, *e.g.*:

$$\underset{\text{Ethylsulphurous chloride.}}{C^2H^5ClSO} + (C^2H^5)HO = HCl + \underset{\text{Ethylic sulphite.}}{(C^2H^5)^2SO^3};$$

and

$$\underset{\text{Ethylsulphurous chloride.}}{C^2H^5ClSO^2} + (CH^3)HO = HCl + \underset{\text{Methylethylic sulphite.}}{(CH^3)(C^2H^5)SO^3}.$$

The **neutral sulphurous ethers** of the alcohol-radicles C^nH^{2n+1} are also produced by the action of alcohols on disulphide of chlorine (see page 535), or on sulphurous chloride; in the latter case, according to the general equation:

$$SOCl^2 + 2(C^nH^{2n+1})HO = 2HCl + (C^nH^{2n+1})^2SO^3.$$

These neutral ethers are resolved by caustic alkalis into the corresponding alcohols and a sulphite of alkali-metal, *e.g.*:

$$(C^2H^5)^2SO^3 + 2KHO = 2(C^2H^5)HO + K^2SO^3.$$

But the neutral sulphurous ethers of other alcohol-radicles (phenyl, naphthyl, &c.) exhibit a different reaction with alkalis; ethylic naphthylsulphite for example, when treated with potash, yields, not sulphite, but naphthylsulphite of potassium. (**Carius**, Ann. Ch. Pharm. cxiv. 140; Jahresb. 1860, p. 421.)

The **acid sulphurous ethers of diatomic alcohol-radicles**—the so-called **disulpho-acids**, are obtained in some cases by the action of strong sulphuric acid upon hydrocarbons: thus, naphthylene-sulphurous or disulphonaphthalic acid, $C^{10}H^8S^2O^6$, is produced in small quantity, together with naphthylsulphurous acid, by the action of sulphuric acid on naphthalene. More frequently, however, they are produced by the action of fuming sulphuric acid on the cyanides of the alcohol-radicles (nitriles), (or on the corresponding amides, which differ therefrom by addition of 1 at. H^2O): thus phenylic cyanide or benzonitrile, treated with fuming sulphuric acid, yields phenylenesulphurous or disulphobenzolic acid:

$$C^7H^5N + 3H^2SO^4 = C^6H^6S^2O^6 + (NH^4)HSO^4 + CO^2.$$

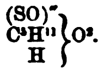
The formation of ethylene-sulphurous acid, and its homologues, may be represented by the general equation:

$$C^nH^{2n+1}.CN + 3H^2SO^4 = (C^nH^{2n})H^2S^2O^6 + (NH^4)HSO^4 + CO^2.$$

They are also produced by the oxidation of the sulphocarbonates of diatomic alcohol-radicles; *e.g.*, ethylene-sulphurous acid, $(C^2H^4)H^2S^2O^6$, by the action of nitric acid on ethylenic disulphocarbonate or trisulphocarbonate (p. 502).

These ethers are dibasic acids, forming acid and neutral salts.

a. Sulphurous Ethers containing Monatomic Alcohol-radicles.



Amylsulphurous Acid, $C^5H^{12}SO^3 = (C^5H^{11})HSO^3 = \left.\begin{matrix}(SO)''\\C^5H^{11}\\H\end{matrix}\right\}O^2$. (**Gerathewohl**, J. pr. Chem. xxxiv. 447.—**O. Henry**, Jun., Ann. Ch. Phys. [3], xxv. 246.—**Medlock**, Ann. Ch. Pharm. lxix. 225.)—This acid is produced by the action of nitric acid on the sulphydrate, disulphide, and sulphocyanate of amyl. When amyl-mercaptan is added by small portions to gently heated nitric acid of specific gravity 1·25, two layers of liquid are obtained, the upper of which is oily, and of variable composition—the lower watery, and consisting of amylsulphurous acid mixed with nitric acid; and on evaporating the latter over the water-bath till the odour of nitrous acid is no longer perceptible, a thick colourless syrup is left, consisting of impure amylsulphurous acid. This product may be used to prepare most of the amylsulphites, inasmuch as on treating the resulting salts with boiling alcohol, the amylsulphite dissolves, while the small quantity of sulphate with which it is mixed remains behind.

The pure acid is obtained by decomposing the lead-salt with sulphuretted hydrogen, and evaporating the filtrate, as a very acid syrup, having a peculiar odour. According to Gerathewohl, it does not crystallise even in a vacuum over oil of vitriol. Medlock, however, obtained it as a deliquescent crystalline mass.

The *amylsulphites* of *ammonium*, *potassium*, and *calcium*, crystallise in colourless laminæ, insoluble in water and in alcohol.—The *barium-salt*, $C^{10}H^{22}Ba''S^2O^6$, forms transparent unctuous scales, which gyrate upon water like amylsulphate or butyrate of barium. It burns in rather strong heat without decomposing.—The *copper-salt* forms bluish-green tables; the *lead-salt*, $C^{10}H^{22}Pb''S^2O^6$, colourless laminæ containing water of crystallisation, which they give off at 120°.—The *silver-salt*, $C^5H^{11}AgSO^3$, crystallises from a moderately concentrated solution in very fine colourless rhombic plates.

DIAMYLIC OR NEUTRAL AMYLIC SULPHITE, $(C^5H^{11})^2SO^3$. (**Carius**, Ann. Ch. Pharm. cvi. 291; cxi. 97; Jahresb. 1858, p. 26; 1859, p. 88.)—Produced by the action of disulphide of chlorine or sulphurous chloride, $(SOCl^2)$, on amylic alcohol, the decomposition in both cases being similar to that which takes place in the preparation of ethylic sulphite (p. 554). The second process is the easier of the two; 1 at. sulphurous chloride being added to 2 at. amylic alcohol, and the resulting liquid freed from hydrochloric acid by passing a stream of carbonic dioxide through it.

Amylic sulphite thus prepared is a nearly colourless oily liquid, smelling like amylic alcohol and ethylic sulphite, giving off sulphurous acid on exposure to moist air, and acquiring a red or brown colour. It is decomposed by water, and more quickly by aqueous alkalis, into amylsulphurous acid and amylic alcohol. When heated above 150° in contact with the air, it begins to decompose into amylic alcohol and sulphurous oxide; but in an indifferent gas, it may, for the most part, be distilled without decomposition at 230°—250.

Benzylsulphurous Acid,* $C^7H^8SO^3 = \left.\begin{matrix}(SO)''\\ C^7H^7\\ H\end{matrix}\right\}O^2$. *Toluenylsulphurous, Sulphotoluic, Sulphotoluenic, Sulphibenzylic,* or *Sulphobenzoenic Acid.* (H. Deville, Ann. Ch. Phys. [3], iii. 172.)—Produced by the action of fuming sulphuric acid on toluene (benzylic hydride, i. 573),† and purified by conversion into a lead-salt, separation by sulphydric acid, and concentration in a vacuum. It crystallises in small very deliquescent laminæ.

Benzylsulphite of ammonium crystallises in small stars; the *potassium-salt* in very soluble anhydrous laminæ; the *barium-salt*, $C^{14}H^{14}Ba''S^2O^6$, in crystalline scales very soluble in water, but not deliquescent.—The *lead-salt* is very soluble.

The benzylsulphites do not precipitate argentic or cupric nitrate.

Cumenylsulphurous Acid, $C^9H^{12}SO^3 = \left.\begin{matrix}(SO)''\\ C^9H^{11}\\ H\end{matrix}\right\}O^2$. *Sulphocumenic Acid.* (Gerhardt and Cahours, Ann. Ch. Phys. [3], i. 87.)—Prepared by adding about 1 pt. of cumene to 2 pts. fuming sulphuric acid, and agitating till the whole is dissolved.—The *barium-salt*, $C^{18}H^{24}Ba''S^2O^6$, obtained by saturating the acid solution with carbonate of barium, crystallises in a mass of nacreous very brilliant laminæ, resembling fish-scales. Its solution is not decomposed by boiling, and does not precipitate the solution of calcic chloride, plumbic acetate, mercuric chloride, cupric chloride, nickel-chloride, or bismuth-chloride.

Ethylsulphurous Ethers.—Three of these compounds are known: viz., ethylsulphurous acid, produced by the action of oxidising agents on sulphydrate and sulphocyanate of ethyl;—ethylsulphurous chloride, by the action of phosphoric oxychloride on metallic ethylsulphites;—and neutral ethylic sulphite, by the action of alcohol on disulphide of chlorine, sulphurous chloride, or ethylsulphurous chloride.

ETHYLSULPHUROUS ACID, $C^2H^6SO^3 = (C^2H^5)HSO^3$. *Sulphetholic Acid. Hyposulphethylic Acid.* (Löwig and Weidmann, Pogg. Ann. xlvii. 153; xlix. 329.—Kopp, Ann. Ch. Pharm. xxxv. 346.—Muspratt, Chem. Soc. Qu. J. iii. 18; Compt. Chim. 1848, p. 10.)—This acid is produced:—1. By the prolonged action of nitric acid (specific gravity = 1·23) on mercaptan. The resulting liquid is evaporated, diluted with water, neutralised with carbonate of lead, filtered, and concentrated; the lead-salt, after crystallisation, is decomposed by sulphydric acid; and the filtrate concentrated by evaporation.—2. By the action of moderately dilute nitric acid on ethylic sulphocyanate. The liquid is cohobated five or six times, then evaporated to a syrup, which after dilution is saturated with carbonate of barium; and the barium-salt thus obtained is decomposed by sulphuric acid. In both modes of preparation sulphuric acid is formed as well as ethylsulphurous acid, and in greater quantity as the nitric acid is more concentrated.—3. By treating ethylic sulphocyanate with a mixture of hydrochloric acid and potassic chlorate.

Ethylsulphurous acid concentrated by evaporation forms a heavy oil, of specific gravity 1·30, in which limpid crystals gradually form, especially at low temperatures. It has no smell, but a very sour taste, with disagreeable aftertaste, like that of phosphoretted hydrogen. It dissolves in all proportions in *water* and in *alcohol*, and absorbs moisture from the air. It bears a rather high temperature without decomposition, but if very strongly heated, gives off sulphuric acid and sulphurous anhydride. Fused with *hydrate of potassium*, it yields a product from which hydrochloric or sulphuric acid eliminates a large quantity of sulphurous acid.

The ethylsulphites, $C^2H^5MSO^3$, are soluble in water and in alcohol, and have a disagreeable taste, like that of the acid. They decompose when strongly heated, turning black, giving off sulphurous anhydride, together with fetid sulphurous vapours, which burn with a violent flame, and leaving a carbonaceous residue containing metallic sulphide and sulphate.—The *ammonium-salt* crystallises in very deliquescent tablets.—The *potassium-salt*, $C^2H^5KSO^3$ (at 120°) forms lamellar, opaque, deliquescent crystals, sparingly soluble in cold, more soluble in boiling alcohol. It gives off 6·75 per cent. water at 120°, and decomposes at a higher temperature.—The *sodium-salt*,

---

* The term benzylsulphurous acid is applied by Kolbe to the compound $C^6H^6SO^3$, more properly called phenylsulphurous or sulphophenylic hydride (p. 562).

† There is formed, at the same time, a crystalline substance, probably homologous with sulphobenzide.

$C^2H^5NaSO^3.xH^2O$, forms deliquescent crystals, exhibiting similar characters.—The *barium-salt*, $C^4H^{10}Ba''S^2O^6.H^2O$, is extremely soluble, but may be obtained in fine rhomboïdal prisms by slow evaporation of a very concentrated solution. It gives off its water at 100°, dissolves very easily in hydrated alcohol, but is insoluble in absolute alcohol, which precipitates it from a strong aqueous solution in silky needles.—The *calcium-salt*, $C^4H^{10}Ca''S^2O^6$ (at 100°), forms limpid crystals resembling the barium-salt, very soluble in water and in alcohol.—The *magnesium-salt* crystallises by cooling in hydrated prisms.—The *cupric salt*, $C^4H^{10}Cu''S^2O^6.5H^2O$, forms light-blue prisms, becoming anhydrous at 120°.—The *ferrous salt*, formed by dissolving metallic iron in a boiling concentrated solution of the acid, crystallises on cooling in colourless prisms. —The *manganese-salt* forms colourless needles.—The *lead-salt*, $C^4H^{10}Pb''S^2O^6$ (at 100°), crystallises from a hot concentrated solution in fine colourless plates.—The *silver-salt*, obtained by saturating the boiling aqueous acid with carbonate of silver, forms colourless laminæ.—The *zinc-salt* forms colourless dendritic crystals, efflorescing in dry air, but absorbing moisture in damp air. The crystallised salt melts when heated, and solidifies in a crystalline mass on cooling. It gives off 8·72 per cent. (2 at.) water at 120°, and 22·96 per cent. (3 at.) more at 180°.

Ethylsulphurous Chloride, $C^2H^5ClSO^2$. (Gerhardt and Chancel, Compt. rend. xxxv. 691.)—This compound, derived from ethylsulphurous acid by substitution of Cl for HO, is easily obtained by distilling ethylsulphite of sodium with excess of phosphoric oxychloride. It is a colourless, slightly fuming liquid, insoluble in *water*, very soluble in *alcohol*, having a specific gravity of 1·357 at 22·5°, and boiling at 171°. Caustic *potash* converts it into a mixture of potassic chloride and ethylsulphite (Gerhardt and Chancel).—When kept in a sealed tube, it is gradually resolved into ethylic chloride and sulphurous anhydride. Heated with *pentachloride of phosphorus* to 120° in a sealed tube, it yields sulphurous chloride, ethylic chloride, and phosphoric oxychloride:

$$C^2H^5ClSO^2 + PCl^5 = SOCl^2 + C^2H^5Cl + POCl^3.$$

Alcohol converts it into neutral ethylic sulphite. (Carius.)

Diethylic Sulphite, $(C^2H^5)^2SO^3$. *Neutral Ethylic Sulphite. Sulphurous Ether.* (Ebelmen and Bouquet, Ann. Ch. Phys. [3], xvii. 66.—Carius, Ann. Ch. Pharm. cvi. 291; cxi. 93; Jahresb. 1858, p. 94; 1859, p. 87.)—This ether is produced:—1. By the action of absolute alcohol on disulphide of chlorine. According to Carius, the first products are sulphurous chloride and ethylic sulphydrate:

$$S^2Cl^2 + C^2H^6O = SOCl^2 + C^2H^6S;$$

and these, by their mutual action, produce ethylic sulphite, together with ethylic chloride, hydrochloric acid, and free sulphur:

$$3SOCl^2 + 4(C^2H^5)HS = (C^2H^5)^2SO^3 + 2C^2H^5Cl + 4HCl + S^6.$$

The alcohol is to be added in excess to the sulphide of chlorine (Carius); the liquid filtered from the precipitated sulphur is distilled; and the portion which goes over, between 150° and 170°, is collected apart. (Ebelman and Bouquet.)

2. By the action of sulphurous chloride on alcohol:

$$SOCl^2 + 2(C^2H^5)HO = 2HCl + (C^2H^5)^2SO^3.$$

The alcohol must be perfectly anhydrous, and added by drops to the sulphurous chloride; but the result is not affected by the proportions in which the two substances are ultimately mixed. (Carius.)

3. By the action of absolute alcohol on ethylsulphurous chloride (Carius):

$$C^2H^5ClSO^2 + (C^2H^5)HO = HCl + (C^2H^5)^2SO^3.$$

Ethylic sulphite is a limpid colourless liquid, having an odour somewhat like that of mint. Boiling-point 160°. Specific gravity of liquid = 1·085 at 16°; of vapour = 4·78. It dissolves in all proportions in *alcohol* and *ether*; *water* precipitates it from the solutions, and gradually decomposes it.—*Chlorine* attacks it strongly, and in bright sunshine forms crystals of trichloride of carbon, C^2Cl^6, together with a strongly fuming liquid containing trichloracetic chloride and chloride of sulphuryl (Ebelmen and Bouquet).—By aqueous *alkalis* or *alkaline carbonates*, it is quickly decomposed into alcohol and an alkaline sulphite. On adding to a dilute solution of the ether in anhydrous alcohol, a quantity of a solution of *potassic hydrate* in absolute alcohol, not sufficient to decompose it completely, a precipitate is formed, consisting of potassic ethylsulphite. When its alcoholic solution is saturated with dry *ammonia-gas*, and heated to 120—140° in a sealed tube, laminar crystals of neutral ammonium-sulphite separate on slow cooling, and the liquid separated therefrom contains ethylamine:

$$(C^2H^5)^2SO^3 + 4NH^3 = (NH^4)^2SO^3 + 2(C^2H^5)H^2N.$$

If the alcoholic solution be saturated with *ethylamine* instead of ammonia, the products are diethylamine and sulphite of ethylamine (Carius).—*Ethylic sulphite* is strongly attached by *pentachloride of phosphorus*, yielding sulphurous chloride, phosphoric oxychloride, and ethylic chloride (Carius):

$$(C^2H^5)^2SO^3 + 2PCl^5 = SOCl^2 + 2C^2H^5Cl + 2POCl^3.$$

ETHYLAMYLIC SULPHITE, $C^7H^{16}SO^3 = \left.\begin{matrix}C^2H^5\\C^5H^{11}\end{matrix}\right\}SO^3$. (Carius, *loc. cit.*)—Produced by the action of ethylsulphurous chloride on amylate of sodium:

$$C^2H^5ClSO^2 + C^5H^{11}NaO = NaCl + (C^2H^5)(C^5H^{11})SO^3.$$

Ethylsulphurous chloride is added to amylic alcohol containing an equivalent quantity of sodium in solution, and the liquid separated from the precipitated chloride of sodium is freed from excess of amylic alcohol by passing a stream of carbonic dioxide through it.

The compound may also be formed by heating ethylsulphurous chloride with amylic alcohol in a sealed tube to 120°; but the hydrochloric acid formed in the reaction acts on another portion of the amylic alcohol, and the water thereby produced decomposes the greater part of the double ether.

Ethylamylic sulphite is a faintly yellowish oily liquid, boiling with partial decomposition between 210° and 225°, and resembling amylic sulphite in all its reactions.

Methylsulphurous Ethers.—There are three compounds of this group, corresponding exactly to the ethylsulphurous ethers: viz., methylsulphurous acid, methylsulphurous chloride, and neutral methylic sulphite; also a methylethylic sulphite.

METHYLSULPHUROUS ACID, $CH^4SO^3 = (CH^3)HSO^3$. *Sulphometholic*, *Methyldithionic*, or *Sulphomethylsulphuric Acid*. (Kolbe, Ann. Ch. Pharm. liv. 174.—Muspratt, *ibid.* lxv. 751; Chem. Soc. Qu. J. iii. 22.)—This acid, discovered by Kolbe in 1845, together with its three chlorinated derivatives, CH^3ClSO^3, $CH^2Cl^2SO^3$, and $CHCl^3SO^3$, is produced: 1. By the electrolytic reduction of either of these chlorinated acids; 2. By the action of nitric acid on sulphocyanate or disulphide of methyl, the operation being conducted in the same manner as for the preparation of ethylsulphurous acid (p. 553). (Muspratt.)

Preparation from Trichloromethylsulphurous Acid.—1. A perfectly neutral solution of potassic trichloromethylsulphite (p. 558), is decomposed by the current of a two-pair Bunsen's battery, the electrodes being formed of amalgamated zinc. The reduction takes place at first with great rise of temperature, but quietly, no hydrogen being evolved at the negative pole till nearly the whole of the trichloromethylsulphite is converted into methylsulphite. After an hour's action of the battery, the liquid becomes so much charged with chloride of zinc, that zinc is deposited at the negative pole. The zinc is then precipitated by carbonate of potassium at the boiling heat; the filtrate evaporated to its former bulk, and the current again made to act upon it, till the quantity of carbonate of zinc (resulting from precipitation of the chloride of zinc, as it forms, by the excess of potassic carbonate) increases to such an amount, that zinc is reduced at the negative pole. The solution is then again precipitated by carbonate of potassium, and the process repeated. The evolution of hydrogen at the negative pole does not begin till 64 pts. of zinc (to 100 pts. of CCl^3KSO^3) have been dissolved at the positive pole. The liquid, in addition to methylsulphite, contains chloromethylsulphite, and a very large quantity of chloride of potassium. It must, therefore, be evaporated to dryness; the residue boiled with alcohol of 80 per cent., filtered from the chloride of potassium, which for the most part remains undissolved; the alcohol distilled off; and the residue, after being diluted with water and mixed with carbonate of potassium, again subjected to the action of the current till the evolution of hydrogen becomes very brisk. This galvanic decomposition (for 70 grammes of trichloromethylsulphite) occupies altogether about ten hours.—2. An amalgam of 1 pt. potassium and 100 pts. mercury is immersed in the aqueous solution of potassic trichloromethylsulphite. Great heat is then evolved, and methylsulphite of potassium is formed, together with hydrate and chloride:

$$CCl^3KSO^3 + 3H^2O + K^6 = CH^3KSO^3 + 3KCl + 3KHO.$$

No hydrogen is evolved till the transformation is complete.

Methylsulphurous acid is extracted from its potassium-salt in the same manner as the corresponding chlorinated acids (p. 557). It forms a thick inodorous liquid, which bears without decomposition a temperature above 300°. It is a strong acid, and forms well-defined salts.

The methylsulphites are soluble in water, and crystallisable; they are decomposed by calcination into metallic sulphide, charcoal, carbonic oxide, and fetid gaseous products containing sulphur.

The *ammonium-salt* forms long deliquescent prisms.—The *potassium-salt*, CH^3KSO^3 (at 100°), crystallises from solution in boiling alcohol of 90 per cent., in a thick pulp of interlaced needles. It becomes moist in the air, but does not deliquesce; its aqueous solution is neutral to test-papers.—An *acid salt*, $CH^3KSO^3.CH^4SO^3$ (at 100°), is obtained by leaving a solution of the neutral salt in methylsulphurous acid to evaporate in a vacuum over oil of vitriol. It forms deliquescent quadrilateral prisms, which strongly redden litmus.

The *barium-salt*, $C^2H^6Ba''S^2O^6$ (at 100°), forms rhombic transparent tablets, permanent in the air; it is precipitated from its aqueous solution by alcohol in shining slender needles.—The *cupric salt*, $C^2H^6Cu''S^2O^6.5H^2O$, forms beautiful very soluble crystals.—The *lead-salt*, $C^2H^6Pb''S^2O^6.H^2O$, obtained by neutralising methylsulphurous acid with carbonate of lead, crystallises in large rhomboïdal prisms, which are permanent in the air, and give off their water of crystallisation at 100°.—A *basic lead-salt*, $C^2H^6Pb''S^2O^6.2Pb''O$ (at 100°), is obtained by boiling the neutral salt with oxide of lead, and evaporating in a vacuum, as a white amorphous mass, the solution of which is precipitated by carbonic acid.

The *silver-salt*, CH^3AgSO^3, crystallises readily in thin anhydrous laminæ, having an acid reaction and sweetish taste, and not very easily altered by exposure to light; the solution may be evaporated by heat without decomposition.

METHYLSULPHUROUS CHLORIDE, CH^3ClSO^2. (Carius, Ann. Ch. Pharm. cxiv. 140; Jahresb. 1860, p. 422.)—Prepared by heating methylsulphurous acid with twice its weight of phosphoric pentachloride, adding a little more of the latter, and isolating by fractional distillation the portion of the product which boils between 150° and 153°. When freshly prepared it is a colourless liquid, having an odour like that of neutral ethylic sulphite, but likewise sharp, and exciting sneezing. It fumes slightly in the air, sinks in water, and is slowly decomposed thereby, yielding hydrochloric and methylsulphurous acid.

DIMETHYLIC or NEUTRAL METHYLIC SULPHITE, $(CH^3)^2SO^3$. (Carius, Ann. Ch. Pharm. cx. 209; cxi. 93; Jahresb. 1859, p. 86.)—Produced by the action of methylic alcohol on disulphide of chlorine or on sulphurous chloride, also by that of methylic alcohol on methylsulphurous chloride, the reactions being exactly similar to those by which ethylic sulphite is obtained (p. 554).

It is a colourless liquid, boiling at 121·5°, under a barometric pressure of 755·4 mm. Specific gravity of liquid = 1·0456 at 16·2° (compared with that of water at 4° as unity): of vapour, obs. = 3·655 to 3·703; calc. = 3·796. When not decomposed by exposure to moist air, it has an agreeable odour resembling that of ethylic sulphate.

It dissolves in all proportions in alcohol and ether; slightly in water, with evolution of sulphurous oxide and formation of methylic alcohol; and reacts with alkalis, ammonia, and pentachloride of phosphorus, exactly like ethylic sulphite.

METHYLETHYLIC SULPHITE, $C^3H^8SO^3 = (CH^3)(C^2H^5)SO^3$. (Carius, Ann. Ch. Pharm. cxi. 93; Jahresb. 1859, p. 88.)—Produced by the action of ethylsulphurous chloride on methylate of sodium, the mode of preparation being similar to that of ethylamylic sulphite (p. 554). It is a colourless fragrant liquid, which, on exposure to the air, takes up water and gives off sulphurous acid. Boiling-point 140° to 141·5°. Specific gravity of the liquid = 1·0675 at 18° (water at 4° = 1); of the vapour = 4·3045. Its reactions are similar to those of ethylic and methylic sulphite.

Chlorinated Methylsulphurous Acids.

Three chlorinated acids are known, derived from methylsulphurous acid by the substitution of one, two, and three atoms of chlorine for hydrogen.

CHLOROMETHYLSULPHUROUS ACID, $CH^3ClSO^3 = (CH^2Cl)HSO^3$. *Chloromethyldithionic Acid, Chlorelayl-hyposulphuric Acid.* (Kolbe, Ann. Ch. Pharm. liv. 174.)—Produced by the partial dechlorination of dichloromethylsulphurous acid, by means of the electric current. To prepare it, the aqueous solution of potassic dichloromethylsulphite, $CHKClSO^3$ (p. 557), is mixed with sulphuric acid, and digested with zinc till saturated therewith. The solution is then left to cool, and decanted from the crystallised zincate of potassium; the rest of the zinc is thrown down from it by boiling with carbonate of potassium; the filtrate is evaporated; and the residue pounded and boiled with alcohol of 80 per cent. On evaporation, chloromethylsulphite of potassium is obtained, mixed however with a considerable quantity of unaltered dichloromethylsulphite. It must therefore be again treated, as above, with sulphuric acid and zinc; and on subsequent treatment with alcohol, but little of the latter salt will remain. To convert this portion likewise, the aqueous solution of the residue, acidulated with a small quantity of sulphuric acid, is exposed to the action of two elements of Bunsen's zinc-carbon battery—the current being conducted into the solution by two amalgamated zinc-plates—till the evolution of hydrogen at the negative pole ceases, and zinc is deposited upon it. The zinc is then precipitated from the solution by carbonate of potassium; the filtrate acidulated with sulphuric acid and again exposed to the electric current; the solution again precipitated with carbonate of potassium; and these operations repeated three or four times, till the whole of the salt is converted into $CClH^2KSO^3$—that is to say, till the salt, when ignited, no longer gives off hydrochloric acid, inasmuch as this acid is evolved from the dichlorinated but not from the monochlorinated salt. To ascertain whether the conversion is complete, a sample of the solution is evaporated to dryness, and exhausted by boiling with absolute alcohol; the crystals, which separate from the alcoholic solution on cooling, are dried and heated in a test-tube; and the condensed drops are mixed with solution of silver. There is no method of separating the two salts. The liquid subjected to the action of the current must always contain free sulphuric acid; otherwise the chloromethylsulphite will be further converted into methylsulphite. As soon as the dichloromethylsulphite has completely disappeared, the liquid is treated with carbonate of potassium to precipitate the zinc; the filtrate evaporated to dryness; the residual mass boiled with alcohol of 80 per cent., which leaves behind the sulphate, and the greater part of the chloride of potassium; the potassium is precipitated from the alcoholic filtrate by sulphuric acid in slight excess; the filtrate evaporated till the boiling-point rises to 130°, and all the hydrochloric acid is expelled; the viscid residue diluted with water; the solution saturated with carbonate of lead, and filtered from the insoluble sulphate of lead; and the filtrate, freed from lead by sulphuretted hydrogen, is again filtered, and concentrated by evaporation. The residue is the concentrated aqueous acid, CH^3ClSO^3.

Chloromethylsulphurous acid is a thickish liquid, syrupy at 16°; strongly acid; yields no crystals; sustains a heat of 140° without decomposition.

The chloromethylsulphites are all soluble in water, and most of them are crystallisable.—The *ammonium-salt* crystallises, by slow evaporation, in deliquescent prisms.—The *potassium-salt*, CH^2KClSO^3, crystallises in needles from a hot saturated solution in alcohol of 96 per cent., the liquid thereby becoming semi-solid. The needles pressed between paper, and dried at 100°, are anhydrous; at a red heat, they give off water and sulphurous oxide, with a trace of sulphur, and leave chloride of potassium much blackened by charcoal:

$$CH^2KClSO^3 = KCl + C + H^2O + SO^2.$$

The salt becomes moist in the air, but does not deliquesce. It does not dissolve in absolute alcohol.

The *sodium-salt* crystallises from boiling alcohol of 96 per cent., in needles united in stellate groups, and deliquescent in the air.—The *barium-salt* forms small rhombic tables, which redden litmus faintly, and have a cooling saline taste.

Lead-salt, $C^2H^4Pb''Cl^2S^2O^6$ (at 100°).—The aqueous acid, saturated with carbonate of lead, and evaporated over oil of vitriol, yields delicate silky needles, united in tufts. After being pressed between paper and dried over oil of vitriol, they appear dull and opaque, and retain 3·7 per cent. (1 at.) water, which escapes at 100°.—The salt dissolves very readily in water, forming a solution which reddens litmus, and tastes sweet at first, but afterwards astringent.

The solution boiled with lead-oxide yields an alkaline filtrate, which deposits carbonate of lead on exposure to the air.

Silver-salt.—The saturated solution of carbonate of silver in the aqueous acid, evaporated over oil of vitriol *in vacuo* and in the dark, leaves a pale-yellow viscid liquid, which with difficulty yields small crystals, having a slight acid reaction, a sweetish and disagreeably metallic taste, and very sensitive to light and heat.

DICHLOROMETHYLSULPHUROUS ACID, $CH^2Cl^2SO^3 = (CHCl^2)HSO^3$. *Dichloromethyldithionic* or *Chloroformyl-hyposulphurous Acid.* (Kolbe, *loc. cit.*)—This acid is obtained:—1. As a zinc-salt, by dissolving zinc in trichloromethylsulphurous acid:

$$2CHCl^3SO^3 + Zn^2 = C^2H^2Cl^4Zn''S^2O^6 + Zn''Cl^2.$$

The zinc is precipitated from the resulting solution by carbonate of potassium; the filtrate evaporated to dryness; and the residue is boiled with alcohol of 96 per cent.: the solution, as it cools, deposits crystals of potassic dichloromethylsulphite.

2. More easily, as a potassium-salt, by boiling dichloromethylsulphurous chloride, $CHCl^3SO^2$ (p. 559), with potash:

$$CHCl\,SO^2 + KHO = CHCl^2KSO^3 + HCl.$$

The excess of potash is neutralised with carbonic acid; the liquid evaporated to dryness; and the dichloromethylsulphite of potassium is separated from chloride of potassium by boiling spirit (as in the first method), and further purified by recrystallisation from water, till it no longer gives a cloud with nitrate of silver.

To obtain the acid from the potassium-salt, the alcoholic solution of this salt is mixed with sulphuric acid; and the liquid filtered from the sulphate of potassium is evaporated as far as possible without decomposition, and, if chloride of potassium be present, till all the hydrochloric acid is driven off. The sulphuric acid is then precipitated from the filtrate by baryta-water, added exactly in the right proportion; the filtrate evaporated as far as possible; and the residue exhausted by boiling ether, which leaves undissolved any salt that may still be present, and on evaporation leaves the acid in the form of a coloured liquid. To decolorise this acid, oxide of lead is dissolved in it, the lead precipitated by sulphuretted hydrogen, and the liquid filtered. The colouring-matter remains with the sulphide of lead, and the filtrate, evaporated *in vacuo*, leaves the crystallised acid.

Dichloromethylsulphurous acid crystallises by evaporation in a vacuum, in small, colourless, deliquescent prisms. Its properties are very much like those of trichloromethylsulphurous acid. It decomposes chlorides, sustains a heat of 140° without alteration, but melts at a higher temperature, with evolution of white vapours and separation of carbon. It is not oxidised by nitric, nitromuriatic, or chromic acid. It dissolves zinc with evolution of hydrogen, forming dichloromethylsulphite, and likewise monochloromethylsulphite of zinc. The quantity of the latter salt is greater as the evolution of hydrogen is kept up for a longer time by continual addition of sulphuric acid; its formation is represented by the equation:

$$2CH^2Cl^2SO^3 \quad + \quad Zn^2 \quad = \quad Zn''Cl^2 \; + \; C^2H^4Cl^2Zn''S^2O^6.$$

The dichloromethylsulphites are soluble in water, some of them also in alcohol. They are distinguished from the chloromethylsulphites by giving off hydrochloric acid by dry distillation, together with sulphurous and carbonic anhydrides; the residue consists of metallic chloride slightly coloured by charcoal:

$$2CHCl^2KSO^3 \quad = \quad 2KCl + C + 2SO^2 + CO^2 + 2HCl.$$

Carbonic oxide is also found among the gaseous products, being probably formed by the action of the free carbon on the carbonic anhydride.

The *ammonium-salt* crystallises by spontaneous evaporation in colourless prisms, permanent in the air, and often an inch long.—The *potassium-salt*, $CHCl^2KSO^3$, forms small pearly scales. It dissolves in water and in boiling alcohol, but not in cold absolute alcohol. It is permanent in the air, neutral to test-papers, and has a slightly saline taste. It bears a heat of 250° without decomposition, but at higher temperatures it is decomposed in the manner above mentioned.—The *silver-salt*, $CHCl^2AgSO^3$, obtained by neutralising the acid with carbonate of silver, is very sensitive to light and heat. When protected therefrom, it may be obtained by evaporation in a vacuum, in small transparent crystals, which may be heated to 150° without decomposing.

TRICHLOROMETHYLSULPHUROUS ACID. $(CCl^3)HSO^3$. *Trichloromethyldithionic* or *Chlorocarbohyposulphuric Acid.* (Kolbe, *loc. cit.*)—Obtained as a potassium—or barium-salt, by gently heating trichloromethylsulphurous chloride, CCl^4SO^2 (p. 559), with potash or baryta; and isolated by decomposing the barium-salt with sulphuric acid, removing the excess of sulphuric acid with carbonate of lead, and the excess of lead by sulphydric acid.

The acid crystallises by evaporation in small colourless prisms, containing $CHCl^3SO^3.H^2O$. The crystals, dried in a vacuum, yield a colourless deliquescent mass, difficult to dry completely. It melts at 130° in its water of crystallisation, and begins to boil at 160°, partly volatilising; while another part is completely resolved into hydrochloric acid, sulphurous oxide, and chloride of carbonyl (phosgene-gas):

$$CHCl^3SO^3 \quad = \quad HCl + SO^2 + COCl^2.$$

It easily dissolves zinc, with evolution of hydrogen, yielding dichloromethylsulphite of zinc. It is not attacked by boiling with fuming nitric, nitromuriatic, or chromic acid. It decomposes all salts of volatile acids, even the chlorides.

The aqueous acid is converted, by a small quantity of potassium-amalgam (1 pt. potassium to 100 pts. mercury), into dichloromethylsulphite of potassium; with a larger quantity of the amalgam, the monochlorinated salt is formed, and with a still larger quantity, the methylsulphite.

The trichloromethylsulphites are soluble in water and in alcohol, and have an astringent metallic taste. When calcined they decompose like the acid, giving off sulphurous oxide and phosgene, and leaving a residue of chloride. The evolution of phosgene distinguishes the trichloromethylsulphites from the monochlorinated and dichlorinated salts.

The *ammonium-salt* forms large regular prisms, permanent in the air, and resolved by heat into sal-ammoniac, sulphurous oxide, and phosgene.—The *potassium-salt*, prepared as above, and purified by recrystallisation, forms thin transparent plates, which have a harsh disagreeable taste, effloresce on exposure to the air, and give off 7·1 per cent (1 at.) water at 100°. It may be heated to 300° without decomposition, but decomposes at a higher temperature in the manner above mentioned. In aqueous solution it is converted by electrolysis, if no free acid is present, into methylsulphite of potassium (p. 555).

The *sodium-salt*, obtained like the potassium-salt, forms thin rhombic tables, which effloresce readily, and are more soluble in water than the potassium-salt.—The *barium-salt*, $C^2Cl^6Ba''S^2O^6.H^2O$, prepared as above, crystallises on cooling from a hot aqueous solution, in small colourless laminæ, but by spontaneous evaporation in tables of larger size. The crystals dried at 100° still retain 3·05 per cent. (1 at.) water, which escapes at 100°.

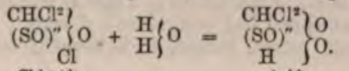
The *lead-salt*, $C^2Cl^6Pb''S^2O^6.2H^2O$, crystallises by spontaneous evaporation of the aqueous solution in broad tables, which redden litmus, and have a sweetish rough taste; they contain 6·1 per cent. (1 at.) of water, which escape at 100°; decomposition begins at 150°. The aqueous solution boiled with oxide of lead, yields an alkaline filtrate, which is precipitated by the carbonic acid of the air, and when evaporated in a vacuum leaves an amorphous basic salt.

The *copper-salt* forms small tables, permanent in the air, and containing 5 at. water, of which only 2 at. go off at 180°—the other three remaining till the salt begins to decompose.

Silver-salt, CCl^3AgSO^3.—The aqueous solution evaporated in a vacuum, and protected from light, yields transparent and colourless prisms, which redden litmus, have a sweetish metallic taste, blacken on exposure to the light, and likewise when their aqueous solution is boiled. But when freed, by heating to 100°, from the 2 at. water of crystallisation which they contain, they remain colourless in sunshine.

Chloromethylsulphurous Chlorides.

Two chlorides are known, derived from di- and tri-chloromethylsulphurous acid, by substitution of Cl for HO. When they are treated with alkalis, the reverse substitution is effected, hydrochloric acid being evolved and the acid produced; *e. g.*:



$$\underset{\text{Chloride.}}{\left.\begin{matrix}CHCl^2\\(SO)''\\Cl\end{matrix}\right\}O} + \left.\begin{matrix}H\\H\end{matrix}\right\}O = \underset{\text{Acid.}}{\left.\begin{matrix}CHCl^2\\(SO)''\\H\end{matrix}\right\}\begin{matrix}O\\O.\end{matrix}}$$

Dichloromethylsulphurous Chloride, $CHCl^2SO^2$. (Kolbe, Ann. Ch. Pharm. liv. 153.—Gerhardt, Compt. chim. 1845, p. 197.)—This compound is formed by the action of reducing agents on trichloromethylsulphurous chloride. When a current of sulphurous oxide gas is passed through an alcoholic solution of the latter body, till the liquid no longer gives a precipitate with water, a solution is formed, containing—besides sulphurous acid—hydrochloric acid, sulphuric acid, and dichloromethylsulphurous chloride:

$$CCl^4SO^2 + SO^2 + 2H^2O = HCl + H^2SO^4 + CHCl^2SO^2.$$

This chloride cannot be completely separated from the bodies with which it is mixed, since it is very easily decomposed by evaporation, yielding phosgene-gas together with sulphuric and sulphurous acids. A small quantity spread out upon a surface soon fills the atmosphere with suffocating vapours of phosgene and sulphurous oxide:

$$CHCl^2SO^2 + O = COCl^2 + SO^2 + HCl.$$

Chlorine passed into the aqueous solution reprecipitates trichloromethylous sulphide.—*Bromine* forms a similar precipitate, containing bromine as well as chlorine.—*Iodine* forms no precipitate. The aqueous solution boiled with *potash* yields chloride and dichloromethylsulphite of potassium.

This compound has not been obtained in the separate state, and therefore its composition has not been determined by analysis. Kolbe assigned to it the formula CCl^2SO^2 (*schwefligsaures Kohlenchlorid*); the more probable view of its composition above given was suggested by Gerhardt. The two formulæ differ only by HCl.

Trichloromethylsulphurous Chloride, CCl^4SO^2. *Sulphite of Perchloride of Carbon. Schwefligsaures Kohlensuperchlorid* (Kolbe). *Chlorunterschwefligsaures Chlorkohlenoxyd* (Berzelius).—This compound, discovered by Berzelius and Marcet (Schw. J. ix. 298), and further examined by Kolbe (Ann. Ch. Pharm. liv. 148), is produced by the action of moist chlorine on carbonic disulphide:

$$CS^2 + 6Cl^2 + 2H^2O = CCl^4SO^2 + SCl^4 + 4HCl.$$

Kolbe prepares it by introducing into a stoppered bottle, having a capacity of about six litres, a quantity of manganic peroxide and hydrochloric acid sufficient to fill about half of it, then adding about 50 grammes of carbonic disulphide, and immediately closing the vessel. The mixture is left for several days in a cool place; then, after frequent agitation, exposed to a temperature of about 30° (most conveniently to the rays of the sun in summer), till the greater part of the carbonic disulphide is transformed. The action is much facilitated by adding from 100 to 200 grms. of commercial nitric acid. All danger of the vessel bursting from internal pressure may be obviated by lifting the stopper from time to time. The mixture is then transferred to a large glass flask, and distilled in an oil-bath into a cooled receiver. Undecomposed carbonic disulphide then passes over first, mixed with a yellowish fetid liquid; and afterwards the trichloromethylsulphurous chloride, which attaches itself in crystals to the sides of the receiver, but is easily detached by slight blows: 50 grms. of carbonic disulphide yield nearly 100 grms. of trichloromethylsulphurous chloride.

This chloride is a white, crystalline, volatile body, insoluble in water and in acids, soluble in alcohol, ether, and carbonic disulphide; its alcoholic solution is precipitated by water. It melts at 135°, and boils without alteration at 170°; distils also with vapour of water. It has an extremely pungent odour, excites tears, and produces a disagreeable roughness in the throat. Its alcoholic solution, when recently prepared, is but slightly clouded by nitrate of silver, precipitation not taking place till the liquid has remained for some time in contact with the air.

The compound sublimes like camphor, in small, colourless, transparent plates, having an adamantine lustre. In the dry state it does not alter the colour of litmus, but reddens it when moist, in consequence of decomposition. The moist crystals are white, opaque, and form vegetations like hoarfrost. It supports a moderately high temperature without decomposition; but when passed through a tube heated to dull redness, it is resolved into chlorine, sulphurous oxide, and perchlorethylene:

$$2CCl^3SO^2 = C^2Cl^4 + 2Cl^2 + 2SO^2.$$

When distilled with a large excess of strong sulphuric acid, it is resolved into sulphurous oxide, hydrochloric acid, and phosgene:

$$CCl^3SO^2 + H^2O = SO^2 + 2HCl + COCl^2.$$

In contact with air and water, it decomposes in a similar manner, yielding hydrochloric acid, sulphurous oxide, sulphuric acid, and carbonic dioxide.

It dissolves in caustic potash, forming trichloromethylsulphite and chloride of potassium.

Naphthylsulphurous Acid, $C^{10}H^8SO^3 = (C^{10}H^7)HSO^3 = \left.\begin{matrix}(SO)''\\ C^{10}H^7.H\end{matrix}\right\}O^2$. *Sulphonaphthalic*, *Hyposulphonaphthalic*, or *Naphthyldithionic Acid.* (Faraday [1827], Ann. Ch. Phys. [2], xxxiv. 164.—Berzelius, *ibid.* lxv. 290.—Wöhler, Ann. Ch. Pharm. xxxvii. 197.—Regnault, Ann. Ch. Phys. [2], lxv. 87.—Laurent, Rev. scient. xiii. 587.—Kimberly, Ann. Ch. Pharm. cxiv. 129.)—This acid is produced, together with naphthylene-sulphurous (disulphonaphthalic) acid, by melting naphthalene with strong sulphuric acid or sulphuric anhydride.—When naphthalene is dissolved to saturation, in strong sulphuric acid heated to 90°, and the solution is exposed to the air, it solidifies completely after some time; and the solidified mass, after being freed from excess of acid by pressure between porous tiles, dissolves completely in water, provided all the naphthalene has been converted into acid products. To separate the two acids, the aqueous solution is neutralised with carbonate of barium, concentrated, and mixed with twice its volume of alcohol, which precipitates naphthylene-sulphite of barium, while the naphthylsulphite remains in solution, and may be crystallised therefrom.—To obtain the free acid, the solution of the barium-salt is precipitated by sulphuric acid; the excess of the latter removed by carbonate of lead; the resulting naphthylsulphite of lead is decomposed by sulphydric acid; and the filtrate is evaporated in a vacuum.

Naphthylsulphurous acid may be obtained, by evaporation of its aqueous or alcoholic solution, as an irregularly crystalline deliquescent mass, containing $C^{10}H^8SO^3.H^2O$. It has a strongly acid, astringent, metallic taste; is extremely soluble in water, oil of turpentine, fixed oils, and alcohol, but very slightly soluble in ether. It melts between 85° and 90°, blackens at about 120°, giving off an odour of naphthalene, and when more strongly heated swells up considerably, leaving a very bulky cinder. The aqueous solution turns brown on boiling.

Naphthylsulphites.—The acid is monobasic. Its salts are soluble in water, for the most part also in alcohol, and have a bitter, almost metallic taste. When heated, they give off a considerable quantity of naphthalene, together with sulphurous oxide, and leave a residue of sulphate and sulphide.—The potassium-salt fused with excess of potassic hydrate is decomposed, with evolution of sulphurous oxide, and formation of a solid body, probably naphthol or naphthylic alcohol. (Wurtz, Compt. rend. lxiv. 750.)

The *ammonium-salt* crystallises in slender needles, permanent in the air. Its solution becomes acid on evaporation. When subjected to dry distillation, it melts, decomposes, and takes fire.—The *potassium-salt*, $2C^{10}H^7KSO^3.H^2O$, crystallises in small, white, very brilliant scales, permanent in the air, and slightly soluble in water.—The *sodium-salt* is similar, and has a strong metallic taste.—The *silver-salt*, $C^{10}H^7AgSO^3$, is moderately soluble, 100 pts. of water at 20° dissolving about 10·3 pts. of it. The solution is not decomposed by boiling.

The *barium-salt*, $C^{20}H^{14}Ba''S^2O^6.2H^2O$, crystallises from a hot saturated solution on cooling, in small tufts or cauliflower-heads; by spontaneous evaporation in irregular scales, grouped like cockscombs. In the dry state it quickly absorbs moisture from the air. It is but sparingly soluble in water, 100 pts. of water dissolving 1·13 pts. of it at 15°, and 4·76 pts. at 100°. It dissolves also in absolute alcohol and in ether. Heated on platinum-foil, it burns with a bright very smoky flame, leaving a blackish residue.—The *strontium-salt* is crystalline.—The *calcium-salt* crystallises with difficulty. When boiled with nitric acid, it yields nitronaphthylsulphite of calcium.—The *magnesium-*, *zinc-*, *nickel-*, *manganous*, and *ferrous* salts are also crystallisable.—The *cupric salt* crystallises in greenish scales containing water, which they partly give off in dry air.—The *neutral lead-salt*, $C^{20}H^{14}Pb''S^2O^6$, crystallises less regularly than the barium-salt. When heated it decomposes, throwing out ramifications in all directions, and increasing considerably in volume. Its solution boiled with oxide of lead yields a basic salt containing $C^{20}H^{14}Pb''S^2O^6.Pb''O$ or $C^{20}H^{14}Pb''S^2O^6.3Pb''O$, according to the quantity of oxide used.—The *mercuric salt*, obtained by dissolving mercuric oxide in naphthylsulphurous acid, is yellow and deliquescent.

Metanaphthylsulphurous Acid.—This name may be applied to an acid, apparently isomeric with naphthylsulphurous acid, which, according to Faraday, is sometimes formed in small quantity in the preparation of the latter, especially when 1 pt. of naphthalene is very strongly heated with 2 pts. of concentrated sulphuric acid, without, however, allowing the mixture to give off sulphurous oxide. On saturating the aqueous solution of the product with carbonate of barium, the barium-salt of this peculiar acid is precipitated, together with sulphate, and may be dissolved out from the latter by boiling water; on evaporating the resulting solution, it is deposited in small hard crystals, slightly soluble in water and in alcohol. This salt contains the same quantity of barium as the ordinary naphthylsulphite, but is distinguished from it by not burning with flame when heated, but merely smouldering (Faraday, Berzelius).—The *potassium-salt* of the same acid crystallises in scales, soluble in water and in alcohol.—The *lead-salt* is very much like the barium-salt. By decomposing it with sulphuretted hydrogen, an acid is obtained, which crystallises in scales, soft to the touch, permanent in the air, but turning brown on exposure to the sun. (Faraday, Berzelius.)

Naphthylsulphurous Chloride, $C^{10}H^7ClSO^2$. (Kimberly, Ann. Ch. Pharm. cxiv. 129.)—Produced by the action of phosphoric pentachloride on naphthylsulphite of sodium dried at 100°. On treating the product with water, and crystallising the undissolved portion from ether free from alcohol, it is obtained pure, in colourless, microscopic, rhombic laminæ. It is inodorous, melts at 65°, and solidifies in globular masses on cooling, but, if kept from agitation and from contact with solid bodies, it remains liquid below 55°. It dissolves very easily in ether, benzol, carbonic disulphide, and phosphoric oxychloride. It is for the most part decomposed by dry distillation, the decomposition beginning at about 120°. It is slowly decomposed by *water*, easily by *potash*, in aqueous and especially in alcoholic solution, yielding alcohol and naphthylsulphurous acid.—*Alcohol* converts it slowly in the cold, quickly when heated, into ethylnaphthylic sulphite:

$$C^{10}H^7ClSO^2 + (C^2H^5)HO = HCl + (C^2H^5)(C^{10}H^7)SO^3.$$

Aqueous *ammonia* converts it into naphthylthionamic acid:

$$C^{10}H^7ClSO^2 + H^3N = HCl + C^{10}H^9NSO^2.$$

Ethylnaphthylic Sulphite, $C^{12}H^{12}SO^3 = \left.\begin{matrix}C^2H^5\\C^{10}H^7\end{matrix}\right\}SO^2$. (Kimberly, *loc. cit.*)—Prepared by heating 1 at. naphthylsulphurous chloride with not more than 2 at. alcohol, in an apparatus so arranged that the vapours may condense and flow back again; then distilling off the excess of alcohol, and washing the residue with water; if the product is coloured, it must be dissolved in ether, and treated with animal charcoal.

Ethylnaphthylic sulphite, when recently prepared, is a viscid liquid at ordinary temperatures, and does not solidify even at −8° to −10°; but after keeping for several days (or, if it has been heated above 50°, after weeks or months), it solidifies in nodules composed of laminar crystals. It is insoluble in water, but mixes in all proportions with alcohol and ether. It is decomposed by distillation, giving off sulphurous oxide, yielding a considerable sublimate of naphthalene, and leaving a small carbonaceous residue.—By aqueous or alcoholic *potash*, it is quickly resolved into alcohol and naphthylsulphite of potassium. In alcoholic solution it is decomposed by water in the same manner as by potash; and when heated with water alone in a sealed tube to about 150°, it is resolved, without blackening or formation of secondary products, into alcohol, naphthalene, and sulphuric acid (probably first into alcohol and naphthylsulphurous acid, which is then further split up into naphthalene and sulphuric acid).—With *pentachloride of phosphorus*, it yields ethylic chloride, naphthylsulphurous chloride, and phosphoric oxychloride:

$$(C^2H^5)(C^{10}H^7)SO^3 + PCl^5 = C^2H^5Cl + C^{10}H^7ClSO^2 + POCl^3.$$

Naphthylthionamic Acid, $C^{10}H^9NSO^2$ = 
$$\left.\begin{array}{c} C^{10}H^7.H \\ (SO)'' \\ H \end{array}\right\} \begin{array}{l} N \\ O. \end{array}$$

Naphthylthionamide.

(Kimberly, *loc. cit.*)—Produced, by triturating naphthylsulphurous chloride with ammonia, as a yellow oil, which solidifies to an amorphous mass. It dissolves easily in ether and in alcohol, and separates from either solution in microscopic crystals, apparently quadratic combinations, P . oP . P∞, with the angle P : P on the lateral edges = 110°. It dissolves also in aqueous ammonia, in strong hydrochloric acid, and in glacial acetic acid, and crystallises from the two latter solutions unaltered. It is inodorous, has a greyish-yellow colour when dry, light-yellow when moistened with aqueous ammonia, gradually turning red on exposure to the air. It melts without decomposition, in boiling water, to a viscid liquid, which solidifies to an amorphous mass; at a higher temperature, it chars and gives off pungent vapours.

It is quickly decomposed by aqueous *potash*, yielding ammonia and naphthylsulphite of potassium. Heated with aqueous *nitrite of potassium*, it gives off nitrogen, and is converted into naphthylsulphite of potassium; part of it is, however, transformed at the same time into a resinous substance, insoluble in water, and detonating slightly when heated.

When the alcoholic solution of the acid, containing a little free ammonia, is mixed with excess of *argentic nitrate*, and the ammonia is allowed to evaporate gradually at ordinary temperatures, argentic naphthylthionamate, $C^{10}H^8AgNSO^2$, is deposited as a white crystalline substance, easily soluble in alcohol, ether, and ammonia, and quickly blackening when exposed to light.

Benzonaphthylthionamic acid, $C^{10}H^8(C^7H^5O)NSO^2$, is produced by fusing naphthylthionamic acid with an equivalent quantity of benzoic chloride, till hydrochloric acid is no longer evolved; and on washing the product with lukewarm water, drying it, and recrystallising from alcohol, it separates in microscopic prismatic crystals, easily soluble in alcohol, ether, aqueous ammonia, and glacial acetic acid. It melts without decomposition at 100°, but decomposes at a higher temperature, and when boiled with aqueous potash, gives off ammonia, and yields benzoate and naphthylsulphite of potassium. When its solution in absolute alcohol is mixed with ammonia and argentic nitrate, and left to evaporate, it deposits argentic benzonaphthylthionamate, $C^{10}H^7Ag(C^7H^5O)NSO^2$, as an amorphous flocculent precipitate, which dissolves somewhat slowly in alcohol, and may be crystallised in microscopic needles by mixing its ammoniacal alcoholic solution with a slight excess of acetic acid, and gently warming the liquid. (Kimberly.)

Bromo-, Chloro-, and Nitro-naphthylsulphurous Acids.

These acids are formed by heating the bromo-, chloro-, and nitro-naphthalenes with fuming sulphuric acid, or (in the case of the monochlorinated compound) with ordinary concentrated sulphuric acid.

Bromonaphthylsulphurous Acid, $C^{10}H^7BrSO^3 = (C^{10}H^6Br)HSO^3$. (Laurent, Compt. chim. 1849, p. 392.)—When the solution obtained by heating bromonaphthalene with fuming sulphuric acid is neutralised with potash, diluted, and boiled, the filtered liquid deposits, on cooling, a crystalline pulp of *potassic bromonaphthylsulphite*, $C^{10}H^6BrKSO^3$, which is colourless, slightly soluble in cold water, moderately soluble in boiling water and alcohol, whence it crystallises in tubercles. Boiling nitric acid converts it into a yellow salt, which takes fire when heated in a close vessel, and probably consists of $C^{10}H^5(NO^2)BrKSO^3$.

A solution of potassic bromonaphthylsulphite poured into a warm moderately concentrated solution of barium-chloride, precipitates the *bromonaphthylsulphite of barium*, $C^{20}H^{12}Br^2Ba''S^2O^6$, as a crystalline salt soluble in cold water. The solution of the potassium-salt forms white precipitates with moderately strong solutions of calcic chloride and plumbic acetate, but does not precipitate the salts of magnesium, manganese, cobalt, nickel, zinc, mercury, and silver.

Dibromonaphthylsulphurous Acid, $C^{10}H^{6}Br^{2}SO^{3} = (C^{10}H^{5}Br^{2})HSO^{3}$. (Laurent, Compt. chim. 1849, p. 392.)—Prepared as above from dibromonaphthalene. —The *potassium-salt*, $C^{10}H^{5}Br^{2}KSO^{3}$, is crystalline, and soluble in boiling alcohol.—The *barium-salt*, $C^{20}H^{10}Br^{4}Ba''S^{2}O^{6}$, is obtained by pouring a solution of the potassium-salt into a boiling and very dilute solution of barium-chloride, and separates, on cooling, as a flocculent precipitate composed of microscopic needles.

Chloronaphthylsulphurous Acid, $(C^{10}H^{6}Cl)HSO^{3}$. (Zinin, J. pr. Chem. xxxiii. 36.)—When a mixture of 2 vols. strong sulphuric acid and 1 vol. chloronaphthalene is heated to 140° for a quarter of an hour, a transparent brownish liquid is obtained, which does not alter on cooling; but is converted, by addition of a few drops of water, into a white, buttery, scarcely crystalline mass, which may be freed from excess of sulphuric acid by spreading it out on a porous tile (Zinin). The same acid appears to be formed, with evolution of hydrochloric acid, on dissolving chloride of naphthalene in fuming sulphuric acid. (Laurent.)

Chloronaphthylsulphurous acid dissolves easily in water and in alcohol; when heated, it melts to a brownish liquid, decomposes, and gives off an odour of naphthalene.

The *ammonium-salt* of this acid is crystalline and very soluble. Its solution forms soluble curdy precipitates with ferrous and argentic salts.—The *potassium-salt* is slightly soluble in water and in alcohol.—The *barium-salt*, $C^{20}H^{12}Cl^{2}Ba''S^{2}O^{6}$, forms microscopic needles of a dull white colour, and very soluble.—The *cupric salt* is bluish and very soluble.—The *ferrous salt* is a white flocculent precipitate.—The *lead-salt* is a white nearly insoluble powder.—The *silver-salt* is a white curdy precipitate, slightly soluble in water, and decomposing at 100°.

Dichloronaphthylsulphurous Acid, $(C^{10}H^{5}Cl^{2})HSO^{3}$. (Zinin, *loc. cit.*)—Prepared like the preceding. It is a white buttery acid, very soluble in water. Its *ammonium-salt* is also very soluble.—The *potassium-salt* and the *barium-salt*, $C^{20}H^{10}Cl^{4}Ba''S^{2}O^{6}$, form small slightly soluble needles.—The *silver-salt*, $C^{10}H^{5}Cl^{2}AgSO^{3}$, crystallises in colourless scales, still less soluble than the potassium-salt.

Trichloronaphthylsulphurous Acid, $(C^{10}H^{4}Cl^{3})HSO^{3}$. (Laurent, Compt. chim. 1849, p. 394.)—Prepared by dissolving trichloronaphthalene in fuming sulphuric acid, neutralising the diluted solution with potash, converting the potassium-salt into a barium-salt, then into a lead-salt, and decomposing the latter with sulphuric acid. The aqueous solution thus obtained solidifies on cooling to a mass of microscopic needles, which may be purified by recrystallisation from boiling alcohol.

The *ammonium-salt* of this acid is easily soluble in water and in aqueous ammonia. Most of the other trichloronaphthylsulphites, even those of potassium and sodium, are but very slightly soluble in cold water; consequently the acid and its ammonium-salt form precipitates even in the cold dilute solutions of the nitrate and sulphite of potassium and sodium, and in those of the chlorides of barium and calcium, and of the sulphates of magnesium, nickel, and copper.

The *potassium-salt* forms opaque microscopic scales, very soluble in boiling water, nearly insoluble in cold water and in boiling alcohol.—The *barium-salt*, $C^{20}H^{8}Cl^{6}Ba''S^{2}O^{6}$, requires from 300 to 400 pts. of boiling water to dissolve it.—An *ammoniacal cupric salt*, $C^{20}H^{8}Cl^{6}CuS^{2}O^{6}.4NH^{3}.4H^{2}O$, is obtained by pouring a solution of the ammonium-salt into cupric acetate, adding ammonia, and heating. The solution, on cooling, solidifies to a filamentous jelly, like the mycodermic substances deposited from tartaric solutions. The washed salt has a lilac colour, changing to blue on drying.

Tetrachloronaphthylsulphurous Acid, $(C^{10}H^{3}Cl^{4})HSO^{3}$. (Laurent, Compt. chim. 1849, p. 397.)—Prepared by heating tetrachloronaphthalene with fuming sulphuric acid.—The *potassium-salt*, $C^{10}H^{3}Cl^{4}KSO^{3}$, is nearly insoluble in cold, slightly soluble in boiling water, very soluble in boiling alcohol, whence it separates in microscopic spherules. Its alcoholic solution does not precipitate acetate of barium, but on addition of water, the liquid coagulates to a gelatinous mass.

Nitronaphthylsulphurous Acid, $C^{10}H^{7}(NO^{2})SO^{3}$. (Laurent, Rév. scient. xiii. 588.)—Nitronaphthalene heated with fuming sulphuric acid, yields a red solution, from which water precipitates more or less unaltered nitronaphthalene. The filtered solution saturated with carbonates yields the nitronaphthylsulphites. The acid is also produced by the action of nitric acid on naphthylsulphurous acid. It crystallises in microscopic rhomboïdal scales. Sulphydrate of ammonium appears to convert it into naphthionic acid (iv. 17).

The nitronaphthylsulphites ignite when heated in close vessels.—The *ammonium-salt* crystallises in needles; the *potassium-salt* by spontaneous evaporation, in irregular crystals.—The *calcium-salt*, $C^{20}H^{12}Ca''(NO^2)^2S^2O^6$, is moderately soluble in water and in alcohol.

Dinitronaphthylsulphurous Acid, $C^{10}H^6(NO^2)^2SO^3$, is formed by the prolonged action of nitric acid on naphthylsulphurous acid.—Its *ammonium-salt*, $C^{10}H^5(NH^4)(NO^2)^2SO^3$, crystallises in yellow needles; it is decomposed by sulphydrate of ammonium, yielding a deposit of sulphur, and a peculiar acid, perhaps nitronaphthionic acid. (Laurent, Compt. rend. xxxi. 537.)

Phenylsulphurous Acid, $C^6H^6SO^3 = (C^6H^5)HSO^3$. *Sulphobenzolic, Sulphobenzenic*, or *Sulphobenzidic Acid*. (Mitscherlich [1834], Pogg. Ann. xxxi. 283, 634.—Stenhouse, Proc. Roy. Soc. xiv. 351.—Wurtz, Compt. rend. lxiv. 749.—Kekulé, *ibid*. p. 752.)—This acid is produced by dissolving benzene in fuming sulphuric acid, diluting with water, filtering to separate any sulphobenzide (p. 486) that may have been formed at the same time, saturating with carbonate of barium, converting the resulting barium-salt into a cupric salt by precipitation with cupric sulphite, purifying the cupric salt by crystallisation, and decomposing it with sulphuretted hydrogen. The acid may also be prepared by gently heating benzene with about an equal volume of ordinary concentrated sulphuric acid; and (according to Stenhouse) this is the best method of obtaining it in large quantities, using 4 vols. sulphuric acid to 5 vols. benzene. Phenylsulphurous acid evaporated to a syrupy consistence, yields a crystalline residue, which decomposes at a higher temperature.

The phenylsulphites or sulphobenzolates, $C^6H^5MSO^3$, are very stable salts, some of them bearing a very high temperature without decomposing. The ammonium-salt, however, decomposes easily at 200°, yielding sulphophenylamide (p. 523), together with sulphurous oxide, ammonia, benzene, and a small quantity of phenylic sulphide; and the sodium- and calcium-salts yield, by dry distillation, phenylic sulphide, $(C^6H^5)^2S$, together with carbonic dioxide and sulphurous oxide. (Stenhouse, iv. 417.)

The phenylsulphites distilled with oxychloride of phosphorus, yield phenylsulphurous or sulphophenylic chloride, $C^6H^5ClSO^2$ (Gerhardt and Chancel). They may be boiled for a long time with excess of aqueous potash without decomposition, but by fusion with potassic hydrate they are resolved into sulphurous acid and phenol (Wurtz, Kekulé):

$$\underset{\text{Potassic phenyl-sulphite.}}{(C^6H^5)KSO^3} + KHO = K^2SO^3 + \underset{\text{Phenol.}}{(C^6H^5)HO.}$$

The *phenylsulphites* of *ammonium*, *potassium*, *sodium*, and *calcium* crystallise easily; the *barium-salt* is obtained only in crystalline crusts; the *zinc-* and *silver-salts* are also crystallisable.—The *cupric salt*, $C^{12}H^{10}Cu''S^2O^6$, forms fine, bulky, hydrated crystals, which give off all their water at 170°. (Mitscherlich.)

Nitrophenylsulphurous acid, $C^6H^5(NO)^2SO^3$, is produced by boiling phenylsulphurous acid with nitric acid.—Its *ammonium-salt*, $C^6H^4(NH^4)(NO^2)SO^3$, is converted by sulphydric acid into phenylsulphamate of ammonium. (Laurent, Compt. rend. xxxi. 538.)

Phenylsulphurous Chloride, $C^6H^5ClSO^2 = \left.\begin{matrix}(SO)''\\ C^6H^5\end{matrix}\right\}\begin{matrix}Cl\\ O\end{matrix}$. *Sulphophenylic* or *Sulphobenzolic Chloride*. (Gerhardt and Chancel, Compt. rend. xxxv. 690.)—Produced by the action of phosphoric oxychloride on a phenylsulphite. To prepare it, benzene is gently heated with an equal volume of strong sulphuric acid, till it is completely dissolved; the liquid, after dilution, is saturated with chalk; the filtered solution of calcic phenylsulphite is exactly decomposed by carbonate of sodium, and the solution of sodic phenylsulphite is filtered and evaporated. This salt having been dried at 150°, is then mixed in a retort by small portions with oxychloride of phosphorus, so as to form a thick pulp. The reaction begins in the cold, and as soon as it ceases, the product is to be distilled as long as any oily matter passes over, and the distillate rectified, collecting apart the latter portions, which distil at 254°. The lower portions contain also a considerable quantity of phenylsulphurous chloride, and may be utilised for the preparation of sulphophenylamide (p. 523).

Phenylsulphurous chloride is a colourless, strongly refracting oil, of specific gravity 1·378 at 23°. It boils at 254°, has a strong odour like that of bitter-almond oil, and fumes slightly in the air. It is scarcely attacked by water, but alkalis instantly convert it into phenylsulphite and chloride of alkali-metal. With aqueous ammonia it yields sal-ammoniac and sulphophenylamide (phenylthionamide).

Phenylsulphurous Hydride, $C^6H^6SO^2$. *Benzylsulphurous Acid*. (Kolbe, Ann. Ch. Pharm. cxix. 153; Jahresb. 1861, p. 627.)—Produced, as a zinc-salt, by the action of zinc-ethyl on phenylsulphurous chloride:

$$2C^6H^5ClSO^2 + Zn''(C^2H^5)^2 = 2C^2H^5Cl + C^{12}H^{10}Zn''S^2O^4.$$

Pure phenylsulphurous chloride is mixed with 3 vols. ether free from water and alcohol, and zinc-ethyl is gradually added to the mixture in a flask filled with dry carbonic dioxide, the liquid becoming hot, and depositing a white powder at each addition. As soon as a portion of the mixture no longer exhibits the smell of the chloride, the pasty mass is to be heated to 100° to expel the ether, and the excess of zinc-ethyl is decomposed by water, which will not dissolve the basic zinc-salt formed in the reaction, even on boiling. On treating it with hydrochloric acid, the whole dissolves, excepting a small quantity of a disagreeably-smelling oil [perhaps $C^6H^4(C^2H^5)SO^2$]; and the decanted liquid, on cooling, deposits phenylsulphurous hydride, in large, mostly stellate prisms, which may be freed from the last traces of the oil by recrystallisation. Its formation from the zinc-salt is represented by the equation:

$$C^{12}H^{10}Zn''S^2O^4 + 2HCl = Zn''Cl^2 + 2C^6H^6SO^2.$$

Phenylsulphurous hydride dissolves slightly in cold, easily in boiling water—freely also in alcohol, and especially in ether. It is inodorous; has a strong acid taste and reaction; cannot be sublimed, melts below 100°, and begins to decompose when heated above 100°. It is oxidised to phenylsulphurous acid, slowly by contact with the air, quickly by nitric acid. By nascent hydrogen (evolved from sulphuric acid by zinc), it is converted into phenylic sulphydrate.

Phenylsulphurous hydride is a monobasic acid, which easily decomposes metallic hydrates and carbonates. According to Kekulé's views of the composition of the aromatic bodies, it may be regarded as benzene-sulphurous acid, $C^6H^5(SO^2H)$, that is as benzene in which 1 at. H is replaced by the sulphurous acid residue, SO^2H; the hydrogen in this residue is still replaceable by metals.

The *ammonium-salt* crystallises in colourless silky laminæ, easily soluble in water, sparingly in alcohol and ether.—The *barium-salt*, $C^{12}H^{10}Ba''S^2O^4$, forms crystalline nodules, easily soluble in water, less soluble in alcohol.—The *cupric salt* separates from a strongly concentrated solution, in yellowish-green laminæ, having a satiny lustre and slightly soluble in alcohol.—The *silver-salt*, $C^6H^5AgSO^2$, separates from a hot aqueous solution on cooling in satiny laminæ, slightly soluble in cold water. The same salt is obtained, as a white curdy precipitate, on mixing the aqueous acid with nitrate of silver.—The *neutral zinc-salt*, $C^{12}H^{10}Zn''S^2O^4$, is obtained by boiling the aqueous acid with zinc-carbonate, or by decomposing the basic salt obtained in the preparation of the acid with carbonic acid, and evaporating the filtrate. It crystallises in oblique rhombic plates with truncated angles, moderately soluble in cold and in hot water.

DIPHENYL-DISULPHUROUS OR DIPHENYL-DISULPHOPHENYLIC ACID, $C^{12}H^{10}S^2O^6$. (Fittig, Ann. Ch. Pharm. cxxxii. 201.)—Formed by dissolving phenyl (iv. 409) in warm concentrated sulphuric acid: the warm much-diluted solution is neutralised with carbonate of potassium; and the sparingly soluble potassium-salt, which separates on cooling, is crystallised several times from water. The acid separated from the lead-salt by sulphuretted hydrogen crystallises by evaporation over oil of vitriol in prismatic deliquescent crystals, which melt at 72·5°, and decompose when heated above 200°. The acid is dibasic.—The *potassium-salt*, $C^{12}H^8K^2S^2O^6$, crystallises in efflorescent prisms or scales, insoluble in alcohol, slightly soluble in cold, more easily in hot water, and decomposing at a red heat.—The *barium-salt*, $C^{12}H^8Ba''S^2O^6$, is a white crystalline precipitate, nearly insoluble in water and in acids.—The *calcium-salt*, $C^{12}H^8Ca''S^2O^6$, is also very difficultly soluble in cold water, and is formed only on heating the solution of the potassium-salt with chloride of calcium.—The *lead-salt* is insoluble in water, but soluble in acids.—The *silver-salt* crystallises in laminæ, more soluble in cold water than the potassium-salt. The salts of other metals do not form precipitates with the solution of the potassium-salt.

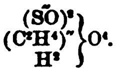
Thymylsulphurous Acid, $C^{10}H^{14}SO^3$. Syn. with CYMYLSULPHUROUS ACID (ii. 298).

Xylylsulphurous Acid, $C^8H^{10}SO^3 = (C^8H^9)HSO^3$. *Sulphoxylenic* or *Sulphoxylolic Acid.* (Cahours, Compt. rend. xxx. 319.—Church, Chem. Soc. Qu. J. xiv. 52.—Völckel, Ann. Ch. Pharm. lxxxvi. 335.—De la Rue and Müller, Chem. Soc. Qu. J. xiv. 54.)—When xylene is left in contact for a week with fuming sulphuric acid, part of it dissolves, and the undissolved portion becomes more or less filled with long, colourless, shining needles of xylylsulphurous acid. They have a strongly acid, afterwards bitter taste; dissolve readily in water and in sulphuric acid; deliquesce quickly on exposure to the air, and may be heated to melting in a vacuum or in vapour of xylene without decomposition; at a higher temperature they become dark-coloured.

Xylylsulphite of barium, $C^{16}H^{18}Ba''S^2O^6$, crystallises in nacreous transparent scales, not altered by boiling with water.

β. Sulphurous Ethers containing Diatomic Alcohol-radicles.

Ethylene-sulphurous Acid, $C^2H^6S^2O^6 = (C^2H^4)H^2(SO^3)^2 =$



$$\left.\begin{matrix}(\overset{''}{SO})^2\\(C^2H^4)''\\H^2\end{matrix}\right\}O^4.$$

Disulphetholic Acid. (Buckton and Hofmann [1856], Chem. Soc. Qu. J. ix. 250; Ann. Ch. Pharm. c. 129.—Husemann, Ann. Ch. Pharm. cxxvi. 269; Jahresb. 1862, p. 428.)—This acid is produced:—1. By heating ethylenic di- or tri-sulphocarbonate (p. 502) with fuming nitric acid:

$$(C^2H^4)COS^2 + 4NO^3H = (C^2H^4)H^2S^2O^6 + 4NO + CO^2 + H^2O.$$
$$(C^2H^4)CS^3 + 6NO^3H = (C^2H^4)H^2S^2O^6 + 6NO + CO^2 + SO^2 + 2H^2O.$$

The liquid is heated as long as nitrous fumes are evolved, then evaporated with repeated addition of water, and neutralised with carbonate of lead; the lead-salt, which crystallises out, is decomposed by sulphuretted hydrogen; and the filtered solution of ethylene-sulphurous acid is evaporated to a syrup. (Husemann.)

2. Together with sulphopropionic acid, by the action of fuming sulphuric acid on propionitrile (cyanide of ethyl) or propionamide:

$$\underset{\text{Propionitrile.}}{C^3H^5N} + 3H^2SO^4 = \underset{\substack{\text{Ethylene-}\\\text{sulphurous}\\\text{acid.}}}{C^2H^6S^2O^6} + \underset{\substack{\text{Acid sulphate}\\\text{of ammonium.}}}{(NH^4)HSO^4} + CO^2.$$

$$\underset{\text{Propionitrile.}}{C^3H^5N} + H^2O + 2H^2SO^4 = \underset{\substack{\text{Sulphopro-}\\\text{pionic acid.}}}{C^3H^6SO^5} + \underset{\substack{\text{Acid sulphate}\\\text{of ammonium.}}}{(NH^4)HSO^4}.$$

Propionamide, (C^3H^7NO), which differs from propionitrile only by H^2O, is acted upon by sulphuric acid in exactly the same manner; and being easier to prepare than propionitrile, is used in preference for the preparation of ethylene-sulphurous acid. For this purpose, a mixture of propionamide with an equal volume of Nordhausen sulphuric acid, is heated as long as carbonic dioxide is evolved and propionic acid distils over. The solid residue is then dissolved in water; the free sulphuric acid is neutralised with finely-pounded marble; the sulphate of ammonium is decomposed by boiling the liquid with carbonate of barium till it no longer gives a permanent precipitate with chloride of barium; and the filtered solution of ethylene-sulphite of ammonium is concentrated to the crystallising-point. To obtain the free acid, this salt is converted into a barium-salt by boiling with baryta-water; the barium-salt is decomposed by sulphuric acid; the acid filtrate is boiled with carbonate of lead; and the resulting lead-salt, after crystallisation, is decomposed by sulphuretted hydrogen. (Buckton and Hofmann.)

The syrupy acid, obtained by carefully evaporating the aqueous solution, solidifies, when left over oil of vitriol, to a radio-crystalline, very deliquescent mass, consisting (according to Husemann) of $C^2H^6S^2O^6.H^2O$. It gives off its 1 at. water at 100°; and the anhydrous acid melts at 94°, and solidifies again at 60° (Husemann); at higher temperatures it chars, and gives off white vapours. (Buckton and Hofmann.)

Ethylene-sulphurous acid is dibasic, forming neutral and acid salts.—The ethylene-sulphites are all soluble and crystallisable.

The *neutral ammonium-salt*, $C^2H^4(NH^4)^2S^2O^6$, crystallises in long monoclinic prisms, often exhibiting the simple combination $\infty P . P\infty$ (Husemann).—The *neutral potassium-salt*, $C^2H^4K^2S^2O^6$, forms thick, four-sided, monoclinic prisms; the *acid potassium-salt*, $2(C^2H^4)HKS^2O^6.3H^2O$, hard, white, crystalline crusts.—The *neutral sodium-salt*, $C^2H^4Na^2S^2O^6$, crystallises in well-defined crystals, belonging to the trimetric system, and exhibiting the combination $\infty P . \breve{P}\infty$.—The *neutral silver-salt*, $C^2H^4Ag^2S^2O^6$, forms thin monoclinic tables; there is also an *acid silver-salt*, $C^2H^5AgS^2O^6.C^2H^4Ag^2S^2O^6$, forming milk-white spherical groups of crystals. (Husemann.)

The *barium-salt*, obtained by boiling the solution of the ammonium-salt with baryta, and precipitating the excess of the latter with carbonic acid, crystallises in stellate groups of six-sided tablets, which contain $C^2H^4Ba''S^2O^6.H^2O$, and become anhydrous at 170° (Buckton and Hofmann).—According to Husemann, a hydrated salt containing $C^2H^4Ba''S^2O^6.2H^2O$, is obtained in small rhombic octahedrons, by saturating the still yellow solution of ethylene-sulphocarbonate in fuming nitric acid with carbonate of barium; whereas the pure acid, saturated in like manner, yields the anhydrous salt, $C^2H^4Ba''S^2O^6$, which is more soluble, and crystallises in slender monoclinic prisms.

The *cupric salt*, $C^2H^4Cu''S^2O^6.4H^2O$, forms light-blue monoclinic prisms, which give off $\frac{5}{8}$ of their water at 100°, and the rest at 170° (Husemann).—The *lead-salt* forms easily soluble crystalline crusts, containing $2C^2H^4Pb''S^2O^6.3H^2O$ (Husemann);

according to **Buckton** and **Hofmann**, it crystallises in thin prisms and four-sided laminæ, and its solution, when quickly evaporated, dries up to a tough gummy mass.—The *magnesium-salt*, $C^2H^4Mg''S^2O^6.6H^2O$, crystallises in colourless, easily soluble, monoclinic prisms and tables, which give off half their water at 100°, and the rest at 180° (**Husemann**).—The *mercuric salt*, $C^2H^4Hg''S^2O^6.6H^2O$, forms long, thin monoclinic prisms; the *mercurous salt*, $C^2H^4Hg^2S^2O^6.H^2O$, forms white crusts, which separate on warming into an acid and a basic salt (**Husemann**).—The *zinc-salt*, $C^2H^4Zn''S^2O^6.6H^2O$, crystallises in nacreous monoclinic tablets, which do not give their last atom of water till heated to 175°. (**Husemann.**)

Appendix to Ethylene-sulphurous Acid: SULPHOPROPIONIC ACID, $C^3H^6SO^5 = C^3H^6O^2.SO^3 = \left.\begin{matrix}(SO)'' \\ (C^3H^4O)'' \\ H^2\end{matrix}\right\}O^3$?—Produced, together with ethylene-sulphurous acid (as above described), by the action of sulphuric acid on propionamide or propionitrile. Its ammonium-salt remains in the mother-liquor of the ethylene-sulphite of ammonium, and may be separated therefrom as a syrupy precipitate by addition of absolute alcohol. On boiling the dilute mother-liquor with carbonate of barium, and concentrating, sulphopropionate of barium, $C^3H^4Ba''S^2O^5$ (at 170°), separates in cubic granules; or if the solution be less concentrated, and left to itself for twenty-four hours, in spherical groups of silky crystals. (**Buckton** and **Hofmann.**)

Methylene-sulphurous Acid, $CH^4S^2O^6 = \left.\begin{matrix}(\overset{\prime\prime}{S}O)^2 \\ (CH^2)'' \\ H^2\end{matrix}\right\}O^4$. *Disulphometholic Acid. Methionic Acid.* (**Liebig**, Ann. Ch. Pharm. xiii. 35.—**Wetherill**, *ibid.* lxvi. 122.—**Strecker**, *ibid.* c. 199.—**Buckton** and **Hofmann**, *ibid.* c. 129; Chem. Soc. Qu. J. ix. 241; Jahresb. 1856, p. 508.)—This acid, discovered by Liebig, is produced: 1. By the action of sulphuric oxide (anhydride) on ethylic ether (**Liebig**, **Wetherill**, **Strecker**).—2. By the action of fuming sulphuric acid on acetamide or acetonitrile (**Buckton** and **Hofmann**). Its mode of formation by this second method is exactly similar to that of ethylene-sulphurous acid from propionamide or propionitrile (p. 566), sulphacetic acid being formed at the same time (p. 475).

To prepare it by the first method (which, however, yields but a small product), sulphuric oxide is passed in the state of vapour, or (preferably) introduced in the solid state, into anhydrous ether contained in a cooled vessel; the resulting solution is shaken up with water; the watery liquid, separated from the ethereal solution of neutral ethylic sulphate, is neutralised with carbonate of barium; the methylene-sulphite of barium thus produced is decomposed by excess of sulphuric acid; the filtered solution is boiled with carbonate of lead; and the resulting lead-salt decomposed by sulphuretted hydrogen. (**Strecker.**)

By evaporating the aqueous solution of methylene-sulphurous acid over the water-bath to a syrup, and leaving it to cool in a vacuum, the acid is obtained as a mass of radiating needles (**Buckton** and **Hofmann**); when left over oil of vitriol, it solidifies in long needle-shaped crystals (**Strecker**). It is very deliquescent, has a very sour taste, and is not decomposed by rather strong heating, by prolonged boiling with nitric acid, or by passing chlorine into its solution.

The **methylene-sulphites**, $(CH^2)M^2S^2O^6$, and $(CH^2)M''S^2O^6$, are easily prepared by digesting the aqueous acid with oxides or carbonates. They are all soluble in water, but insoluble in alcohol.

The *ammonium-salt*, $CH^2(NH^4)^2S^2O^6$, crystallises in needles (**Strecker**); in prisms of 97·45, bevelled at the ends, which bear a heat of 190° without decomposition.—The *potassium-salt* crystallises in shining needles or granules, soluble in 14 pts. of water at 22° (**Buckton** and **Hofmann**).—The *sodium-salt* crystallises in needles (**Strecker**).—The *barium-salt*, $CH^2Ba''S^2O^6.2H^2O$, forms nacreous rectangular plates, which give off their water at 150° (**Buckton** and **Hofmann**); at 140° (**Strecker**).

The *cupric salt*, obtained by precipitating the barium-salt with cupric sulphate, crystallises in blue rhombic prisms, containing $CH^2Cu''S^2O^6.5H^2O$, which effloresce and turn whitish on exposure to the air, and become anhydrous at 100° (**Strecker**). Buckton and Hofmann obtained a cupric salt in green needles.

The *neutral lead-salt*, $CH^2Pb''S^2O^6.2H^2O$, obtained by boiling the acid with carbonate of lead, crystallises in large, transparent, colourless rhombic prisms (in small square laminæ, according to **Buckton** and **Hofmann**), which give off their water at 100°. By boiling this salt with plumbic hydrate, a less soluble *basic salt* is obtained, separating from the cooling solution in colourless crystals, which, after drying over oil of vitriol, appear to consist of $C^2H^2Pb^3S^4O^{12}.H^2O$; they have an alkaline reaction, and absorb carbonic acid from the air. (**Strecker.**)

The *silver-salt*, $CH^2Ag^2S^2O^6$, crystallises in groups of thin needles or broad plates, which may be heated to 150° without decomposition (**Buckton** and **Hofmann**), but blacken slightly when exposed to light (**Strecker**). Its concentrated solution is instantly decomposed by ethylic iodide, yielding argentic iodide, alcohol, and free methylene-sulphurous acid, but no ethereal compound. (**Buckton** and **Hofmann**.)

The *zinc-salt*, which is produced with evolution of hydrogen, by dissolving zinc in the aqueous acid, is difficult to crystallise, and is not precipitated by alcohol. (**Buckton** and **Hofmann**.)

Naphthylene-sulphurous Acid, $C^{10}H^8S^2O^6 = (C^{10}H^6)''H^2S^2O^6$. *Disulphonaphtholic*, *Thionaphthic*, or *Hyposulphonaphtholic Acid*. (**Berzelius**, Ann. Ch. Phys. [2], lxv. 290.—**Laurent**, Compt. chim. 1849, p. 390.—**Dusart**, Compt. rend. lxiv. 859.)—Berzelius obtained this acid in small quantity, together with naphthylsulphurous acid (p. 560), by the action of sulphuric acid on naphthalene; and separated the two by the different solubilities of their barium-salts, the naphthylene-sulphite being the more soluble of the two. On partially saturating the diluted solution with carbonate of barium, the naphthylsulphite separates out first; and on completing the saturation of the remaining liquid, concentrating it over the water-bath, and mixing it with two or three times its volume of alcohol, the naphthalene-sulphite is deposited in granular crystals (**Berzelius**). **Dusart**, by using a larger proportion of sulphuric acid, and applying a stronger heat, has succeeded in converting the whole of the naphthalene into naphthylene-sulphurous acid. For this purpose, 10 pts. of naphthalene are strongly heated with 25 pts. of concentrated sulphuric acid, till a sample of the liquid, saturated with a strong solution of sodic carbonate, remains clear, and no longer deposits a crystalline precipitate of sodic naphthylsulphite. The solution is then diluted with water, and saturated with alkaline carbonate; the greater part of the sulphate removed by crystallisation, and the remainder from the mother-liquor by addition of alcohol. The evaporated solution yields crystals of naphthylene-sulphite, which may be purified by recrystallisation.

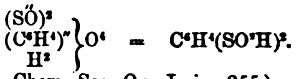
Naphthylene-sulphurous acid, separated from its barium-salt by sulphuric acid, dries up in a vacuum to a brown lamellar mass, having a sour and bitter taste, and soluble in alcohol (Berzelius). The acid is dibasic. The **naphthylene-sulphites**, $C^{10}H^6M^2S^2O^6$ and $C^{10}H^6M''S^2O^6$, resemble the naphthylsulphites; they are very soluble in water, but in general less soluble in alcohol than the naphthylsulphites. They have an acid slightly metallic taste, bear a considerable degree of heat without decomposition, but at very high temperatures give off vapours of naphthalene, with a small quantity of sulphurous oxide (**Berzelius**). They are decomposed by fusion with hydrate of potassium, with formation of metallic sulphite and the potassium-salt of **naphthylenic alcohol**, $C^{10}H^8O^2 = (C^{10}H^6)''H^2O^2$:

$$\underset{\text{Potassic naphthylene-sulphite.}}{C^{10}H^6K^2S^2O^6} + 4KHO = 2K^2SO^3 + 2H^2O + \underset{\text{Potassic naphthylenate.}}{C^{10}H^6K^2O^2}.$$

The naphthylenic alcohol precipitated from its potassium-salt by an acid, and purified from accompanying tarry matter, by solution in water and crystallisation, forms small rhombohedral crystals, soluble in water, and easily soluble in potash. The latter solution instantly burns black in contact with the air, and if afterwards neutralised yields a black precipitate of an acid body, which in strong solutions solidifies to a jelly. (**Dusart**.)

Naphthylene-sulphite of ammonium is obtained, by spontaneous evaporation, as a granular mass; its solution becomes acid when evaporated by heat.—The *potassium-salt* is granular, and slightly soluble in alcohol.—The *barium-salt*, $C^{10}H^6Ba''S^2O^6$, is but slightly soluble in water, even at the boiling heat; very slightly soluble in alcohol; on evaporating the aqueous solution, it remains as an amorphous mass (**Berzelius**).—The *lead-salt*, $C^{10}H^6Pb''S^2O^6.2H^2O$, is very much like the barium-salt, easily soluble in water, but nearly insoluble in alcohol. It retains its 2 at. water at 100°, but gives it up at 220°. (**Laurent**).

Phenylene-sulphurous Acid, $C^6H^6S^2O^6$ =



$$C^6H^6S^2O^6 = \left.\begin{matrix}(S\overset{\prime\prime}{O})^2\\(C^6H^4)''\\H^2\end{matrix}\right\}O^4 = C^6H^4(SO^3H)^2.$$

Disulphobenzolic Acid. (**Buckton** and **Hofmann**, Chem. Soc. Qu. J. ix. 255.)—Produced, together with sulphobenzoic acid (p. 486), by heating benzonitrile (phenylic cyanide) with fuming sulphuric acid. The product, after dilution, is treated with carbonate of barium, as in the preparation of ethylene-sulphurous acid; and the filtered solution of the barium-salts, which is very dark-coloured, is decomposed by sulphuric acid, then boiled with oxide of lead, filtered, and treated with sulphydric acid. The acid liquid is then saturated with carbonate of barium, and the resulting solution treated with alcohol, which throws down first sulphobenzoate, and afterwards phenylene-sulphite of barium.

The acid is, however, more easily obtained by heating phenylsulphurous (sulphobenzolic) acid (p. 563) with fuming sulphuric acid. The product is very dark-coloured, but may be rendered colourless by conversion into a lead-salt, and separation by sulphydric acid. The liquid saturated with carbonate of barium, and evaporated, yields *phenylene-sulphite of barium*, $C^6H^4Ba''S^2O^6$, as an apparently amorphous mass, which, however, appears distinctly crystalline under the microscope. When strongly heated on platinum-foil, it burns, with evolution of sulphurous oxide.

Tritylene-sulphurous or **Propylene-sulphurous Acid,** $C^3H^8S^2O^6 = (C^3H^6)H^2S^2O^6$. *Disulphopropolic Acid.*—Produced, together with sulphobutyric acid, $C^4H^8SO^5$, by heating butyramide with fuming sulphuric acid. The barium-salts of the two acids are both very soluble in water, and very difficult to separate; but on treating the concentrated solution with absolute alcohol, the sulphobutyrate, $C^4H^6Ba''S^2O^5$, separates first; and by continued fractional precipitation with alcohol, a barium-salt is at length obtained, having nearly the composition of the tritylene-sulphite, $C^3H^6Ba''S^2O^6$. By slow evaporation of its aqueous solution, it is obtained in very minute crystals, appearing under the microscope as thin pearly plates. (Buckton and Hofmann, Chem. Soc. Qu. J. ix. 253.)

Sulphuric Compounds.

TRIOXIDE OF SULPHUR. SULPHURIC OXIDE OR ANHYDRIDE, SO^3. *Anhydrous Sulphuric Acid.*—This compound is formed: 1. By the direct oxidation of sulphurous oxide. A perfectly dry mixture of this gas with oxygen, subjected to the action of a rapid stream of electric sparks, slowly diminishes in volume, and deposits sulphuric oxide. The oxidation may also be effected by passing the mixture of the two gases through a red-hot tube containing platinum-black or platinised pumice (Piria, Cimento, ii. 293).—2. By the decomposition of acid sulphates. Acid sulphate of sodium, $NaHSO^4$, heated to dull redness, gives off water, leaving the anhydrosulphate, $Na^2SO^4.SO^3 = 2NaHSO^4 - H^2O$; and this compound, distilled at a higher temperature, gives off white fumes of sulphuric oxide, leaving the neutral sulphate, Na^2SO^4. Ferric, platinic, antimonious, and bismuthic sulphates also give off sulphuric oxide when heated.—3. By the distillation of fuming sulphuric acid. This liquid, prepared at Nordhausen in Saxony, by the dry distillation of dehydrated sulphate of iron, may be regarded as a solution of sulphuric oxide, SO^3, in the strongest sulphuric acid; and when distilled at a gentle heat, gives off the sulphuric oxide in white fumes, while ordinary sulphuric acid, H^2SO^4, remains behind. The sulphuric oxide may be condensed in a dry receiver surrounded by cold water.—4. By distilling strong sulphuric acid with phosphoric oxide (anhydride), sulphuric oxide then passing over, and glacial phosphoric acid remaining behind:

$$H^2SO^4 + P^2O^5 = 2HPO^3 + SO^3.$$

Properties.—Sulphuric oxide crystallises in beautiful white slender needles, arranged in feathery and star-shaped groups, and forming an opaque mass, resembling asbestos. It is tough, and difficult to cut. When recently solidified from the liquid or gaseous state, it melts at about 18°, but quickly passes into another modification, in which it does not melt below 100°, volatilising slowly at the same time, and returning to the first modification (Marignac, Ann. Ch. Pharm. lxxxviii. 228). In the melted state it forms a liquid thinner than oil of vitriol, and probably colourless when pure, but usually exhibiting a brownish colour from the presence of organic matter. It boils at 35°. The specific gravity of the solid oxide is 1·9456 at 13° (Morveau); of the liquid, 1·97 at 20° (Bussy). The density of the vapour is, according to Mitscherlich's observation, 3·01; the calculated density is $\frac{32 + 3 \, . \, 16}{2} \times 0{\cdot}0693 = 2{\cdot}76$.

Reactions.—1. Sulphuric oxide has a most powerful affinity for water, in which it dissolves, forming sulphuric acid. When dropped into water, it hisses like red-hot iron. Wood, paper, and organic bodies in general are quickly carbonised and destroyed by it; when perfectly dry, however, it may be held for a while between the fingers without inconvenience, but it soon absorbs moisture, and then exerts a painful corrosive action.—2. It does not alter the colour of litmus or any other vegetable substance, unless moisture is present.—3. It dissolves without alteration in anhydrous carbonic disulphide, forming a clear solution, which fumes in the air, and solidifies at low temperatures to a deliquescent, interlaced, crystalline mass.

4. Sulphuric oxide is a non-conductor of electricity, and is not decomposed even by the current of a battery of 14 Bunsen's elements. But when dissolved in concentrated sulphuric acid, it is resolved by electrolysis into oxygen at the positive, and sulphur at the negative pole. With certain proportions of the acid and oxide, part of the sulphur, instead of being separated in the free state, reduces the sulphuric acid to sulphurous

acid, and sulphurous oxide is evolved at the negative pole. (Geuther, Ann. Ch. Pharm. cix. 130.)

5. The vapour of sulphuric oxide is resolved, at a strong red heat, into sulphurous oxide and oxygen, 2 vols. SO^3 yielding 2 vols. SO^2 and 1 vol. oxygen.—6. *Phosphorus* takes fire in the vapour at ordinary temperatures, and precipitates the sulphur in the form of a thick crust (Vogel).—7. When *phosphoretted hydrogen-gas* is passed over sulphuric oxide at ordinary temperatures, sulphurous oxide is abundantly evolved, and the sides of the vessel become coated with red oxide of phosphorus [? amorphous phosphorus] (H. Rose).—8. Dry *sulphydric acid* decomposes sulphuric oxide, with formation of sulphuric acid, and separation of sulphur, which partly dissolves, with blue colour, in the sulphuric acid (Geuther):

$$4SO^3 + 3H^2S = 3H^2SO^4 + S^4.$$

9. Metallic *mercury*, heated with sulphuric oxide, abstracts part of the oxygen, forming sulphurous oxide and mercuric oxide, which unites with undecomposed sulphuric oxide, forming mercuric sulphate.—Red-hot *iron* decomposes the vapour, forming sulphide of iron and ferroso-ferric oxide; *zinc*, under similar circumstances, forms sulphide and oxide of zinc. (Albert d'Heureuse, Ann. Ch. Pharm. lxviii. 242.)

10. When sulphuric oxide vapour is passed over anhydrous *baryta* or *lime* heated to low redness, combination takes place, attended with vivid incandescence, and the base is converted into sulphate.

11. When dry *monosulphide of potassium* is brought in contact with an excess of fused sulphuric oxide, an energetic action takes place, resulting in the formation of anhydrosulphate of potassium and sulphuric oxide:

$$5SO^3 + K^2S = K^2SO^4.SO^3 + 4SO^2.$$

Galena is slowly converted by the liquid oxide into sulphate of lead, while sulphurous oxide and sulphur are set free, the latter dissolving in the excess of sulphuric oxide and forming a blue liquid:

$$2SO^3 + Pb''S = Pb''SO^4 + SO^2 + S.$$

Native *sulphide of antimony* dissolves more quickly, with blue coloration and formation of sulphurous oxide and antimonious sulphate, which separates as a basic salt on dilution.—Ferrous sulphide, iron pyrites, and copper pyrites do not act on fused sulphuric oxide. (Geuther, Ann. Ch. Pharm. cxi. 177.)

12. With *pentachloride of phosphorus*, sulphuric oxide yields oxychloride of phosphorus and sulphuric chloride (Schiff, Ann. Ch. Pharm. cii. 111):

$$SO^3 + PCl^5 = POCl^3 + SO^2Cl^2.$$

13. Sulphuric oxide dissolves *sulphur* in various proportions, forming a brown, a green, and a blue liquid, the first of which contains the largest and the last the smallest quantity of sulphur. These solutions are formed by placing flowers of sulphur and sulphuric oxide in alternate layers in a glass tube, sealing it, and heating it to 16°—19°. They are decomposed by water, yielding sulphuric and sulphurous acids and free sulphur. (Wach, Schw. J. l. 1.)

14. Sulphuric oxide unites with a tenth of its weight of *iodine*, forming a compound of a fine green colour, which may be crystallised.

15. Vapour of *nitric peroxide* is rapidly absorbed by sulphuric oxide; and if the action be moderated at first, by passing the vapour slowly and cooling the vessel, and finally assisted by gentle heating till the sulphuric oxide becomes saturated, a white crystalline mass is formed, fusible without decomposition at a gentle heat, and agreeing nearly in composition with the formula $NO^2.SO^3$. When strongly heated, it decomposes, with evolution of oxygen, and a small quantity of nitric peroxide; and if the heating be discontinued as soon as the evolution of oxygen ceases, there remains a hard crystalline compound, similar in appearance to the former, but consisting of $N^2O^3.2SO^3 = 2(NO^2.SO^3) - O$ (Weber, Pogg. Ann. cxxiii. 337; Jahresb. 1864, p. 155).—This latter compound, which may be regarded as anhydrosulphate of nitrosyl or azotyl, $(NO)^2SO^4.SO^3$, is likewise obtained, according to De la Provostaye (Ann. Ch. Phys. [2], lxxiii. 362), by passing the vapour of nitric peroxide into liquid sulphurous oxide:

$$2SO^2 + 4NO^2 = (NO)^2S^2O^7 + N^2O^3;$$

and, according to Brüning (Ann. Ch. Pharm. xcviii. 377), by the action of nitric oxide on sulphuric oxide:

$$3SO^3 + 2NO = (NO)^2S^2O^7 + SO^2.$$

16. A compound of sulphuric oxide with *nitrous chloride*, $NOCl.SO^3$, is obtained by passing the vapours evolved from nitromuriatic acid, and dried by chloride of calcium, over sulphuric oxide till it is saturated. This compound is white and

lamino-crystalline, like stearic acid. When gently heated, it melts without coloration, but at a higher temperature, turns yellow and decomposes. With water it yields sulphuric acid, hydrochloric acid, and the decomposition-products of nitrous acid. In strong sulphuric acid it dissolves, with evolution of hydrochloric acid; and on heating the solution, a liquid distils over, consisting essentially of sulphuric chlorhydrate, SO^3HCl. (Weber, Pogg. Ann. cxxiii. 233.)

17. Dry *ammonia-gas* is absorbed by sulphuric oxide, forming sulphamate of ammonium, $N^2H^6SO^3$ (p. 476).

Sulphato-iodic Oxide or *Anhydride*, $I^2O^5.SO^3$.—This compound is formed by the prolonged action of dry sulphurous oxide on pulverised iodic oxide (I^2O^5) at 100°. A small quantity of iodine is at first liberated, and the iodic oxide is then converted into a light-yellow granulo-crystalline mass, which is quickly decomposed by water, with separation of iodine. By absolute alcohol it is quickly resolved into sulphuric and iodic oxides. With alcoholic potash it forms iodate and sulphate of potassium. Strong sulphuric acid does not act upon it at ordinary temperatures; hydrochloric acid dissolves it, with evolution of chlorine, and formation of chloride of iodine. (Kämmerer, J. pr. Chem. lxxxii. 72; Jahresb. 1861, p. 134.)

Sulphato-acetic Oxide or *Anhydride*.—Vapour of sulphuric oxide is absorbed by cooled acetic oxide, forming a yellow gummy mass, which dissolves in water; the solution, when neutralised with baryta-water and filtered, yields crystals of baric sulphacetate. (Schützenberger, Compt. rend. liii. 538; Jahresb. 1861, p. 439.)

Sulphuric oxide unites with *acetic acid*, *benzoic acid*, and many other organic acids, forming sulphacetic acid, $C^2H^4O^2.SO^3$, sulphobenzoic acid, $C^7H^6O^2.SO^3$, &c.; and with many *hydrocarbons*, forming sulphoacids, which may be regarded as sulphurous ethers (p. 550): *e.g.*, with benzol, C^6H^6, it forms sulphobenzolic or phenylsulphurous acid, $C^6H^6SO^3 = (SO)''.C^6H^5O.HO$, &c.

Chlorosulphuric Oxide or *Anhydride*, $S^2O^5Cl^2$.—This compound, first obtained by H. Rose, by the action of sulphuric oxide on disulphide of chlorine (p. 535), is also produced, according to Rosenstiehl (Compt. rend. liii. 658), by heating sulphuric oxide with dry pulverised chloride of sodium, distilling, and rectifying, to remove the last traces of sulphuric oxide. It is a colourless oil, of specific gravity 1·762 (Rosenstiehl); 1·818 at 16° (Rose); boiling at 145° (Rose), between 145° and 150° (Rosenstiehl). It is violently decomposed by water, and quickly chars organic bodies. With manganates it evolves chlorine; with alkaline chromates it forms chromic oxychloride, CrO^2Cl^2:

$$\underset{\substack{\text{Potassic}\\\text{chromate.}}}{K^2CrO^4} + \underset{\substack{\text{Chlorosul-}\\\text{phuric oxide.}}}{S^2O^5Cl^2} = \underset{\substack{\text{Potassic}\\\text{anhydro-}\\\text{sulphate.}}}{K^2S^2O^7} + \underset{\substack{\text{Chromic}\\\text{oxychloride.}}}{CrO^2Cl^2}.$$

With dry acetate of sodium, it forms chloride of acetyl. (Rosenstiehl.)

SULPHURIC ACID, $H^2SO^4 = H^2O.SO^3 = \left.\begin{matrix}(SO^2)''\\H^2\end{matrix}\right\}O^2 = (SO^2)''.HO.HO$.—This highly important acid is produced, as already observed, by the hydration of the anhydride; by the decomposition of sulphuric chloride; by the oxidation of sulphur, sulphydric acid, and sulphurous acid; and by the decomposition of the polythionic acids (p. 540).

Preparation.—By *the oxidation of Sulphurous Acid*.—Sulphuric acid is produced by passing moist sulphurous oxide and air through tubes containing spongy platinum heated to low-redness. Sulphurous acid is also slowly converted into sulphuric acid by mere exposure to air, and immediately by treatment with powerful oxidising agents. The enormous quantities of sulphuric acid manufactured in this country (more than 100,000 tons annually), are made by burning sulphur or roasting pyrites, and oxidising the resultant sulphurous vapour by means of moist air and certain oxides of nitrogen. For this purpose, the sulphurous acid vapour is mixed with vapour of nitric acid evolved by decomposing a nitrate with sulphuric acid. This acid immediately converts a portion of the sulphurous acid into sulphuric acid, and is itself reduced to nitric oxide, NO; and this gas coming in contact with air, is converted into nitric peroxide, NO^2, which reacts with another portion of sulphurous oxide and with water, in such a manner as to form sulphuric acid and nitric oxide:

$$NO^2 + SO^2 + H^2O = H^2SO^4 + NO.$$

The nitric oxide thus liberated again absorbs oxygen to form nitric peroxide, which again oxidises the moist sulphurous vapours into sulphuric acid, with liberation of nitric oxide, and so on continuously. Theoretically, therefore, a small quantity of nitric oxide should suffice to produce an indefinitely large amount of sulphuric acid. Sometimes, when there is but a small quantity of water present, the sulphurous oxide and nitric peroxide react in the manner already mentioned (p. 570), producing anhydrosulphate of nitrosyl, $(NO)^2S^2O^7$, which, together with certain other sulphates of nitrosyl, formed from it by the action of water and of the sulphuric acid already produced, is deposited as a white crystalline mass on the sides of the vessel or chamber in which the reaction takes place. The formation of these crystalline compounds is not, however, a necessary stage in the process, and in fact, when steam is largely introduced into the chamber (as in the present mode of making the acid), it does not take place at all.

The exact changes which nitric oxide, sulphurous oxide, oxygen, and water undergo, in presence of one another, have been minutely studied by several chemists, particularly by Provostaye and Desains, but without any very definite results. The description above given must indeed be considered rather as a general than a strictly accurate account of the reaction. (See *Gmelin's Handbook*, ii. 445—451; also Weber, Jahresb. 1863, p. 738; 1865, p. 93; Bull. Soc. Chim. 1867, i. 151.)

In the manufacture of sulphuric acid on the large scale, sulphur is burnt slowly on an iron plate forming the floor of a sort of furnace, the amount of air admitted being regulated by means of a smaller iron plate forming the door of the furnace, so that the sulphur when once ignited may go on burning and producing sulphurous oxide with tolerable uniformity. Upon the iron plate on which the sulphur is burnt is also placed an iron pot containing a mixture of nitrate of sodium and sulphuric acid, which continues to generate nitric acid for some time. The sulphurous oxide and nitric acid vapour, from one or several furnaces, are conveyed by means of flues into a large leaden chamber having a capacity of from 50,000 to 100,000 cubic feet or more. Within this chamber, into which steam is admitted continuously by several jets, the reaction chiefly occurs. The nitric acid is soon reduced to nitric oxide, after which the succession of changes already pointed out takes place; and dilute sulphuric acid collects on the floor of the chamber, whence it is drawn off into leaden evaporating pans. The vapours escaping from the large chamber are usually passed into one or two smaller subsidiary chambers also supplied with steam. In these a further condensation occurs, and a still weaker acid is produced, which is run back into the large chamber to become more concentrated. In some manufactories, the vapours from the subsidiary chambers are then passed through coke-scrubbers—that is, through columns packed with coke, over which water is constantly pouring; and here a further condensation occurs, and a very dilute acid is produced, which is pumped up into the subsidiary leaden chambers. In a few factories, Gay-Lussac's scrubber is used instead of the water-scrubber. The coke in this case is kept moistened with concentrated sulphuric acid, which completely absorbs the nitric oxide gas. The acid is then pumped into a second similar scrubber, in which it is robbed of its nitric oxide by means of the sulphurous oxide proceeding from the burning sulphur. In a theoretically perfect operation, there should be no final escape into the atmosphere of any other gas than the nitrogen of the air admitted into the furnace, and thence into the chamber; but in practice a small quantity of sulphurous or nitrous gas, or both, escapes condensation, although the amount of sulphuric acid finally produced usually approximates very closely to the theoretical quantity.

The acid withdrawn from the leaden chambers has generally a specific gravity of about 1·55. By evaporation in a series of shallow leaden pans, its specific gravity is raised to above 1·7. This acid is usually dark-coloured, from the presence of organic matter, and is technically known by the name of "brown acid." The further concentration has to be effected in retorts of glass or platinum. With glass retorts the operation is intermittent. A number of large glass retorts are heated on a sand-bath until the requisite concentration is attained. Throughout the process, a diluted sulphuric acid, containing sulphurous acid from the reaction of the organic matter and sulphuric acid, distils over. This is returned to the leaden chamber, and the concentrated colourless acid is siphoned off from the retorts into carboys. With a platinum retort the process it continuous. Brown acid is constantly admitted at the top, concentrated acid withdrawn from the bottom, and diluted sulphuric acid, with sulphurous acid, distilled off into receivers, whence it is pumped back into the chambers. In commerce, the concentrated colourless acid, having a specific gravity reaching to 1·842, or approximating very closely thereto, is alone known by the name of "oil of vitriol."

The process above described is substantially the same as that introduced by Dr. Roebuck about the year 1720. It is known as the English mode of manufacture, and the product is called "English oil of vitriol." This oil of vitriol always contains lead, and not unfrequently other impurities, chiefly arsenic and nitrous or nitric acid. By diluting it with water, the lead is thrown down as a white precipitate, which becomes black by the action of sulphuretted hydrogen. The arsenic may be recognised by Reinsch's or Marsh's tests, or by neutralising the diluted acid with carbonate of potassium, filtering from the resulting sulphate of potassium, and treating the acidulated filtrate with sulphuretted hydrogen, when a yellow precipitate will be produced. The nitrous or nitric acid can be detected by pouring in a dilute solution of sulphate of iron, so as to float on the top of the acid. Where the two liquids meet, a brownish-purple ring of discoloration will be produced. The addition of sulphide of barium to arsenical sulphuric acid produces a precipitate of mixed sulphide of arsenic and sulphate of barium, which may be separated by subsidence and decantation. The acid may be purified from arsenic by heating it nearly to the boiling-point, and passing a current of hydrochloric acid gas through it; whereby the arsenic is carried over as volatile chloride of arsenic, while the nitric and nitrous acids are expelled almost completely.[*] The nitrous or nitric acid may also be entirely decomposed into water and nitrogen-gas, by heating the acid with a little sulphate of ammonia; and, lastly, by distilling the sulphuric acid after the separation of the arsenic and nitrous acid, it may be obtained quite pure. The distillation must be effected in large retorts, heated, not at the bottom, but somewhat at the sides, to avoid the violent percussive ebullition which results from directly heating the deposit of sulphate of lead which gradually forms at the bottom of the retort. The vapour of oil of vitriol has a very small latent heat, and, under any circumstances, the ebullition of the acid is somewhat percussive. The presence of platinum-clippings in the retort prevents this action to a considerable extent.

According to **Nicklès** (Compt. rend. xlv. 250; Jahresb. 1857, p. 119), commercial oil of vitriol often contains hydrofluoric acid, but may be freed therefrom by diluting it with twice its bulk of water, and gently heating it for about fifteen hours—the hydrofluoric acid then volatilising.

For further details respecting the manufacture, purification, and concentration of sulphuric acid, see Richardson and Watts's *Chemical Technology*, vol. i. pt. i. pp. 51–117, and pt. v. pp. 198–222.

Properties and Reactions.—Pure oil of vitriol, or normal sulphuric acid, H^2SO^4, is a heavy, oily, colourless, inodorous liquid, having a specific gravity of 1·842. It boils at 327°, and freezes at $-35°$. It is very hygrometric, and, when exposed to moist air, will even double its weight in the course of a few days. Hence it is in constant requisition as a desiccating agent. It abstracts water from many organic substances, and thereby gives origin to new compounds. Thus alcohol, acetone, formic acid, glycerin, &c., when dehydrated by sulphuric acid, produce olefiant gas, mesitylene, carbonic oxide, and acrolein respectively. In many cases, the organic substances acted upon by sulphuric acid are completely broken up or destroyed; as is especially the case with woody fibre, sugar, and bodies of allied composition, which, by the loss of water, become thoroughly charred or carbonised. This charring effect of strong sulphuric acid is highly characteristic. The diluted acid slowly destroys organic fibres, without charring them. But tissues, moistened with dilute sulphuric acid and then heated, become charred from the concentration of the acid which gradually takes place. The admixture of the strong acid with water is attended by a great development of heat. On mixing 4 parts by weight of oil of vitriol with 1 part of water, the temperature rises from 0° to 100°. The cooled mixture of water and acid occupies a volume considerably less than that of the two separate liquids.

Sulphuric acid is reduced to sulphydric acid by passing its vapour, with excess of *hydrogen*, through a tube heated to redness.—*Phosphorus* takes fire in sulphuric acid vapour, and liberates sulphur. At increased temperatures, not only *zinc*, *iron*, *copper*, *mercury*, *silver*, and most of the metals save gold and platinum, but also *charcoal* and *sulphur*, exert a reducing action upon strong sulphuric acid, and evolve sulphurous acid. All the metals of the zincic and ferric families, with the exception of copper, readily displace hydrogen from the diluted acid to form their respective sulphates of metal. At ordinary or somewhat increased temperatures, sulphuric acid decomposes the salts of nearly all other acids, with production of the corresponding sulphates, and liberation of the respective acids. By its action on certain highly-oxidised metallic compounds, such as the peroxides of lead and manganese, and the manganic, chromic, and ferric acids, or their salts, it produces sulphates of the respective metals, with evolution of oxygen-gas. Sulphuric acid, like the anhydride, absorbs nitric oxide gas, forming a crystalline sulphate of nitrosyl (p. 577), which dissolves unchanged in an excess of acid. The vapour of sulphuric acid is decomposed, at a red heat, into water, sulphurous oxide, and oxygen.

Sulphuric acid reacts with a large number of hydrogenised bodies, alkaline, neutral and acid, to form new compounds by the elimination of water. The typical reactions are the following:

$$(1.)\quad H^2SO^4 + 2A - 2H^2O = X.$$

In accordance with this reaction, the neutral sulphates of ethyl and phenyl, also sulphobenzide and sulphonaphthalene, are formed by the action of sulphuric acid upon alcohol, phenol, benzene, and naphthalene, respectively. All these products are neutral in their properties.

---

[*] On the preparation of sulphuric acid free from arsenic, for medico-legal purposes, see **Bloxam** (Chem. Soc. Qu. J. xv. 52); also **Buignet** and **Bussy** (J. Pharm. [3] xliv. 177; xlvi. 252; Jahresb. 1863, p. 151; 1864, p. 144).

$$(2.)\quad H^2SO^4 + A - H^2O = Y.$$

In accordance with this reaction, sulphanilic acid, ethylsulphuric acid, phenylsulphuric acid, phenylsulphurous acid, and naphthylsulphurous acid are formed by the action of sulphuric acid upon aniline, alcohol, phenol, benzene, and naphthalene, respectively. All these products have the properties of monobasic acids. Sulphuric acid also reacts, in accordance with the above equation, upon benzoic and other monobasic acids; but then the products of its action (sulphobenzoic acid, for instance) have the properties of dibasic acids. The rule which applies to all such reactions as those now under consideration, is that the basicity of the product equals the sum of the basicities of the reagents, minus as many units of basicity as there are atoms of water eliminated (see ACIDS, i. 49).

$$(3.)\quad 2H^2SO^4 + A - 2H^2O = Z.$$

In accordance with this reaction, methylene-sulphurous, ethylene-sulphurous, naphthylene-sulphurous, and phenylene-sulphurous acids (p. 551), also disulphanilic acid (p. 479), have been obtained. Agreeably to the above rule, all these products have the properties of dibasic acids. In the actual reactions, Nordhausen acid, or even sulphuric anhydride, is frequently employed.

Hydrates of Sulphuric Acid.—There are two, if not more, well-defined hydrates of sulphuric acid—namely, the monohydrate, $H^2SO^4.H^2O$, and the dihydrate, $H^2SO^4.2H^2O$. The first compound has a specific gravity of 1·78, and solidifies at 8° or 9°, forming a mass of colourless six-sided prisms, whence it is called glacial sulphuric acid. It boils at 205°—210°, giving off a weak acid vapour. It may be obtained by evaporating any dilute sulphuric acid at a temperature of 205°, until it ceases to lose water. The second hydrate results from the mixture of 1 at. oil of vitriol with 2 at. water. This proportion corresponds with the maximum condensation (nearly 8 per cent.) which results from the union of the acid and water. Its specific gravity is 1·62. It boils at 193°, giving off nothing but water until the temperature rises to 205°. It may be obtained by evaporating any more dilute acid at 100°, until it ceases to lose water. Both these hydrates dissolve snow with production of intense cold.

Fuming Sulphuric Acid.—This is a mixture or compound of sulphuric acid and sulphuric anhydride, obtained by the decomposition by heat of certain sulphates. The anhydrosulphates of the alkali-metals, $M^2SO^4.SO^3$, and the sulphates of the triatomic metals—iron (ferricum), bismuth, antimony, &c.—when subjected to dry distillation, give off sulphuric oxide or anhydride (p. 569), and if moisture is present, part of this compound is converted into sulphuric acid. At Nordhausen, in Saxony, an impure ferric sulphate, obtained by exposing ferrous sulphate (green vitriol) to a moderate heat in contact with the air, is distilled in earthern retorts arranged in a reverberatory furnace; and the distillate, consisting chiefly of sulphuric anhydride, is received in a small quantity of water or, more frequently, in ordinary oil of vitriol. The product thus obtained is a heavy brown oily liquid, known as Nordhausen, or Saxon, or fuming oil of vitriol. It has a specific gravity of 1·9, a composition corresponding nearly with the formula $H^2S^2O^7$, or $H^2SO^4.SO^3$, and is probably a definite compound analogous to the metallic anhydrosulphates above mentioned. It solidifies at 0°, forming colourless transparent crystals. When gently heated, it breaks up into sulphuric oxide, SO^3, which distils over, and sulphuric acid, H^2SO^4, which remains.

According to R. Müller (Ann. Ch. Pharm. cxxii. 1; Jahresb. 1862, p. 93), a crystalline compound of this acid with nitric peroxide, containing $H^2S^2O^7.N^2O^4$, is produced by the action of nitric peroxide in excess on ordinary concentrated sulphuric acid: $2H^2SO^4 + 2NO^2 = H^2S^2O^7.N^2O^4 + H^2O$. It dissolves in concentrated more readily than in dilute sulphuric acid, and separates unaltered on diluting the former solution with water.

Uses of Sulphuric Acid.—Sulphuric acid is the starting-point of nearly all important chemical manufactures. It is largely used in the preparation of nitric acid from the nitrates of potassium and sodium, of hydrochloric acid and chlorine from chloride of sodium, and consequently in the preparation of various bleaching compounds. Superphosphate of lime and artificial manures generally, of which many thousand tons are annually consumed in this country, are made by the action of sulphuric acid on bones, coprolites, &c. But the greatest consumption of this acid is in the manufacture of sulphates, especially of sulphate of sodium from the chloride, which is the first step in the manufacture of commercial soda or carbonate of sodium. It is also largely used for dissolving silver-alloy. The fuming acid is used chiefly for dissolving indigo, the solution constituting the important dyestuff called Saxony-blue (iii. 258). (Odling's *Manual of Chemistry.*)

Otto's Table of the Strength of Sulphuric Acid of different Densities at the Temperature of 15° C.

Per cent. of H^2SO^4.	Specific Gravity.	Per cent. of SO^3.	Per cent. of H^2SO^4.	Specific Gravity.	Per cent. of SO^3

Derivatives of Sulphuric Acid.

Sulphuric Bromide, SO^2Br^2. *Bromide of Sulphuryl. Bromosulphuric Acid.* —Prepared like the corresponding chlorine-compound. It is a white crystalline body, which volatilises at ordinary temperatures, and when heated in a sealed tube with excess of silver-sulphate, yields silver-bromide and sulphuric oxide, $SO^2Br^2 + Ag^2SO^4 = 2AgBr + SO^3$. (Odling and Abel, Chem. Soc. Qu. J. vii. 2.)

Sulphuric Chlorhydrate, $HClSO^3 = (SO^2)''\left\{\begin{matrix}Cl\\HO\end{matrix}\right.$. *Chlorhydrosulphurous Acid.* (A. W. Williamson, Proc. Roy. Soc. vii. 11.)—This compound, derived from sulphuric acid, $(SO^2)''.HO.HO$, by the substitution of 1 at. Cl for 1 at. HO, is the first product of the action of phosphoric pentachloride upon strong sulphuric acid:

$$(HO)^2SO^2 + PCl^5 = Cl(HO)SO^2 + HCl + POCl^3.$$

It is also produced by the action of water on sulphuric chloride:

$$Cl^2SO^2 + H^2O = Cl(HO)SO^3 + HCl;$$

by the direct combination of hydrochloric acid gas and sulphuric oxide; and by the action of platinum-black on an imperfectly dried mixture of chlorine and sulphurous oxide. It appears also to be identical with the compound which H. Rose obtained by distilling disulphide of chlorine with fuming sulphuric acid (p. 535).

Sulphuric chlorhydrate is a colourless liquid, which boils at 145°, and is at the same time partially resolved into sulphuric acid and sulphuric chloride: $2HClSO^3 = H^2SO^4 + Cl^2SO^2$.—By *pentachloride of phosphorus* it is converted into sulphuric chloride.—When poured into *water*, it sinks to the bottom, and gradually dissolves, with formation of sulphuric and hydrochloric acids. It has decidedly acid properties, and forms definite salts, in which its hydrogen is replaced by metals: thus it dissolves *chloride of sodium* at a gentle heat, with evolution of hydrochloric acid and formation of the salt $NaClSO^3$.—With *nitrate of sodium*, it yields sulphate of sodium and chloride of nitryl:

$$Na(NO^2)O + HClSO^3 = NaHSO^4 + NO^2Cl.$$

Ethyl- and phenyl-compounds analogous to sulphuric chlorhydrate are produced by the direct combination of ethylic and phenylic chloride with sulphuric oxide.—The *ethyl-compound*, $C^2H^5ClSO^3$, is a colourless, oily, pungent liquid, heavier than water, at the bottom of which it will lie for weeks without thoroughly decomposing. Sulphuric and hydrochloric acids may, however, be detected immediately after its immersion, and on neutralising the liquid with baryta, a soluble barium-salt is formed, probably the ethylsulphate.—A similar compound is formed by *chloride of methyl*, and apparently also by *chloride of acetyl*. (R. Williamson, Chem. Soc. Qu. J. x. 100.)

The *phenyl-compound*, $C^6H^5ClSO^3$, is a liquid which, when treated with excess of milk of lime, forms a soluble calcium-salt, $C^{12}H^8Ca''Cl^2S^2O^6$, which separates on evaporation in flat tabular crystals. (Hutchings, Chem. Soc. Qu. J. x. 102.)

Sulphuric Chloride, SO^2Cl^2. *Chloride of Sulphuryl. Sulphuric Chloraldehyde. Chlorosulphuric Acid.* (Regnault, Ann. Ch. Phys. [2], lxix. 170; lxxi. 445.—A. W. Williamson, Proc. Roy. Soc. vii. 11.)—This compound, which may be regarded as sulphuric acid in which 2 at. HO are replaced by 2 at. Cl, was discovered by Regnault, who first obtained it, mixed with chloride of ethylene, by passing dry chlorine into a mixture of ethylene-gas and sulphurous oxide; afterwards, in greater quantity, by exposing a mixture of chlorine and sulphurous oxide gases to strong sunshine for a considerable time. The resulting liquid may be freed from excess of chlorine by agitation with mercury and subsequent distillation. It is also produced by the action of phosphoric pentachloride on sulphuric oxide; but it is best obtained by distilling strong sulphuric acid with the pentachloride, or sulphate of lead with the oxychloride of phosphorus:

$$\begin{array}{rcrcl}
SO^3 & + & PCl^5 & = & SO^2Cl^2 + POCl^3 \\
H^2SO^4 & + & 2PCl^5 & = & SO^2Cl^2 + 2POCl^3 + 2HCl \\
3PbSO^4 & + & 2POCl^3 & = & 3SO^2Cl^2 + Pb^3P^2O^8
\end{array}$$

Sulphuric chloride is a colourless fuming liquid, of specific gravity 1·66. It boils at 77°, and may be distilled unchanged over caustic lime or baryta. When poured into water, it sinks in the form of oily drops, which gradually disappear, being converted into hydrochloric and sulphuric acids:

$$SO^2Cl^2 + 2H^2O = 2HCl + H^2SO^4.$$

With alcohol it behaves in a similar manner, thus:

$$SO^2Cl^2 + 2(C^2H^5)HO = 2C^2H^5Cl + H^2SO^4.$$

In the actual reaction, however, the sulphuric acid is converted into ethylsulphuric acid by the intervention of another atom of alcohol:

$$H^2SO^4 + (C^2H^5)HO = H^2O + (C^2H^5)HSO^4.$$

With dry ammonia-gas, or with commercial sesquicarbonate of ammonia, it forms sulphamide, according to Regnault:

$$SO^2Cl^2 + 4NH^3 = 2NH^4Cl + N^2H^4SO^2.$$

According to H. Rose, however, the product thus obtained is a mixture of sal-ammoniac and neutral sulphamate of ammonium (p. 476).

Nitrososulphuric Acid, $H^2SO^3(NO)^2$. *Nitrosulphuric Acid. Azotylsulphuric Acid. Nitrosulphurous Acid.*—A dibasic acid, known only in its alkaline salts, which are produced by the simultaneous action of sulphurous and nitric oxides on caustic alkaline solutions. (See Nitrososulphates, iv. 116.)

Sulphates of Nitrosyl or Azotyl.—These are salts produced by the action of sulphuric acid and sulphuric anhydride on the oxides of nitrogen. Three of them are known, corresponding exactly in composition to the sulphites of sodium, thus:

Sodium-salts.		Nitrosyl-salts.
$HNaSO^4$	Acid sulphate	$H(NO)SO^4$
Na^2SO^4	Neutral sulphate	$(NO)^2SO^4$
$Na^2S^2O^7$	Anhydrosulphate	$(NO)^2S^2O^7$.

Acid sulphate of nitrosyl was obtained by Weltzien (Ann. Ch. Pharm. cxv. 213; Jahresb. 1860, p. 106), as a white crystalline mass, by passing nitrous anhydride into normal sulphuric acid:

$$2H^2SO^4 + (NO)^2O = H^2O + 2H(NO)SO^4.$$

It is probably identical with the compound formed by heating the anhydrosulphate with sulphuric acid containing a little water, and crystallising:

$$(NO)^2S^2O^7 + H^2O = 2H(NO)SO^4.$$

Neutral sulphate of nitrosyl, $(NO)^2SO^4$, has been described by Gay-Lussac, Provostaye, Mitscherlich, and others. It is produced by the action of nitric peroxide on sulphuric acid, thus:

$$H^2SO^4 + 4NO^2 = (NO)^2SO^4 + 2HNO^3.$$

By this process, Gay-Lussac obtained it crystallised in four-sided prisms. It is also said to be produced by the action of nitric oxide on sulphuric acid (Henry and Plisson); by that of nitric peroxide on sulphurous acid (H. Davy); by dissolving the anhydrosulphate in a small quantity of hot oil of vitriol (Provostaye), and in other ways. (*Gmelin's Handbook*, ii. 447.)

The *anhydrosulphate of nitrosyl*, $(NO)^2S^2O^7 = (NO)^2SO^4.SO^3$, is formed by the action of sulphurous oxide on nitric peroxide (Provostaye), also of sulphuric ode on nitric oxide (Brüning); and by heating the compound $NO^2.SO^3$, resulting from the direct combination of nitric peroxide and sulphuric oxide (P. Weber)—(see p. 570). It is a hard, white, amorphous mass, which fuses when heated, and volatilises without decomposition. It dissolves in concentrated sulphuric acid, apparently without change; but with slightly diluted sulphuric acid, it forms a bulky crystalline substance, probably the acid sulphate of nitrosyl. When heated, it gives off brown vapours; and as the distillation is continued, the distillate approaches more and more to the composition $N^2O^3.3SO^3$, or $(NO)^2SO^4.2SO^3$. (Weber, Jahresb. 1862, p. 94.)

All the sulphates of nitrosyl are deliquescent, and are immediately decomposed by water into sulphuric acid and nitric oxide gas.

The crystals which form in the leaden chambers during the manufacture of oil of vitriol, when only an insufficient quantity of steam is admitted, are perhaps a mixture of the different sulphates of nitrosyl just noticed. According to Weber, however (*loc. cit.*), they consist entirely of the acid sulphate, $H(NO)SO^4$.

Metallic Sulphates.

General formula, M^2SO^4, or a multiple thereof.—The sulphates form a very abundant class of salts, which are usually obtained, as above mentioned, by the action of sulphuric acid on metals, or on their hydrates, oxides, and salts. Some of them are formed by the decomposition of other sulphates: *e.g.*, ferrous sulphate by the action of metallic iron on cupric sulphate, and the latter by the action of metallic copper on the sulphate of silver produced in the process of gold-refining (ii. 925). Insoluble sulphates (as those of barium and lead) are formed by precipitation, and the sulphates of potassium and sodium may be formed by fusing the insoluble sulphates of barium, strontium, calcium, and lead with potassic or sodic carbonate, or by boiling the insoluble sulphate with a solution of alkaline carbonate. Lastly, sulphates are formed by the oxidation of sulphides: the sulphates of iron, zinc, and copper are obtained in this manner, by oxidation of the native sulphides of those metals.

The sulphates may be divided into the following groups:—

1. Type, $H^2SO^4 = \left.\begin{matrix}(SO^2)''\\H^2\end{matrix}\right\}O^2$.—This group includes the sulphates of the monatomic metals and the neutral sulphates of the diatomic metals. With the alkali-metals, sulphuric acid forms acid and neutral salts: *e.g.*, $KHSO^4$ and K^2SO^4; also double salts,

such as $(NH^4)NaSO^4$. Potassium and sodium also form anhydrosulphates, composed of a molecule of the neutral salt united with sulphuric anhydride: *e.g.*, $NaSO^4.SO^3$. All the sulphates of the alkali-metals are soluble in water; the neutral potassium-salt, however, is much less soluble than any of the others.

The diatomic metals—that is to say, all the earth-metals excepting aluminium, thorinum, and zirconium, and the greater number of the heavy metals,—form neutral sulphates, represented by the general formula $M''SO^4$. The sulphates of barium, strontium, calcium, and lead are found native. The barium- and lead-salts are insoluble in water; the strontium-salt almost insoluble; the calcium-salt slightly soluble; the magnesium-salt and the heavy metal sulphates are freely soluble, except that of mercury, $Hg''SO^4$, which is decomposed by water. The heavy metal sulphates have an acid reaction, and all of them, except the sulphate of lead, and perhaps those of manganese and zinc, are decomposed by ignition.

2. *Sulphates formed on the Type of a Double Molecule of Sulphuric Acid*, $H^4S^2O^8 = \left.\begin{matrix}(\overset{\prime\prime}{S}O^2)^2\\ H^4\end{matrix}\right\}O^4$.—This group includes a few simple sulphates (e. g., stannic sulphate, $Sn^{iv}S^2O^8$, and zirconic sulphate, $Zr^{iv}S^2O^8$) and a large number of double sulphates, containing: (*a*), 1 atom of a diatomic and 2 atoms of a monatomic metal, such as potassio-cupric sulphate, $K^2Cu''S^2O^8$; (*β*), 1 atom of monatomic and 1 atom of triatomic metal, such as common alum, or potassio-aluminic sulphite, $KAl'''S^2O^8$. All these double sulphates are soluble salts, decomposible into their constituent salts by excess of water or by diffusion. The sub-group *a* likewise includes the acid sulphates of barium and calcium, $Ba''H^2S^2O^8$ and $Ca''H^2S^2O^8$.

3. Type, $H^6S^3O^{12} = \left.\begin{matrix}(\overset{\prime\prime}{S}O^2)^3\\ H^6\end{matrix}\right\}O^6$.— This group includes the neutral sulphates of the triatomic metals: *e.g.*, $\overset{\prime\prime\prime}{Al}{}^2S^3O^{12}$, $\overset{\prime\prime\prime}{Fe}{}^2S^3O^{12}$, &c. These salts are often found native: they are soluble, strongly acid compounds, decomposible by ignition. To the same group belong certain acid and double sulphates of the alkali-metals: *e.g.*, $K^4H^2S^3O^{12}$ and $K^4Li^2S^3O^{12}$.

There are also a few sulphates derived from higher multiples of H^2SO^4, which will be noticed further on.

Nearly all sulphates are crystallisable. The insoluble or difficultly soluble sulphates of lead, barium, strontium, and calcium occur native, in large well-defined crystals; many soluble sulphates also in smaller crystals, or crystalline masses. Many crystalline sulphates contain considerable quantities of water of crystallisation: thus the sulphates of iron, cobalt, nickel, manganese, zinc, and magnesium crystallise with 7 at. water; the double sulphates of the alkali-metals and the metals of the ferromagnesian group with 6 at. water; the alums with 12 at. water.

Among the crystalline sulphates, there are several isomorphous groups—viz., the anhydrous sulphates of potassium and sodium (trimetric); the anhydrous sulphates of calcium, strontium, barium, and lead (trimetric); the pentahydrated sulphates of manganese and copper (triclinic); the hexhydrated sulphates of zinc, nickel, and cobalt (monoclinic); the hexhydrated double sulphates of the alkali-metals with magnesium, zinc, nickel, cobalt, iron, manganese, and copper—*e.g.*, $K^2Mg''S^2O^8.6H^2O$ (monoclinic); and the alums, or dodecahydrated double sulphates of the alkali-metals with the sulphates of triatomic metals—*e.g.*, $KAl'''S^2O^8.12H^2O$ (monometric, and mostly octahedral).

The simple sulphates of the ferromagnesian family, with 5 or 7 at. water, retain 1 at. with very considerable force. Thus sulphate of magnesium, $MgSO^4.7H^2O$, loses 6 at. water at a temperature not much above 100°; but it holds back the seventh atom, even when heated to upwards of 200°. This last atom of water retained by the ferromagnesian sulphates was called, by Graham, constitutional water. The monohydrated sulphates of the form $M''SO^4.H^2O$ are analogous to glacial sulphuric acid, $H^2SO^4.H^2O$.

The dodecahydrated double sulphates of the alkali-metals and triatomic metals constitute the true alums. The sulphates of ammonium, potassium, and sodium are capable of forming alums with the aluminic, ferric, chromic, and manganic sulphates: the existence of sodium-iron-alum and sodium-manganese-alum appears, however, to be doubtful. Alums have also been formed containing the monatomic metals, thallium and silver: *e.g.*, silver-aluminium-alum, $AgAl'''S^2O^8.12H^2O$; and Wurtz has obtained an ethyl-ammonium-alum, $(C^2H^8N)Al'''S^2O^8.12H^2O$. In addition to these, there are several pseudo-alums, derived in like manner from 2 at. sulphuric acid, but having a different number of atoms of crystallisation-water, or a different crystalline form—*e.g.*, $KCr'''S^2O^8.6H^2O$; or containing diatomic metals, and derived from 4 at. sulphuric acid, such as $Mn''(Al''')^2S^4O^{16}.24H^2O$; $Fe''(Fe''')^2S^4O^{16}.24H^2O$, &c.

The genuine alums are all soluble in water, forming solutions which have a styptic taste, and marked acid reaction. The first effect of heat upon the alums is to drive off their water of crystallisation; a further degree of heat renders the dried residues very difficultly soluble in water, while a still higher temperature converts them into basic salts by the loss of sulphuric anhydride. The ammonium-alums, when heated, leave a residue of pure trioxide. The fixed alkali-alums leave a residue of trioxide mixed with sulphate of alkali-metal. It requires a very powerful and prolonged heat to drive off the last traces of sulphuric acid from the trioxides thus produced.

Basic Sulphates.—Most of the alums yield more or less defined basic salts. The best known of these is the native crystalline alum-stone, having the formula $KAlS^2O^8.Al^2O^3.4H^2O$. It corresponds in composition with the basic ammonium-alum formed by digesting gelatinous alumina in a hot solution of the normal alum, and having the formula $(NH^4)AlS^2O^8.\ Al^2O^3.\ 4H^2O$.

The diatomic metals yield a large number of basic sulphates, which may be regarded as normal sulphates, combined with metallic oxide replacing the water of hydrated sulphuric acid on its salts. Thus there is a dibasic sulphate of zinc, $Zn''SO^4.Zn''O$, corresponding to glacial sulphuric acid, $H^2SO^4.H^2O$; a tribasic sulphate of mercury, $Hg''SO^4.2Hg''O$, corresponding to the second hydrate of sulphuric acid, $H^2SO^4.2H^2O$; and a tribasic sulphate of copper, $Cu''SO^4.2Cu''O.3H^2O$, corresponding to blue vitriol, $Cu''SO^4.5H^2O$. Much more highly basic sulphates may also be obtained, and will be described in their places. Most of these basic sulphates are insoluble in water, and those few which are soluble are decomposed by a great excess of water into metallic oxide or hydrate and normal metallic sulphate.

Respecting the reactions of sulphates, see p. 536.

Sulphates of Aluminium.—*a*. The *normal* (or *neutral*) *sulphate*, $Al^2(SO^4)^3 = Al^2O^3.3SO^3$, occurs, as a hydrate containing 18 at. water, in delicate fibrous masses or crusts, in various localities: as at Bilin in Bohemia, on the volcanic island of Milo in the Grecian Archipelago, in the crater of the volcano of Pasto, at Copiapo in Chile, Adelaide in Australia, &c.; it is known mineralogically as *alunogen*, *hair-salt*, *feather alum*, and *halotrichite*. Hardness = 1·5 to 2. Specific gravity = 1·6 to 1·8. Lustre vitreous. Colour white, or tinged with yellow and red. Subtranslucent to subtransparent.

This salt is prepared on the large scale as concentrated alum, for use in dyeing instead of common alum, by treating pure clay with strong sulphuric acid. The clay, which must be as free as possible from iron, is heated to redness to render it porous, then finely ground, and mixed with half its weight of sulphuric acid of specific gravity 1·45, in a reverberatory furnace, the hearth of which has the form of a walled pan. The mixture is heated till the acid begins to volatilise; the mass is exposed to the air for several days, then treated with water; and the resulting solution of aluminic sulphate is freed from iron by careful precipitation with ferrocyanide of potassium. The solution thus purified is then evaporated to a syrup, and transferred to small leaden pans, in which it solidifies to a crystalline mass (Dumas). According to Hurier and Brunel (Pharm. Centr. 1852, p. 544), this salt may also be obtained [anhydrous] by heating ammonium-alum in iron cylinders, the sulphite of ammonium thereby evolved being received in water, and reconverted into sulphate by oxidation in the air. According to Persoz (Ann. Ch. Phys. [3], lvi. 102), a solution of alum, or of sulphate, nitrate, or chloride of aluminium, mixed with a large excess of boiling concentrated sulphuric acid, deposits the anhydrous sulphate as a white powder.

Neutral aluminic sulphate crystallises with difficulty in thin, flexible, nacreous laminæ, having a sweetish taste, soluble in 2 pts. of water, insoluble in alcohol. According to Persoz, the crystallisation is much facilitated by adding alcohol to the solution. The salt when heated melts in its water of crystallisation, swells up strongly, and leaves a white porous mass, consisting of the anhydrous sulphate, which dissolves very slowly in water, and when heated to redness leaves pure alumina.

β. Basic Salts.—*Dibasic aluminic sulphate*, $2Al^2O^3.3SO^3 = Al^2(SO^4)^3.Al^2O^3$, is obtained by heating a solution of the normal sulphate with alumina or with the following salt, filtering while hot, and evaporating to dryness at a gentle heat. It is a gummy mass, which is decomposed by water into the normal sulphate and the tribasic salt. (Maus, Pogg. Ann. xi. 80.)

The *tribasic sulphate*, $3Al^2O^3.SO^3.9H^2O$, or $Al^2(SO^4)^3.2Al^2O^3.9H^2O$, occurs native as *aluminite*, a white, opaque, earthy mineral, of specific gravity 1·70; it is also precipitated from the solution of the normal sulphate on addition of a small quantity of ammonia. It dissolves in hydrochloric acid, and at a red heat gives off sulphuric oxide, and leaves alumina.

The *tetrabasic salt*, $4Al^2O^3.3SO^3.36H^2O$ or $Al^2(SO^4)^3.3Al^2O^3.36H^2O$, is produced by digesting finely-divided calcic carbonate, for several days, in a cold solution of alum in excess. It is perceptibly crystalline, and very soluble in dilute acids, even in warm acetic acid.—The same salt is obtained by the action of zinc on a cold solution of normal aluminic sulphate. The action is very slow, even when electrolytically accelerated by placing the materials on a platinum-dish; but after a week, a transparent jelly is obtained, which, when separated by washing from zinc and excess of aluminic sulphate, and dried over oil of vitriol, solidifies in small transparent masses having a vitreous fracture. (Debray, Bull. Soc. Chim. [2], vii. 1.)

The *pentabasic salt*, $5Al^2O^3.3SO^3.20H^2O$, is obtained by gently boiling a solution of the normal salt with zinc in a platinum-dish. A granular precipitate is thereby formed, easy to wash, and soluble in dilute acids; it gives off its water at 100°. (Debray.)

γ. Double Salts of Aluminic Sulphate. Alums.—The formula of normal aluminic alum is $Al'''M(SO^4)^2.12H^2O$, M denoting a monatomic, and for the most part an alkali-metal. Their general characters have been already described (p. 579).

Ammonio-aluminic Sulphate, $Al(NH^4)SO^4.12H^2O$. *Ammonia-alum.*—This salt is prepared, like potash-alum, by adding sulphate or chloride of ammonium to a solution of aluminic sulphate. It is also found native as *tschermigite*, at Tschermig in Bohemia, in octahedrons and fibrous masses: hardness = 1 to 2; specific gravity = 1·56. According to Buignet (Jahresb. 1861, p. 15), the specific gravity of the artificially prepared crystals is 1·653. It is more soluble in water than potash-alum, 100 pts. of water dissolving 5·22 pts. of it at 0°, and 421·9 pts. at 100°. In other respects it bears the closest resemblance to potash-alum, and is used for the same purposes; in fact, the application of the alums as mordants, &c., depends upon the sulphate of aluminium which they contain, not on the alkaline sulphate. When heated to redness, it leaves anhydrous alumina, and when heated with alkalis, it gives off ammonia.—A *basic ammonia-alum*, analogous to basic potash-alum, is obtained by gradually adding ammonia to a boiling solution of the normal alum, but not to complete saturation.

Argento-aluminic sulphate, or *Silver-alum*, $AlAg(SO^4)^2.12H^2O$, is obtained by heating equivalent quantities of argentic and aluminic sulphate with a small quantity of water, in an oil-bath, till the argentic sulphate is completely dissolved. It crystallises in octahedrons, and is resolved by water into its component salts. (Church, Chem. News, ix. 155.)

Cæsio-aluminic sulphate, or *Cæsium-alum*, $AlCs(SO^4)^2.12H^2O$, crystallises in octahedrons, having a glassy lustre (Bunsen). 100 pts. of water at 17° dissolve 0·619 pt. of this salt; in hot water it dissolves as easily as potash-alum. (J. Redtenbacher, J. pr. Chem. xciv. 42.)

Potassio-aluminic sulphate, or *Potash-alum*, $AlK(SO^4)^2.12H^2O$.—This is the salt to which the name alum is most generally applied. It is obtained by adding sulphate or chloride of potassium to a solution of sulphate of aluminium. The sulphate of aluminium is sometimes prepared for this purpose from clay by the action of sulphuric acid in the manner already described, but more frequently by the calcination of aluminous schists, which are argillaceous rocks containing considerable quantities of sulphide of iron. The sulphide of iron is converted, by exposure to the air, into ferrous sulphate and free sulphuric acid:

$$2FeS^2 + O^7 + H^2O = Fe''SO^4 + H^2SO^4;$$

and the sulphuric acid, acting on the alumina contained in the clay, forms sulphate of aluminium. These aluminous schists are found in two different geological positions—viz., in the transition strata [alum-slate], in which position they are largely impregnated with bitumen; and in the lower tertiary strata, just above the chalk [alum-earth]. The latter are much less compact than the former; consequently their oxidation is easier, and sometimes takes place spontaneously. The greater part of the alum manufactured in England, France, and Germany is obtained from the aluminous schists.

The most extensive alum manufactory in Great Britain is at Hurlett, near Paisley. The next in magnitude is at Whitby, of whose state and processes an instructive account was published by Mr. Winter in the twenty-fifth volume of "Nicholson's Journal." The stratum of aluminous schist is about twenty-nine miles in width, and is covered by strata of alluvial soil, sandstone, ironstone, shell, and clay. The alum-schist is generally found disposed in horizontal laminæ. The upper part of the rock is the most abundant in sulphur, so that a cubic yard taken from the top of the stratum is five times more valuable than the same bulk 100 feet below.

If a quantity of the schist be laid in a heap, and moistened with sea-water, it will take fire spontaneously, and continue to burn till the whole inflammable matter is consumed. Its colour is bluish-grey. Specific gravity = 2·48. It imparts a bituminous principle to alcohol.

The rock, broken into small pieces, is laid on a horizontal bed of fuel, composed of brushwood, &c. When about four feet in height of the rock is piled on, fire is set to the bottom, and fresh rock continually poured upon the pile. This is continued until the calcined heap is raised to the height of 90 or 100 feet. Its horizontal area is at the same time progressively extended, till it forms a great bed nearly 200 feet square, having about 100,000 yards of solid measurement. The rapidity of the combustion is allayed by plastering up the crevices with small schist moistened. Notwithstanding this precaution, a great deal of sulphuric or sulphurous acid is dissipated. 130 tons of calcined schist produce, on an average, one ton of alum. This result has been deduced from an average of 150,000 tons.

The calcined mineral is digested with water in pits usually containing about 60 cubic yards. The liquid is drawn off into cisterns, and afterwards pumped up again upon fresh calcined *mine.* This is repeated until the specific gravity becomes 1·15. The half-exhausted schist is then covered with water to take up the whole soluble matter. The strong liquor is drawn off into settling cisterns, where the sulphate of lime, iron, and earth are deposited. At some works the liquid is boiled, which aids its purification. It is then run into leaden pans 10 feet long, 4 feet 9 inches wide, 2 feet 2 inches deep at the one end, and 2 feet 8 inches at the other. This slope facilitates the emptying of the pans. Here the liquor is concentrated at the boiling heat. Every morning the pans are emptied into a settling cistern, and a solution of chloride of potassium (either pretty pure from the manufacturer, or crude and compound from the soap-boiler) is added. The quantity of chloride necessary is determined by a previous experiment in a basin, and is regulated for the workmen by the hydrometer. By this addition, the pan-liquor, which had acquired a specific gravity of 1·4 or 1·5, is reduced to 1·35. After being allowed to settle for two hours, it is run off into the coolers to be crystallised. At a greater specific gravity than 1·35, the liquor, instead of crystallising, would, on cooling, solidify in a magma resembling grease. Urine is occasionally added, to bring it down to the proper density.

After standing four days, the mother-waters are drained off, to be pumped into the pans on the succeeding day. The crystals of alum are washed in a tub and drained. They are then put into a lead pan, with as much water as will make a saturated solution at the boiling-point. Whenever this is effected, the solution is run off into casks. At the end of ten or sixteen days, the casks are unhooped and taken asunder. The alum is found exteriorly in a solid cake, but in the interior cavity in large pyramidal crystals, consisting of octahedrons, inserted successively into one another. This last process is called "roching." Mr. Winter says that 22 tons of chloride of potassium will produce 100 tons of alum, to which 31 tons of the black ashes of the soap-boiler, or 73 of kelp, are equivalent. Where much iron exists in the alum-ore, the alkaline chloride, by its decomposition, gives rise to an uncrystallisable chloride of iron. For this reason it is preferable to the sulphate of potassium.

Alum may also be obtained from cryolite, $Al^2F^6.3NaF$, by heating the mineral with three times its weight of strong sulphuric acid, whereby anhydrous neutral sulphate of aluminium and acid sulphate of sodium are obtained; treating the resulting mass with a small quantity of cold water to remove the acid sodium-salt; then digesting the anhydrous sulphate of aluminium with warm water, to convert it into the hydrated salt, and adding the proper quantity of sulphate of potassium. The alum thus obtained is nearly if not quite free from iron. (Persoz, Ann. Ch. Phys. [3] lvi. 105.)

At Tolfa near Rome, and in two or three other localities, there is found a mineral called *alunite* or *alum-stone*, consisting of common alum together with normal hydrate of aluminium, $AlK(SO^4)^2.2AlH^3O^3$. Now when this mineral is calcined, at a moderate heat, the hydrate of aluminium is decomposed into water and anhydrous alumina, while the sulphate of aluminium and potassium remains unaltered, provided the heat has been prevented from rising too high; and on treating the calcined mass with water, the double sulphate dissolves, while the alumina remains behind. The mineral before calcination is quite insoluble in water. The solution when evaporated yields the alum in cubic crystals, generally having a reddish tint produced by ferric oxide. This kind of alum, called *Roman alum,* is much valued by dyers, because the iron which it contains is in an insoluble state, and therefore cannot exert any injurious effect on the colours.—Alum prepared in the ordinary way always contains iron in the soluble state, viz. as ferric sulphate, $Fe^2(SO^4)^3$, which, being isomorphous with sulphate of aluminium, is difficult to remove by successive crystallisation. It may be precipitated by ferrocyanide of potassium, as described in the preparation of sulphate of aluminium; but a cheaper way, recommended by Thénard, is to dissolve the alum in boiling water, and stir the solution briskly with rods as it cools. The salt is thus reduced to a fine granular powder, which, when washed two or three times with cold water, yields alum containing only a trace of iron. [On the manufacture of alum, see further *Ure's Dictionary of Arts,* &c. i. 101—118.]

Alum sometimes occurs in nature ready-formed. This is the case at Pozzuoli near Naples, where it effloresces on the surface of the soil. It is dissolved out by water, and crystallised by evaporation.

Alum generally crystallises in regular octahedrons and in cubes. Its specific gravity is 1·7. The octahedral crystals are the most common, and are always deposited from boiling concentrated solutions. The cubic crystals have an especial tendency to form in solutions containing an excess of alumina, and at a temperature not exceeding 50°, as in the preparation of Roman alum. If carbonate of potassium be added to a solution of octahedral alum in water at 40° or 45°, till the precipitate ceases to redissolve completely, and the filtered liquor be then left to itself at a gentle heat, cubic alum will be obtained quite free from iron. On the other hand, when a solution of cubic alum in cold water is abandoned to spontaneous evaporation, the alum is deposited in octahedrons. The two forms are identical in composition (**Löwel**, Compt. rend. xxxvi. 595). Sometimes intermediate forms occur, like *figs.* 194, 195, 196 (CRYSTALLOGRAPHY, ii. 129), or combinations of the cube and octahedron with other forms of the monometric system, like *figs.* 199, 202, 204, 205, 208, 209, 212, 273 (ii. 130–132); also aggregates and distorted forms, like *figs.* 316, 317, 347, 348, &c. (ii. 159, 164).

According to Poggiale, 100 pts. of water dissolve 3·29 pts. of crystallised alum at 0°; 9·52 pts. at 10°; 22 pts. at 30°; 31 pts. at 60°; 90 pts. at 70°, and 357 pts. at 100° (*Graham's Elements*, 2nd edition, i. 607). The solution has a sweet and strongly astringent taste, an acid reaction, and dissolves zinc and iron, with evolution of hydrogen.—When 2 pts. of alum are dissolved in 1 pt. of boiling water, and the solution is left to cool in a closed vessel, no crystallisation takes place; but as soon as the vessel is opened, small octahedral crystals begin to form on the surface, and in a short time the crystallisation extends through the whole mass. This is an instance of supersaturation similar to that exhibited by sulphate of sodium. (**Löwel**, Ann. Ch. Phys. [3], xiii. 405.)

Crystallised alum effloresces slightly on exposure to the air. According to **Hertwig** (Pogg. Ann. lv. 99), it gives off 5 at. water at 100°, and 4½ at. more at 120°, leaving a residue containing $2AlK(SO^4)^2.5H^2O$. This residue evolved 4 at. water at 180°, leaving $2AlK(SO^4)^2.H^2O$; and at 200°, half of this remaining quantity is given off, leaving $4Al^2K(SO^4)^3 + H^2O$. According to **Gerhardt** (J. Pharm. [2], xii. 57) crystallised alum gives off 10 at. water at 120°, leaving a residue easily soluble in water; and at 200°, the whole is expelled, and the remaining anhydrous alum, sometimes called *burnt alum*, is insoluble. Alum heated to redness with charcoal in a close vessel yields a mixture called *Homberg's pyrophorus*, which becomes red-hot on exposure to the air. It consists of very finely-divided charcoal and sulphide of potassium, intermixed with sulphate of aluminium.

Alum is used in large quantities in many manufactures, especially in dyeing as a mordant. When added to tallow, it renders that substance harder. Printers' cushions and the blocks used in the calico-manufactory are rubbed with burnt alum, to remove any greasiness that might prevent the ink or colour from sticking. Wood sufficiently soaked in a solution of alum does not easily take fire, and the same is true of paper impregnated with it, which is moreover fitter for keeping gunpowder, as it excludes moisture. Paper impregnated with alum is also useful in whitening silver and silvering brass without heat. Alum mixed with milk facilitates the separation of the butter. Alum is also used in tanning. In medicine it is employed as an astringent.—On this addition of alum to bread, see i. 658.

Basic Alum, $\left.\begin{matrix}K^2O\\3Al^2O^3\end{matrix}\right\}4SO^3 = AlK(SO^4)^2.Al^2O^3$.—This compound occurs native with different proportions of water, as *Alunite* and *Löwigite*.

Alunite or *Alum-stone*, $AlK(SO^4)^2.Al^2O^3.3H^2O = AlK(SO^4)^2.2AlH^3O^3$,* is found chiefly in volcanic districts, as at Tolfa near Civita Vecchia, at the Solfatara near Naples, and at Puy de Garcy in Auvergne. It occurs in rhombohedral crystals, having the angle R : R = 89° 10′; oR : R = 124° 40′, and length of principal axis = 1·2523. Observed planes R, oR, $\frac{6}{7}$R, $\frac{1}{84}$R, − $\frac{6}{5}$R, and − 2R (**Breithaupt**). Cleavage nearly perfect parallel to the base, indistinct parallel to R. It also occurs massive, with a granular or impalpable texture. Hardness = 3·5 to 4. Specific gravity = 2·58 to 2·752. It has a vitreous lustre, white colour (sometimes greyish or reddish), and white streak. Transparent to subtranslucent. Fracture flat, conchoïdal, or uneven; of massive varieties splintery, sometimes earthy. Brittle. The crystals of this mineral are nearly pure; the massive varieties contain silica sometimes to the amount of 60 per cent. It is used for the preparation of Roman alum (p. 581).

A salt identical in composition with alunite is precipitated as a crystalline powder when a solution of alum is boiled with gelatinous alumina.

---

* The formula given for this mineral at p. 161. vol. i., is incorrect.

Löwigite, $\begin{matrix}K^2O\\3Al^2O^3\end{matrix}4SO^3.9H^2O = 2[AlK(SO^4)^2.2AlH^3O^3].3H^2O$, occurs at Tolfa near Rome and at Taberze in Upper Silesia, in amorphous nodules having a perfectly crystalline fracture; hardness between 3 and 4; specific gravity = 2·58. At the temperature of boiling sulphur, it gives off 2·18 per cent. (= 1 at.) water, and at a slightly higher temperature 5·67 per cent. water together with sulphuric acid, leaving a residue, from which water extracts sulphate of potassium, but only small quantities of alumina. (F. Römer and Löwig, Jahresb. 1856, p. 877.—A. Mitscherlich, J. pr. Chem. lxxxiii. 474.)

A salt having the same composition is produced, with evolution of hydrogen, by the action of zinc on a solution of common alum. The action is slow, even in a warm solution, unless assisted by placing the zinc in contact with lead or platinum. By operating in a platinum capsule at 100°, the salt is readily obtained as a crystalline precipitate. Like alunite and löwigite, it is nearly insoluble in nitric and in hydrochloric acids, and can only be attacked by sulphuric acid diluted with an equal bulk of water. (Debray, Bull. Soc. Chim. [2], vii. 9.)

Rubidio-aluminic sulphate, or *Rubidium-alum*, $AlRb(SO^4)^2.12H^2O$, forms large, transparent, non-efflorescent, octahedral crystals, modified with faces of the cube and dodecahedron (Kirchhoff and Bunsen). 100 pts. of water at 17° dissolve 2·27 pts. of it; in hot water it dissolves as easily as potash-alum. (J. Redtenbacher, Jahresb. 1865, p. 704.)

Sodio-aluminic sulphate, or *Soda-alum*, $AlNa(SO^4)^2.12H^2O$, is found native, in fibrous crusts or masses, on the island of Milo in the Grecian Archipelago, at the Solfatara near Naples, and near Mendoza on the east of the Andes. It may be prepared artificially in the same manner as common potash-alum, and obtained in large splendid octahedrons, by leaving a solution of the component salts to evaporate spontaneously in a rather deep glass vessel, and covered with a layer of alcohol. It is much more soluble than potash-alum, 10 pts. of water at ordinary temperatures dissolving 11 pts. of it.

Thallio-aluminic sulphate, or *Thallium-alum*, $AlTl(SO^4)^2.12H^2O$, crystallises in regular octahedrons. (Lamy.)

Pseudo-alums containing Diatomic Metals.—*Ferroso-aluminic sulphate*, $\left.\begin{matrix}Al^2O^3\\Fe''O\end{matrix}\right\}4SO^3.24H^2O = \overset{\prime\prime\prime}{Al}{}^2Fe''(SO^4)^4.24H^2O$, is produced (according to Klauer) when a solution of the component salts, mixed with excess of sulphuric acid, is left to stand in a warm place, and crystallises after a few days in tufts of silky fibres.

The same salt occurs native, as *halotrichite* or *feather-alum* (in part), at Bodenmais and Morsfeld in Rhenish Bavaria, at Oroomiah in Persia (where it is used for making ink), and probably at Roseville, Richmond County, New York. It forms fibrous, silky, yellowish-white crystals, which become dull and pulverulent on exposure, and taste like common alum, but somewhat inky (Berthier, Rammelsberg, B. Silliman, Jun., *Dana's Minerology*, ii. 383).—The *hversalt* of Forchhammer, from Iceland, is an allied alum having the alumina partly replaced by ferric oxide, and the ferrous oxide by magnesia.—The *halotrichine* of Scacchi is a silky mineral from the Solfatara, containing $\left.\begin{matrix}2Al^2O^3\\3Fe''O\end{matrix}\right\}5SO^3.54H^2O$.

Ferroso-potassio-aluminic sulphate, $\left.\begin{matrix}Al^2O^3\\12Fe''O\\2K^2O\end{matrix}\right\}17SO^3.24H^2O$, remains in the earthy residue left on distilling the sulphurous soil of the crater of the Solfatara near Naples. It crystallises in bottle-green octahedrons, which are permanent in the air, and dissolve sparingly in water. (Dufrénay.)

Magnesio-aluminic sulphate, or *Magnesia-alum*, $Al^2Mg(SO^4)^4.24H^2O$, crystallises from a solution of the constituent salts containing a considerable excess of acid, in long needle-shaped crystals. It occurs native in similar crystals, as *feather-alum* or *pickeringite*. A specimen from Iquique in Peru was found by Hayes (Sill. Am. J. xlvi. 368) to contain 12·180 per cent. alumina, 4·682 magnesia, 36·322 sulphuric anhydride, and 45·450 water, besides 0·430 ferrous and manganous oxides, 0·126 lime, and 0·604 silica (= 99·744), agreeing nearly with the preceding formulæ. The magnesium is often replaced to a considerable extent by manganese, forming mangano-magnesian alum.

According to Klauer, a mixture of magnesic and aluminic sulphates containing free acid sometimes yields, by slow evaporation, warty groups of small prismatic crystals, containing $Al^2Mg^3(SO^4)^6.36H^2O$.

Manganoso-aluminic sulphate, or *Manganese-alum*, $Al^2Mn(SO^4)^4.24H^2O$, occurs, with the manganese more or less replaced by magnesium, in snow-white silky fibres, at

Lagoa Bay in South Africa (Apjohn, Phil. Mag. [3], xii. 103), near the Bosjeman river in South Africa (Stromeyer, Pogg. Ann. xxxi. 137), and near Lake Utah in North America (Smith, Sill. Am. J. [2], xviii. 372):

	SO^3.	Al^2O^3.	MnO.	MgO.	K^2O.	H^2O.	KCl.		
Lagoa Bay	33·51	10·65	6·60	0·36	. .	48·15	. .	=	99·27
Bosjeman river	36·77	11·51	1·95	3·69	. .	45·74	0·20	=	99·86
Lake Utah	38·85	10·40	2·12	3·94	0·20	46·00	. .	=	100·51

The deposit at Lagoa Bay is twenty feet thick, and is made up of fibrous crystals six inches long.

Sulphates of Ammonium.—*Acid*, $(NH^4)HSO^4$.—*Neutral*, $(NH^4)^2SO^4$.—Already described under AMMONIACAL SALTS (i. 193).

Ammonio-sodic sulphate, $(NH^4)NaSO^4.2H^2O$, crystallises from a mixture of sodic sulphate and ammonic chloride, or of ammonic sulphate and sodic chloride, either by slow evaporation, or from a solution concentrated by heat till a crystalline film forms on the surface. It is permanent in the air, gives off its crystallisation-water over oil of vitriol, and slowly recovers it on exposure to the air at 15° or 16°. Specific gravity of the crystallised salt = 1·63 at 15°; that of a solution of various strengths is as follows:

Percentage of crystallised salt	31·8	25·44	15·9	12·72	6·3
Specific gravity	1·1749	1·1380	1·0849	1·0679	1·0337

At a stronger heat, the dehydrated salt gives off ammonia, and leaves acid sulphate of sodium. (Schiff, Ann. Ch. Pharm. cxiv. 68.)

Sulphates of Antimony.—*Neutral antimonious sulphate*, $\overset{\prime\prime}{Sb}{}^2(SO^4)^3$, formed by boiling antimony with strong sulphuric acid, is a white saline mass, which is resolved by water into an insoluble basic and a soluble acid salt. According to Brandes, the salt crystallises, from solution in excess of sulphuric acid, in small needles.

Several basic sulphates of antimony are known.—A *sesquibasic salt*, $Sb^2O^3.2SO^3 = Sb^2O^3.2Sb^2(SO^4)^3$, is produced, according to Péligot, in small shining crystals, by treating oxychloride of antimony (algaroth-powder) with fuming sulphuric acid.—The *tribasic salt*, $Sb^2O^3.SO^3 = 2Sb^2O^3.Sb^2(SO^4)^3$, is obtained by digesting the preceding salt in the pulverised state with alcohol, and remains as a white powder on filtration (Brandes).—The *hexbasic salt*, $2Sb^2O^3.SO^3 = 5Sb^2O^3.Sb^2(SO^4)^3$, is formed from the sesquibasic salt by boiling with water.

An *acid antimonious sulphate*, $Sb^2O^3.4SO^3 = Sb^2(SO^4)^3.SO^3$, is formed, with evolution of hydrochloric acid, by treating powder of algaroth with strong sulphuric acid. It crystallises in needles, which, however, cannot be obtained in the dry state, except by keeping them for a long time in a vacuum on a plate of baked pipe-clay. (Péligot.)

Sulphates of Barium.—The *neutral sulphate*, $Ba''SO^4$, occurs very abundantly in nature as *Heavy spar* or *Barytes*, sometimes in crystals belonging to the trimetric system, sometimes massive (see HEAVY SPAR, iii. 137). It may be obtained as a crystalline powder by fusing 12 grms. of potassic sulphate with 52 grms. anhydrous chloride of barium in a well-closed crucible, and dissolving out the soluble salts with water. The crystals thus obtained agree in form and specific gravity with native heavy spar. (Manross, Ann. Ch. Pharm. lxxxii. 348; Jahresb. 1852, p. 9.)

By precipitating the solution of a barium-salt with sulphuric acid or a soluble sulphate, sulphate of barium is obtained, as a heavy, white, amorphous powder, of specific gravity 4·02—4·51 (Schröder, Jahresb. 1859, p. 12), insoluble in water, very slightly soluble in dilute acids, somewhat more soluble in strong sulphuric, nitric, and hydrochloric acids (ii. 503). It dissolves also to a perceptible extent in aqueous nitrate of ammonium, especially when the boiling solutions of a sulphate and a barium-salt, previously mixed with a little nitrate of ammonium, are poured alternately into a boiling solution of the same salt (Mittenzwei, J. pr. Chem. lxxv. 214). According to Scheerer (*ibid.* p. 113), the precipitation of sulphuric acid by barium-salts is retarded by the presence of metaphosphoric acid, but not of pyrophosphoric or orthophosphoric acid.

Sulphate of barium boiled with a concentrated solution of a fixed alkaline carbonate is decomposed, but never completely, into alkaline sulphate and barium-carbonate; a somewhat more complete decomposition is obtained by fusion with alkaline carbonates. Sulphate of barium is reduced to sulphide by ignition with charcoal or organic matter; also, according to Wurtz, by ignition in a stream of coal gas; or, according to Deville, in a stream of hydrogen mixed with vapour of carbonic disulphide.

Native sulphate of barium, in the state of powder and mixed with white lead, is used as a pigment; alone it has not sufficient body; the amorphous sulphate is prepared on the large scale by precipitation, and forms the pigment called **permanent**

The *acid salt*, $\mathrm{Ba''H^2(SO^4)^2}$, is produced (according to Berzelius) by pouring strong sulphuric acid on the ignited neutral sulphate, and leaving it to stand in a closed vessel in a warm place. According to Liès-Bodart and Jacquemin (J. pr. Chem. lxxv. 314), strong sulphuric acid dissolves oxide, chloride, sulphide, chlorate, phosphate, &c. of barium, forming acid sulphate of barium, which crystallises in microscopic prisms; and if the mother-liquor be left in an open vessel, so that it may slowly absorb moisture, it deposits silky needles containing $\mathrm{Ba''H^2(SO^4)^2.2H^2O}$. Both the anhydrous and the hydrated crystals are immediately decomposed by water.

Bario-sodic sulphate, $\mathrm{Ba''Na^2(SO^4)^2}$, is produced (according to Berthier) by fusing its constituent salts together in equivalent quantities, and forms on cooling an opaque very hard mass, having a pearly lustre.

Sulphates of Bismuth.—When bismuth is heated with strong sulphuric acid, sulphurous oxide is evolved, and the metal is converted into a white insoluble powder, consisting of the *normal sulphate*, $\overset{\prime\prime\prime}{\mathrm{Bi}}\mathrm{{}^2O^3.3SO^3}$ or $\overset{\prime\prime\prime}{\mathrm{Bi}}\mathrm{{}^2(SO^4)^3}$, which is decomposed by water, yielding a very acid salt, which dissolves; and a *tribasic sulphate*, $\mathrm{Bi^2O^3.SO^3.H^2O}$, or $\mathrm{2Bi^2O^3.Bi^2(SO^4)^3.3H^2O}$, which remains.—There is also a *sesquibasic sulphate*, $\mathrm{Bi^2O^3.2SO^3.3H^2O}$, or $\mathrm{Bi^2O^3.2Bi^2.(SO^4)^3.9H^2O}$, which is obtained in small delicate needles, when an acid solution of nitrate of bismuth is mixed with sulphuric acid. (Heintz.)

Bismutho-potassic sulphate, $\mathrm{Bi'''K^3(SO^4)^3}$, is precipitated on dropping an acid solution of bismuth-nitrate into a concentrated solution of potassic sulphate, the latter not being in excess. The white pulverulent precipitate must be dried on a porous tile in the exsiccator. It is decomposed by water. If a dilute solution of potassic sulphate be used, the precipitate has the composition $\overset{\prime\prime\prime}{\mathrm{Bi}}\mathrm{{}^2K^4(SO^4)^5}$. (Heintz.)

Sulphates of Cadmium.—The *neutral salt*, $\mathrm{Cd''SO^4}$, forms (according to Stromeyer) efflorescent crystals containing 4 at. water. According to Kühn and v. Hauer (J. pr. Chem. lxiv. 477; Chem. Soc. Qu. J. viii. 250), an acid solution of the salt, concentrated at the boiling heat, deposits nodular crystals, which contain $\mathrm{Cd''SO^4.H^2O}$, and give off their water at 100°; their specific gravity is 2·939 (Buignet, Jahresb. 1861, p. 15). The crystals formed at ordinary temperatures contain $\mathrm{3Cd''SO^4.8H^2O}$, give off nearly 3 at. water at 100°, and the rest at a low red heat (v. Hauer); their specific gravity is 3·05 (Gieseke, Jahresb. 1860, p. 17). According to Rammelsberg (Pogg. Ann. cxv. 579), they are isomorphous with the sulphates of didymium and yttrium containing corresponding quantities of water. W. Delffs (Pharm. Centr. 1854, p. 380) recommends sulphate of cadmium as a distinguishing test between several organic acids, inasmuch as it forms precipitates with oxalates, mellitates, citrates, cuminates, and cinnamates at ordinary temperatures,—with tartrates, racemates, fumarates, and suberates only when heated,—and does not precipitate the aconitates, malates, succinates, benzoates, or salicylates under any circumstances.

Ammoniacal cadmic sulphate, $\mathrm{Cd''SO^4.6NH^3}$, or *Sulphate of tetrammonio-cadmio-diammonium*, $\mathrm{N^2[H^2(NH^4)^4Cd'']SO^4}$, is formed, as a white powder, when anhydrous cadmic sulphate is allowed to absorb ammonia-gas till it is saturated. (H. Rose.)

Ammonio-cadmic sulphate, $\mathrm{Cd''(NH^4)^2(SO^4)^2.6H^2O}$, separates in monoclinic crystals, from a solution containing equivalent quantities of the component salts.—The corresponding *potassium-salt*, which is isomorphous with it, is not so easily formed, inasmuch as the solution is apt to deposit sulphate of potassium; it is efflorescent.—The *magnesium-salt*, $\mathrm{Cd''Mg''(SO^4)^2.6H^2O}$, crystallises from dilute sulphuric acid, half saturated with cadmic, and half with magnesic carbonate, in easily soluble four-sided prisms.—The *sodium-salt*, $\mathrm{Cd''Na^2(SO^4)^2.6H^2O}$, separates from concentrated solution in small nodules. (v. Hauer.)

Sulphate of Cæsium. See Cæsium (i. 1115).

Sulphates of Calcium.—The *neutral sulphate*, $\mathrm{Ca''SO^4}$, occurs native, both in the anhydrous state as anhydrite (i. 295), and as a hydrate, $\mathrm{Ca''SO^4.2H^2O}$, forming gypsum and its several varieties (ii. 962). The anhydrous sulphate may be obtained in crystals having the form and specific gravity (2·9) of anhydrite, by fusing potassic sulphate with excess of calcic chloride (Manross, Jahresb. 1852, p. 9; see also Simmler, *ibid.* 1859, p. 132). The hydrated salt is formed by precipitating a solution of calcic chloride with a soluble sulphate or dilute sulphuric acid. It is very slightly soluble in water, the anhydrous salt nearly insoluble. According to Lassaigne, 1 pt. of the hydrate dissolves in 332 pts. of water at any temperature; but according to Poggiale, the solubility is greatest at 35°, 1 pt. of the salt dissolving at that temperature in 393 pts. water, at 0° in 488 pts., and at 100° in 460 pts. Water containing hydrochloric or nitric acid dissolves it in larger quantity, in consequence of partial decomposition; the solubility is likewise increased by the presence of common salt;

hence the occurrence of gypsum in salt-springs. Calcic sulphate dissolves also in excess of a saturated solution of sodic hyposulphite, with moderate facility at ordinary temperatures, more quickly on warming, being at the same time converted into calcic hyposulphite, which unites with the excess of sodic hyposulphite, forming a soluble double salt; and on adding alcohol to the solution, this double salt is precipitated as a heavy oily liquid, which solidifies in needle-shaped crystals. The solubility of calcic sulphate in sodic hyposulphite affords a means of separating it from baric sulphate. (Diehl, J. pr. Chem. lxxix. 430.)

Gypsum heated to 100° or 120° gives off three-fourths of its water somewhat quickly, but the last fourth is not expelled below 200°—250°. The hydrated calcic sulphate deposited in steam-boilers has the same composition as gypsum dried at 100°, viz. $2CaSO^4.H^2O$, and a specific gravity of 2·7. Dehydrated gypsum melts at a red heat without decomposition, and on cooling assumes the crystalline structure of anhydrite. When gypsum dehydrated at a moderately high temperature, and pulverised, is agitated with water, it takes up 2 at. water, and solidifies to a very hard mass, the solidification being quicker in proportion as the gypsum has been dehydrated at a lower temperature; if this temperature exceeds a certain limit, the gypsum bakes together, and is then incapable of taking water. The hydrated gypsum expands in solidifying, so that it easily fills the cavities of any mould in which it is cast: hence the use of gypsum or plaster of Paris in taking casts (ii. 962). Calcic sulphate ignited with charcoal or organic matter is reduced to sulphide.

Acid sulphate of calcium, or *Calcio-hydric sulphate*, $Ca''H^2(SO^4)^2$, is produced, (according to Berzelius) by digesting the anhydrous neutral salt with sulphuric acid at 80°—100°. It forms a granular mass, the particles of which appear under the microscope as short, colourless, transparent prisms. It absorbs moisture from the air, and is then quickly decomposed into sulphuric acid and the neutral sulphate.

Calcio-sodic sulphate, $Ca''Na^2(SO^4)^2$, occurs native as glauberite or brongniartin (ii. 845), in transparent rhombic prisms. According to Berthier, it may be obtained in the same form by fusing a mixture of calcic and sodic sulphates. When 50 pts. of sodic sulphate are heated with 25 pts. water in which 1 pt. of gypsum has been stirred up, the liquid deposits at 80° a pulp of crystalline needles, consisting of the salt $Ca''Na^4(SO^4)^3.2H^2O$. At a higher temperature, these needles are converted into microscopic, rhombohedral, anhydrous crystals of glauberite, $Ca''Na^2(SO^4)^2$. The latter is also formed immediately, if twice the above quantity of water is used at the beginning of the process, and the liquid heated to boiling. These artificial crystals of glauberite are transparent, like the native crystals from Villarubia, but become opaque and much more friable by ignition.

Sulphate of calcium likewise unites by fusion with the fluorides of barium, strontium, and calcium, forming clear fluid masses, which become milk-white on solidifying.

Sulphates of Cerium.—α. *Ceric Salts. Neutral* or *normal Ceric sulphate*, $Ce^2(SO^4)^3 = Ce^2O^3.3SO^3$, obtained by dissolving ceric oxide in sulphuric acid and evaporating, forms efflorescent crystals belonging to the hexagonal system, which dissolve in a small quantity of water, but are decomposed by a larger quantity, with precipitation of a basic salt requiring 2,500 pts. of water to dissolve it (Mosander). On dissolving this basic salt in sulphuric acid, the neutral salt crystallises out again with 9 at. water (Hermann, J. pr. Chem. xxx. 184).—The *basic salt* contains, according to Hermann, $3Ce^2O^3.4SO^3.9H^2O$, or $4Ce^2(SO^4)^3.5Ce^2O^3.27H^2O$. Marignac regards it as a ceroso-ceric salt. A basic ceric sulphate, the composition of which is not given, is prepared, according to Holzmann (J. pr. Chem. lxxv. 321; Jahresb. 1858, p. 132), by dissolving the brown powder obtained by roasting a mixture of cerous oxalate and *magnesia alba* (i. 832) in boiling nitric acid, heating the solution till nearly all the free nitric acid is expelled, triturating 100 grms. of the crystalline mass which forms on cooling with 100 cub. cent. of water, and adding the quickly filtered solution to 2 litres of boiling water previously mixed with 12 cub. cent. of sulphuric acid. The basic ceric sulphate which then separates is to be washed by decantation with water containing the same quantity of sulphuric acid.

Potassio-ceric sulphate, $\overset{'''}{Ce}{}^2K^4(SO^4)^5 = \left.\begin{matrix}Ce^2O^3\\2K^2O\end{matrix}\right\}5SO^3$, is obtained, by immersing crystallised potassic sulphate in a solution of ceric sulphate, as a lemon-yellow powder, which dissolves in water and crystallises therefrom, but is insoluble in a saturated solution of potassic sulphate. When ignited it turns white, gives off sulphuric oxide and oxygen, and leaves ceroso-potassic sulphate (Hermann).—*Ammonio-cerous sulphate* forms monoclinic crystals.

β. *Cerous Salts.*—*Neutral cerous sulphate*, $Ce''SO^4.3H^2O$, is obtained by dissolving cerous carbonate in sulphuric acid, or (according to Marignac) by dissolving ceroso-ceric sulphate in water acidulated with sulphuric or nitric acid, diluting the yellowish-red solution with water, and boiling the insoluble salt, which separates after washing, with sulphuric or hydrochloric acid, till it dissolves, and forms a perfectly colourless solution. This solution, when evaporated, yields cerous sulphate in colourless rhombic octahedrons (sometimes reddish from the presence of didymium). According to Otto, they contain 3 at. water, which is expelled by heat. They dissolve with moderate facility in cold water, and the solution, when heated, deposits reddish prisms of a much less soluble salt, containing $2CeSO^4.3H^2O$; they must be taken out of the hot liquid and pressed, as if the mother-liquor is left to cool upon them, they redissolve (Otto). According to Hermann (J. pr. Chem. xcii. 113; Jahresb. 1864, p. 194), four other hydrates—containing respectively $3CeSO^4.5H^2O$, $CeSO^4.2H^2O$, $3CeSO^4.8H^2O$, and $CeSO^4.3H^2O$, separate from moderately warm solutions of cerous sulphate, under apparently similar circumstances, and cannot be obtained at pleasure. They all crystallise in rhombic forms, and appear to be homœomorphous. The $\frac{8}{3}$-hydrate is the most frequent, separating both on warming and by slow evaporation, in short prisms, which retain their lustre on exposure to the air.

Ammonio-cerous sulphate separates, on boiling a solution of its component salts, as a crystalline powder, which, by solution and recrystallisation, may be obtained in obtuse rhombohedrons.

Potassio-cerous sulphate, $Ce''K^2(SO^4)^2$, separates as a white powder, on immersing solid potassic sulphate in a solution of cerous sulphate which may contain free acid. It is insoluble in a saturated solution of potassic sulphate, but dissolves slightly in pure water, and crystallises on cooling from solution in boiling water. The formation of this salt affords a means of separating cerium from most other metals (i. 833). It melts without decomposition when heated (Berzelius).—Another *potassio-cerous sulphate*, $\overset{\prime\prime\prime}{Ce}{}^2K^2(SO^4)^3$, separates (according to Hermann) as a white powder, on mixing the concentrated solutions of equal weights of potassic and cerous sulphates.

Sodio-cerous sulphate, $\overset{\prime\prime\prime}{Ce}{}^2Na^2(SO^4)^3$, analogous to the potassium-salt last-mentioned, separates as a white granular precipitate, on heating a mixed solution of the component salts to the boiling-point. (Beringer.)

γ. *Ceroso-ceric Salts.*—The salt $3CeO.2Ce^2O^3.4SO^3.H^2O$ is formed, according to Marignac, as a yellow mass, by treating ignited ceric oxide with sulphuric acid. It dissolves easily in water strongly acidulated with sulphuric or nitric acid, and is reduced to cerous sulphate by boiling with nitric or hydrochloric acid. According to Rammelsberg (Pogg. Ann. cviii. 40; Jahresb. 1859, p. 136), the yellowish-red solution of ceroso-ceric oxide in sulphuric acid yields, by slow evaporation, first brown-red hexagonal crystals of a salt, *A*, containing $\overset{\prime\prime\prime}{Ce}{}^2\overset{\prime\prime}{Ce}{}^3(SO^4)^6.18H^2O = 3Ce''SO^4.\overset{\prime\prime\prime}{Ce}{}^2(SO^4)^3.18H^2O$, which are decomposed by water, with separation of a sulphur-yellow basic salt; afterwards a yellow indistinctly crystalline salt, *B*, containing $\overset{\prime\prime\prime}{Ce}{}^2Ce''(SO^4)^4.8H^2O$, or $Ce''.\overset{\prime\prime\prime}{Ce}{}^2(SO^4)^4.8H^2O$, which is decomposed by water in the same manner as the former. The light-yellow precipitate, separated from either of these salts by water, contains $2Ce^3O^4.3SO^3.6H^2O$, and, as well as the salts *A* and *B* themselves, leaves, when strongly ignited, a residue of pure ceroso-ceric oxide (Rammelsberg). According to Hermann (Jahresb. 1864, p. 194), Rammelsberg's yellow-red salt *A* contains $2Ce''.SO^4.\overset{\prime\prime\prime}{Ce}{}^2(SO^4)^3.27H^2O$, and his yellow salt *B* consists of $Ce''SO^4.\overset{\prime\prime\prime}{Ce}{}^2(SO^4)^3.8H^2O$. Hermann supposes also that there are several other yellow ceroso-ceric sulphates. The composition of basic *ceroso-ceric sulphate* likewise varies, according to Hermann, with its mode of preparation.

A solution of the salt *A* yields, on addition of potassic sulphate, a yellow crystalline precipitate, varying in composition according to the proportions in which the two salts are mixed, and the temperature and concentration of the solutions, but generally consisting of a mixture of at least two compounds—viz., $3K^2SO^4.3Ce''SO^4.\overset{\prime\prime\prime}{Ce}{}^2(SO^4)^3.6H^2O$ and $6K^2SO^4.3Ce''SO^4.\overset{\prime\prime\prime}{Ce}{}^2(SO^4)^3.6H^2O$. Rammelsberg is, however, of opinion that the composition of these salts may be more correctly expressed by regarding the cerous oxide and potash as bases which replace one another isomorphously. Marignac (Ann. Min. [5] xv. 275) obtained, by spontaneous evaporation of a solution containing potassic and ceroso-ceric sulphates, small yellow crystals having the composition $Ce^3O^4.4SO^3 + 4(K^2O.SO^3) + 4H^2O$ or $4K^2SO^4.Ce''SO^4.\overset{\prime\prime\prime}{Ce}{}^2(SO^4)^3.4H^2O$, and consisting of monoclinic combinations $+P . -P . oP . \infty P\infty . [\infty P\infty] . [\frac{1}{2}P\infty] . +\frac{1}{2}P\infty$, &c.; sometimes pyramidal, from predominance of $+P$ and $-P$; sometimes tabular, by predominance of oP. Angle $+P : +P$ (clinod.) $= 83° 7'$; $-P : -P$ (clinod.) $= 92° 23'$; $oP : \infty P\infty = 100° 40'$; $oP : +P = 104° 20'$; $oP : -P = 116° 20'$; $oP : [\frac{1}{2}P\infty] = 134° 10'$.

—*Ammonio-ceroso-ceric sulphates* are obtained in the same manner as the potassic salts Besides a crystallo-granular precipitate containing $4(NH^4)^2SO^4.2Ce''SO^4.\overset{\prime\prime\prime}{Ce}{}^2(SO^4)^3.4H^2O$, large, orange-red, monoclinic crystals are formed, containing $9(NH^4)^2SO^4.Ce''SO^4.2\overset{\prime\prime\prime}{Ce}{}^2(SO^4)^3.12H^2O$, easily soluble in water, and leaving pure ceroso-ceric oxide when ignited (Rammelsberg). Marignac obtained an ammonio-ceroso-ceric salt, analogous in form and composition to his potassio-ceroso-ceric salt.

Sulphates of Chromium. (Schrötter, Pogg. Ann. liii. 513.—Traube, Ann. Ch. Pharm. lxvi. 87, 168.—Moberg, *ibid.* lxvi. 92.—Leykauf, J. pr. Chem. xix. 225. —Löwel, Ann. Ch. Phys. [3] xl. 42; xliv. 313; Jahresb. 1855, p. 376.)—*a. Chromic Salts.*—The *normal* or *neutral salt*, $\overset{\prime\prime\prime}{Cr}{}^2(SO^4)^3$ or $\overset{\prime\prime\prime}{Cr}{}^2O^3.3SO^3$, exhibits a violet and a green modification. The violet sulphate is obtained by leaving 8 pts. of chromic hydrate dried at 100°, and 8 or 10 pts. of strong sulphuric acid, in a loosely-stoppered bottle for several weeks. The solution, which is green at first, gradually becomes blue, and deposits a greenish-blue crystalline mass. On dissolving this substance in water, and adding alcohol, a violet-blue crystalline precipitate is formed; and by dissolving this precipitate in very weak alcohol, and leaving the solution to itself for some time, small regular octahedrons are deposited, containing $Cr^2(SO^4)^3.15H^2O$. Another mode of preparing it is to dissolve 5 pts. of chromic hydrate in 12½ pts. strong nitric acid; dilute the solution with 12½ pts. of water; and after boiling for a quarter of an hour, and leaving the liquid to cool (whereupon it turns red), add 7½ pts. strong sulphuric acid previously diluted with 15 pts. of water, and cooled. On shaking up this solution with 120 pts. of alcohol, the salt separates in small crystals, which must be washed with alcohol and dried between filter-paper. (Löwel, Ann. Ch. Phys. [3] xl. 42.)

The *green sulphate*, $\overset{\prime\prime\prime}{Cr}{}^2(SO^4)^3.5H^2O$, is prepared by dissolving chromic oxide in strong sulphuric acid at a temperature between 50° and 60°; also by boiling a solution of the violet sulphate; or by heating the crystals of the violet salt to 100°, whereupon they give up 10 at. water, and melt to a green liquid which solidifies to a green amorphous mass. The liquid, when quickly evaporated, yields a green non-crystalline salt having the same composition as the violet sulphate. The green sulphate dissolves readily in alcohol, forming a blue solution; but the violet salt is insoluble in alcohol. The solution of the green sulphate is not completely decomposed by soluble barium-salts at ordinary temperatures, a boiling heat being required to complete it; the violet sulphate, on the contrary, is deprived of all its sulphuric acid by barium-salts at ordinary temperatures. When either the green or the violet sulphate is heated to 190°, with excess of sulphuric acid, a light-yellow mass is obtained, which, when further heated, leaves a residue of anhydrous chromic sulphate, having a *red* colour. This anhydrous salt is completely insoluble in water, and dissolves with difficulty even in acid liquids.

Basic Salts.—The *sesquibasic sulphate*, $Cr^2O^3.2SO^3$, or $Cr^2O^3.2Cr^2(SO^4)^3$, is formed (according to Schrötter) when recently precipitated and still moist chromic hydrate is dissolved to complete saturation in moderately dilute sulphuric acid. The green solution thus formed leaves, on evaporation, a green residue, which appears dark ruby-red by transmitted light, is perfectly amorphous, and when heated to redness is converted, without change of colour, into chromic oxide. It dissolves readily in a small quantity of water; the solution exhibits a dark ruby colour by transmitted light, and on dilution with water, especially if heated, deposits a light-green powder.—The $\frac{9}{2}$-*basic salt*, $3Cr^2O^3.2SO^3.12H^2O = 7Cr^2O^3.2Cr^2(SO^4)^3.36H^2O$, is the light-green powder which separates on heating the dilute solution of the preceding salt (Schrötter).—The *dibasic salt*, $2Cr^2O^3.3SO^3 = Cr^2O^3.Cr^2(SO^4)^3$, is produced (according to Krüger) when a solution of chromic sulphate is heated till the original green colour changes to rose-red. It is insoluble in water.—The precipitates formed by alkalis in solutions of chromic sulphate are likewise basic salts, which however vary greatly in composition, according to the concentration of the liquid and the quantity of alkali added.

Double Salts of Chromic Sulphate. Chrome-alums.—*Ammonia-chrome-alum*, $Cr'''(NH^4)(SO^4)^2.12H^2O$, is prepared, like the corresponding potassium-salt, with sulphate of ammonium and chromic sulphate (Schrötter), or acid chromate of ammonium (Traute). It is less soluble than the potassium-salt, and crystallises more readily in splendid ruby-coloured octahedrons, which yield a lavender-blue powder. Specific gravity = 1·738. From a concentrated solution of violet chromic sulphate, it is precipitated, on addition of ammonium-sulphate, as a violet-blue crystalline powder. It is not precipitated from its aqueous solution by alcohol. The crystals effloresce slowly in contact with the air, and melt at 100°, with loss of 9 at. water, the residue slowly solidifying to a green gummy mass containing 3 at. water, which is the double salt corresponding to the green modification of chromic sulphate. At 200°, the other 3 at. water are given off, the green anhydrous salt then remaining.

The violet solution, prepared in the cold, passes at 75° into the green modification, and is then no longer crystallisable; if, however, it be left to itself for ten or twelve days after cooling, the violet colour is restored, and with it the capability of crystallisation.

Potassio-chromic Sulphate, or *Potassic Chrome-alum*, $\mathrm{Cr'''K(SO^4)^2.12H^2O}$.—This salt is produced: 1. By mixing the solutions of potassic chromate and violet chromic sulphate, adding a small quantity of sulphuric acid, and leaving the solution to evaporate.—2. By heating potassic dichromate with strong sulphuric acid:

$$\mathrm{K^2CrO^4.CrO^3 \ + \ 4H^2SO^4 \ = \ 2Cr'''K(SO^4)^2 \ + \ 4H^2O \ + \ O^2.}$$

The reduction of the chromic acid is, however, greatly facilitated by adding alcohol or other organic substance. Chrome-alum is, in fact, often obtained as a secondary product in the oxidation of organic bodies with sulphuric acid and potassic chromate, as in the preparation of valerianic acid from amylic alcohol. A very convenient mode of reduction also is to pass sulphuric oxide gas through the liquid. In this case only 1 at. sulphuric acid need be added, the reaction being represented by the equation:

$$\mathrm{K^2CrO^4.CrO^3 \ + \ H^2SO^4 \ + \ 3SO^2 \ = \ 2Cr'''K(SO^4)^2 \ + \ H^2O.}$$

Chrome-alum crystallises, by slow evaporation, in splendid octahedrons, sometimes very large and of a dark purple almost black colour: the smaller crystals exhibit, by transmitted light, a very fine ruby-red colour. The salt dissolves at ordinary temperature in 7 pts. of water. The solution has a dingy-blue colour, with a tinge of red, and when mixed with alcohol deposits the chrome-alum unaltered. When heated to 70° or 80°, it becomes green, perhaps from formation of green chromic sulphate or the corresponding modification of chrome-alum, which, like green chromic sulphate itself, is uncrystallisable. The green solution, if left at rest for some weeks, gradually recovers its violet colour, and then again yields crystals. The change of the purple into the green salt has sometimes been supposed to be attended with separation of the potassic and chromic sulphates; but, according to Schrötter and Löwel, it arises merely from loss of crystallisation-water. A solution of chrome-alum which has become green and uncrystallisable by heating, does not deposit any sulphate of potassium, even when concentrated; neither does that salt separate when the crystals are melted in a sealed tube; but the green liquid obtained by either of these processes yields, when heated in a dry atmosphere, a dark-green mass containing $\mathrm{CrK(SO^4)^2}$, with scarcely 3 at. water. The violet crystals containing $\mathrm{12H^2O}$, when left for several days in dry air, at a temperature between 25° and 30°, give off 6 at. water, and assume a lilac colour. At 100° another quantity of water goes off, and the crystals become green; and, by gradually raising the temperature to about 350°, the whole of the water may be expelled without causing the salt to melt. The anhydrous crystals are green, and dissolve without residue in boiling water, but at a temperature somewhat above 350°, they suddenly become greenish-yellow, without perceptible loss of weight, and are afterwards perfectly insoluble in water. (Löwel; see also Siewert, Ann. Ch. Pharm. cxxvi. 86; Jahresb. 1863, p. 223.)

Krüger, by precipitating a concentrated green solution of chrome-alum prepared at a high temperature, obtained a green viscid mass containing $\mathrm{Cr^2O^3.2SO^3 + K^2O.SO^3}$ or $\mathrm{\overset{'''}{Cr}{}^4K^6(SO^4)^9.Cr^2O^3}$. According to Otto, the aqueous solution of this salt, when left at rest for a very long time, is completely converted into violet crystals. Leykauf has proposed the use of the green mass for colouring oil-varnishes, caoutchouc, &c., and its solution as a green ink.

Sodio-chromic Sulphate, or *Sodic Chrome-alum*, $\mathrm{Cr'''Na(SO^4)^2.12H^2O}$.—Prepared by cautiously adding alcohol to a mixture of 1 at. acid chromate of sodium and 4 at. sulphuric acid. It is much more soluble than the corresponding ammonium- and potassium-salts, and cannot therefore be obtained in well-developed crystals. Under the exsiccator it separates as a violet warty mass. At 100° it gives off 8 at. water, leaving a green modification with 4 at. water. (Schrötter.)

Potassio-aluminio-chromic sulphate, $\mathrm{Cr'''Al'''K^2(SO^4)^4.24H^2O}$, and the corresponding *ammonium-salt*, are prepared by mixing the solutions of equivalent quantities of the alumina- and chrome-alums, and leaving the liquid to evaporate. They crystallise in large octahedrons having a dark-amethyst colour. The solutions are decomposed by boiling, and on cooling yield crystals of the alumina-alum. (Vohl.)

β. *Chromous Sulphates.*—When the metallic powder obtained by the action of potassium on chromic chloride is treated with dilute sulphuric acid, hydrogen is evolved, and a solution obtained, which exhibits the characters of a chromous salt (Péligot). The solution, mixed with ammonia and sal-ammoniac, absorbs oxygen, nitric oxide, acetylene, and allylene, but not carbonic oxide, ethylene, or tritylene. (Berthelot, Bull. Soc. Chim. [2], vii. 194.)

Potassio-chromous sulphate, $\mathrm{Cr''K^2(SO^4)^2 6H^2O}$, is obtained by dissolving potassic sulphate in a cold saturated solution of chromous chloride (i. 941), and adding alcohol till a precipitate begins to form. If the solution be then left for some weeks in a closed vessel, potassio-chromous sulphate crystallises from it in fine blue rhombic prisms, which turn green on exposure to the air. (Péligot.)

Sulphates of Cobalt.—The *neutral cobaltous salt*, $Co''SO^4.7H^2O$, occurs native as cobalt-vitriol or bieberite, sometimes in monoclinic crystals, but usually in stalactites and crusts, in the rubbish of old mines at Bieber, near Hanau, and at Leogang in Salzburg. It is prepared artificially by heating metallic cobalt with strong sulphuric acid, or by treating cobaltous oxide or carbonate with the dilute acid. The red solution, left to evaporate at ordinary temperatures, yields red crystals having the form of ferrous sulphate, and, like the latter, containing 7 at. water. At 20°—30°, on the other hand, it separates in crystals with 6 at. water, isomorphous with hexhydrated sulphate of magnesium (p. 601) (Mitscherlich). It dissolves in 24 pts. of cold water, and is insoluble in alcohol. It effloresces in the air, gives off its water of crystallisation when heated, and is thereby converted into the rose-red anhydrous salt, which bears a moderately strong red heat without decomposition, but is decomposed by continued strong ignition.—A flesh-coloured *basic sulphate*, insoluble in water, is formed by treating the solution of the neutral salt with a quantity of alkali not sufficient for complete precipitation.

Ammoniacal cobaltous sulphate, $Co''SO^4.6NH^3$, or *Sulphate of tetrammonio-cobaltoso-diammonium*, $N^2[Co''(NH^4)^4H^2]SO^4$, is a white powder, produced (according to H. Rose) by the action of dry ammonia-gas on anhydrous cobaltous sulphate; also (according to Frémy) by the action of aqueous ammonia on cobaltous sulphate.

Respecting the ammoniated cobalt-salts obtained by the action of ammonia on cobaltous salt in contact with the air, see COBALT-BASES, AMMONIACAL (i. 1051). On the pentammoniated cobaltic salts, see also C. D. Braun (Ann. Ch. Pharm. cxxxviii. 109; Bull. Soc. Chim. 1866, ii. 316).

Double Salts of Cobaltous Sulphate.—*Ammonio-cobaltous sulphate*, $Co''(NH^4)^2(SO^4)^2.6H^2O$, and *Potassio-cobaltous sulphate*, $Co''K^2(SO^4)^2.6H^2O$, are red double salts, isomorphous with the corresponding salts of iron, magnesium, and manganese.

Potassio-ferroso-cobaltous sulphate, $Co''Fe''K^4(SO^4)^4.12H^2O$, and the corresponding *ammonium-salt* are produced by spontaneous evaporation of a mixed solution of the component salts. They both crystallise in reddish, oblique, rhombic prisms, which oxidise and crumble to a yellowish-brown powder on exposure to the air. On dissolving this powder in water, the original double salt is reproduced. (Vohl, Ann. Ch. Pharm. xciv. 57; Jahresb. 1855, p. 312.)

Magnesio-cobaltous sulphate, $\overset{''}{Co}{}^3Mg''(SO^4)^4.28H^2O$, is found native (according to Winkelblech) at Bieber in Hesse, as a red stalactitic mass, also called *cobalt-vitriol*.

Potassio-magnesio-cobaltous sulphate, $Co''Mg'K^4(SO^4)^4.12H^2O$, and the corresponding *ammonium-salt* are formed on mixing the solutions of the component salts, and crystallise very easily in large rose-coloured, oblique, rhombic prisms, which give off all their water between 160° and 180°, assuming a fine light-blue colour. (Vohl.)

Potassio-manganoso-cobaltous sulphate, $Co''Mn''K^4(SO^4)^4.12H^2O$, and the corresponding *ammonium-salt*, prepared like the preceding, crystallise in fine red prisms and tables, the ammonium-salt being, however, more inclined to the tabular, the potassium-salt to the prismatic form. (Vohl.)

Potassio-niccolo-cobaltous sulphate, $Co''Ni''K^4(SO^4)^4.12H^2O$, and the corresponding *ammonium-salt*, prepared in like manner, crystallise in large tables and prisms having a dingy greenish-grey colour. (Vohl.)

Potassio-zinco-cobaltous sulphate, $Co''Zn''K^4(SO^4)^4.12H^2O$, and the corresponding *ammonium-salt* crystallise in rose-red prisms and tables. When heated to 180°, they give off all their water, assuming a blue colour, which partially disappears on cooling. The ammonium-salt leaves, after prolonged ignition, a fine green-coloured mass, from which water extracts only a portion of the cobaltous sulphate. (Vohl.)

Sulphates of Copper.—*a.* Cupric Salts. *Normal* (or *neutral*) *cupric sulphate*, $Cu''SO^4.5H^2O$, also called *Blue vitriol* and *Copper vitriol*.—This salt occurs very frequently as a secondary product, in mines where sulphuretted copper-ores undergo disintegration, and is found either crystallised in clefts and cavities, or dissolved in the waters of the mine, or in the water used for washing the ore.—It is produced artificially by boiling cupric oxide (scale-oxide of copper) with dilute sulphuric acid, and crystallises out on cooling; or by heating metallic copper with strong sulphuric acid, whereupon sulphurous oxide is evolved, and anhydrous cupric sulphate is precipitated as a white powder, mixed with a brown mass of cuprous and cupric sulphides (p. 340). On digesting this mass with hot water, the cupric sulphate dissolves out, and may be crystallised from the solution.

Cupric sulphate is extensively used in the arts, and is prepared on the large scale, either from artificially prepared sulphide of copper, or by roasting and lixiviation of sulphuretted copper-ores, or from the coarse copper (*Kupferstein*, ii. 27, 34) produced in the smelting of copper, and consisting mainly of the sulphides of copper and iron. The most usual mode of preparation is from artificial sulphide of copper. For this purpose, plates of copper (*e.g.*, old sheathings of ships' bottoms) are heated to strong redness on the hearth of a reverberatory furnace; a certain quantity of sulphur is then thrown in, and all the doors closed. The copper is thereby converted into sulphide, and as soon as the combination is complete, the draught of air is re-established, and the mass is heated to redness, whereby the sulphide of copper is oxidised to cupric sulphate and cupric oxide:

$$Cu^2S + O^5 = Cu''SO^4 + CuO.$$

The roasted mass is thrown, while still hot, into water containing sulphuric acid, and the resulting solution is evaporated to the crystallising-point. The crystals of cupric sulphate thus obtained are nearly pure.

The preparation of cupric sulphate by roasting copper-glance, purple copper, &c., or coarse copper, is precisely similar, and the solution obtained by lixiviating the roasted products also yields nearly pure cupric sulphate in the first and second crystallisations; but the mother-liquors contain a large proportion of ferrous sulphate, and frequently also salts of manganese, cobalt, &c., so that when evaporated to dryness they yield a very impure cupric sulphate: on this account it is better to precipitate the copper from these liquors by metallic iron, and then treat it with sulphuric acid.

Very pure cupric sulphate is obtained as a secondary product in the treatment of auriferous silver with sulphuric acid. From the solution of argentic sulphate thus produced, the silver is precipitated by metallic copper, and a solution of cupric sulphate is formed (ii. 925).

The blue vitriol of commerce is generally pure, with the exception of a small quantity of ferrous sulphate. From this it cannot be freed by mere recrystallisation, as the two salts are very apt to crystallise together isomorphously (p. 592); but if the solution be first heated with a little nitric acid, to convert the ferrous into ferric sulphate, it will then yield pure crystals of the cupric salt. The solution, after treatment with nitric acid, may also be digested with cupric oxide, which will precipitate the iron as ferric oxide. Another mode of removing the iron is to boil the solution with peroxide of lead, and precipitate the ferric oxide thereby produced with a small quantity of carbonate of barium. (Wurtz.)

Cupric sulphate crystallises with 5 at. water in large, azure-blue, triclinic prisms, having the form and modifications shown in *figs.* 313, 314, and 315 (CRYSTALLOGRAPHY, ii. 158). Angle $\infty\bar{P}\infty : \infty{,}P = 154° 3'$; $\infty\bar{P}\infty : \infty P'_{,} = 149° 7'$; $\infty\bar{P}\infty : \infty P' = 110° 10'$; $\infty\bar{P}\infty : \infty'P$ (behind) $= 126° 40'$; $\infty\breve{P}\infty : \infty\bar{P}\infty = 79° 19'$; $\infty P'_{,} : \infty{,}'P = 123° 10'$; $P' : \infty\breve{P}\infty = 103° 27'$; $P' : \infty P'_{,} = 127° 40'$; $P' : \infty\bar{P}\infty = 120° 50'$. The face $\infty\bar{P}\infty$ is striated parallel to the principal axis. The salt has a nauseous metallic taste and acid reaction. Specific gravity = 2·274 (Kopp); 2·302 (Buignet, Jahresb. 1861, p. 15). The crystals effloresce superficially on exposure to the air, give off 4 at. water at 100°, and the remaining 1 at. at 200°, leaving the anhydrous salt as a white saline mass, which is decomposed at a bright red heat, giving off sulphurous oxide and oxygen, and leaving cupric oxide. The anhydrous salt has a very powerful attraction for water, which it absorbs rapidly from the air, becoming hot and assuming a blue colour: on this account it is used for dehydrating alcohol.

Hydrated cupric sulphate dissolves in 3½ pts. of cold and in a much smaller quantity of boiling water. According to Poggiale, 100 pts. of water dissolve the following quantities at various temperatures:—

Temperature.	Quantities of salt dissolved.	
	Crystallised.	Anhydrous.
10°	36·9	20·9
20°	42·3	23·5
40°	56·9	30·3
80°	118·0	53·1
100°	203·3	75·3

Cupric sulphate is insoluble in absolute alcohol, and less soluble in hydrated alcohol as the proportion of alcohol is greater. According to Schiff (Ann. Ch. Pharm. cxviii. 362; Jahresb. 1861, p. 87), 100 pts. of spirit of various strengths, saturated with cupric sulphate ($CuSO^4.5H^2O$) at 15°, contain the following quantities of the pentahydrated salt:

Percentage of alcohol by weight	0	10	20	40
Quantity of salt in 100 pts.	27·2*	13·3	3·1	0·25

* This number, which gives the quantity of the hydrated salt dissolved in pure water at 15°, does not agree with Poggiale's determinations.

Hydrochloric acid dissolves cupric sulphate, with considerable reduction of temperature, forming a green liquid, which, when evaporated, yields crystals of cupric chloride. According to Kane, both the anhydrous salt and the pulverised hydrate rapidly absorb 2 at. hydrochloric acid gas.

When a strong solution of sugar is added to a strong solution of cupric sulphate, a white easily soluble precipitate is gradually formed, consisting of a compound of 1 at. cupric sulphate with 1 at. sugar ($C^{12}H^{22}O^{11}$) and 4 at. water. (**Barreswil**, J. pr. Chem. xxxv. 253.)

When a solution of cupric sulphate is mixed with ferrous sulphate, or with sulphate of zinc, magnesium, or nickel in excess, the cupric sulphate crystallises isomorphously with these salts in the most varying proportions, the crystals having the form of ferrous sulphate and containing 7 at. water. If, on the other hand, the cupric sulphate is in excess, the crystals have the form of blue vitriol, and contain 5 at. water (**Mitscherlich**). According to Rammelsberg, a solution containing 1 at. ferrous to 4 at. cupric sulphate yields crystals having the form of the latter.

Cupric sulphate is used for the preparation of many blue and green pigments (such as Bremer blue, Schweinfurt green, &c.), and very largely in the electrotype process. It is also used in medicine. Its purity may generally be recognised by the form and colour of the crystals. A tinge of green indicates the presence of a ferrous salt; blue vitriol thus contaminated does not dissolve completely in ammonia. The presence of zinc is easily recognised in the liquid which remains after precipitating the copper by sulphydric acid.

Basic Salts.—There are several basic cupric sulphates, forming greenish powders, and obtained for the most part by digesting a solution of the normal salt with cupric hydrate or carbonate, or by imperfect precipitation with potash. Some of them also occur native.

A *dicupric salt*, $2Cu''O.SO^3.H^2O$ or $Cu''SO^4.Cu''H^2O^2$, is produced, according to **Thompson**, by digesting the normal salt with cupric oxide in equivalent quantities; and the anhydrous salt, $2CuO.SO^3$ or $CuSO^4.CuO$, according to **Roucher** (J. Pharm. [3] xxxvii. 249; Jahresb. 1861, p. 193), as an orange-yellow pulverulent mass, by the normal salt to dullredness for several hours.

The *tricupric salt*, $3CuO.SO^3 = CuSO^4.2CuO$, is produced by the action of water on the anhydrous dicupric salt, which, when exposed to moist air, is converted into a green mixture of the normal salt and the salt $3CuO.SO^3.2\frac{1}{2}H^2O$; and when immersed in hot water, yields a solution of the normal salt, and a residue consisting of $3CuO.SO^3.3H^2O$.

The *tetracupric salt*, $4CuO.SO^3.3H^2O = CuSO^4.3CuH^2O^2$, occurs native as *brochantite* (i. 664), in emerald-green rhombic prisms, at Ekaterinenberg in Siberia, at Retzhanya in Hungary, and at Krisuvig in Iceland (*krisuvigite*). It is produced artificially:—1. By precipitating a solution of blue vitriol with a quantity of potash just sufficient to render the liquid alkaline; it then falls as a light-blue precipitate containing 3 at. water if separated from concentrated, and 5 at. water if from dilute solutions (**J. Denham Smith**). Kuhn found this precipitate to contain 4 at. water, and observes that the complete precipitation of the copper from 1 at. normal cupric sulphate ($CuSO^4$) requires exactly $\frac{3}{4}$ at. potash (KHO). According to **Field** (Phil. Mag. [4] xxiv. 123), the tetrahydrated salt, $4CuO.SO^3.4H^2O$ or $CuSO^4.3CuH^2O^2.H^2O$, is precipitated as a shining green powder, when a small quantity of potash is added to a large excess of blue vitriol, the liquid boiled, and the precipitate thoroughly washed. The same composition is exhibited by brochantite from Acandallo in Chile: specific gravity = 3·81.—2. The same hydrate is obtained, according to **Vogel** and **Reischauer** (Jahresb. 1859, p. 215), by precipitating blue vitriol with an insufficient quantity of ammonia. If the ammonia is added in excess, the tetrabasic salt is likewise formed, but mixed with cupric hydrate, from which however it quickly separates in microscopic crystals, while the cupric hydrate is converted into oxide.—3. The tetrabasic salt is also formed, mixed however with cupric hydrate, when metallic copper is left in a solution of ammonium-sulphate exposed to the air. (**Vogel** and **Reischauer**.)—4. The tetracupric salt with $3\frac{1}{2}$ at. water $= 2(CuSO^4.3CuO).7H^2O = 2(CuSO^4.3CuH^2O^2).H^2O$, is formed on mixing a dilute solution of blue vitriol with the acetate of an alkali-metal, magnesium, manganese, cobalt, nickel, zinc, cadmium, or copper; thus with sodic acetate:

$$4CuSO^4 + 6C^2H^3NaO^2 + 3H^2O = CuSO^4.3CuO + 3Na^2SO^4 + 6C^2H^4O^2.$$

The precipitate, which forms slowly in the cold (or with the acetates of zinc, nickel, and cobalt, not at all), but immediately on boiling, is flocculent at first, but soon becomes granular; it has a fine green colour, nearly equal to that of Schweinfurt green, and is so nearly insoluble in boiling water that it is perceptibly formed in liquids containing only $\frac{1}{50,000}$ pt. of sodic acetate; in dilute acids, on the contrary (even in acetic acid), it is easily soluble, and somewhat soluble in cupric sulphate. By repeated evaporation with sodic acetate it is gradually decomposed, with deposition of black cupric oxide, and formation of a blue sodio-cupric acetate. Tetracupric sulphate is also formed on mixing boiling solutions of normal cupric sulphate and formate, propionate, or valerate of sodium, but not with glycollate or lactate of sodium, or with lactate of zinc; further by mixing a solution of cupric acetate (or formate, propionate, valerate, or lactate) heated to 95°, with a boiling-hot solution of a sulphate, or by boiling it with dilute sulphuric acid. With sodic sulphate the reaction is:

$$Na^2SO^4 + 4C^4H^6Cu''O^4 + 3H^2O = CuSO^4.3CuO + 2C^2H^3NaO^2 + 6C^2H^4O^2;$$

with cupric sulphate it is represented by the equation:

$$CuSO^4 + 3C^4H^6CuO^4 + 3H^2O = CuSO^4.3CuO + 6C^2H^4O^2.$$

In either case the mixture must be repeatedly evaporated to dryness to expel the acetic acid. (Casselmann, Zeitschr. Anal. Chem. iv. 24; Jahresb. 1865, p. 272.)

A *pentacupric salt*, $5CuO.SO^3.H^2O = CuSO^4.4CuO.H^2O$ [?], is obtained, according to Denham Smith, as a light-blue precipitate, by treating blue vitriol with a slight excess of potash, and washing, pressing, and drying it as quickly as possible.

An *octocupric salt*, $8CuO.SO^3.12H^2O$, is obtained, according to Kane, by adding caustic potash to a solution of blue vitriol till the copper is completely precipitated. It is described as a grass-green powder, which gives off 6 at. water at 150°, and the remainder at 260°. Neither Smith nor Kühn was able to prepare the octobasic salt by this process: the latter always obtained the tetracupric salt.

A still more highly basic sulphate (containing only 5 to 7 per cent. SO^3) is produced, according to Vogel and Reischauer, by diluting a solution of ammoniacal cupric sulphate with a large quantity of water; but it is perhaps only a mixture. Indeed, it is doubtful whether any cupric sulphate more basic than the tetracupric salt has been obtained as a definite compound.

Ammoniacal Cupric Sulphates.—A solution of cupric sulphate mixed with excess of ammonia, forms a deep blue liquid, which, on addition of alcohol, yields crystals of the compound $Cu''SO^4.4NH^3.H^2O$; and this, when heated to 149°, yields the salt $CuSO^4.2NH^3$, or $N^2H^6Cu''SO^4$, as an apple-green powder. Anhydrous cupric sulphate rapidly absorbs dry ammonia-gas, and forms a blue powder consisting of $CuSO^4.10NH^3$. (See COPPER-BASES, AMMONIACAL, ii. 80.)

Double Salts.—*Ammonio-cupric sulphate*, $Cu''(NH^4)^2(SO^4)^2.6H^2O$, crystallises by evaporation of the mixed solutions of its component salts, in blue easily soluble crystals (Mitscherlich).—The corresponding *potassium-salt*, $Cu''K^2(SO^4)^2.6H^2O$, crystallises by spontaneous evaporation, in large, regular, light-blue, monoclinic crystals (Mitscherlich). By heating the crystals, the anhydrous salt is obtained as a green friable mass, which melts at a red heat, giving off part of its acid (Vogel). When cooled after fusion, it solidifies in a blue crystalline mass, which soon decrepitates and falls to powder (Graham, Phil. Mag. [3] iv. 418). It dissolves easily in water, and the solution, when heated to 60°, deposits a light-green crystalline powder, consisting of a basic double salt, $\overset{''}{Cu}{}^3K^2(SO^4)^4.Cu''O.4H^2O$ (Brunner, Pogg. Ann. l. 43), from which water extracts sulphate of potassium, leaving tetracupric sulphate.

By mixing the solutions of the ammonio- and potassio-cupric salts just described with the corresponding double sulphates of cobalt, iron, magnesium, manganese, nickel, and zinc, complex salts are obtained, having a composition which may be illustrated by that of the magnesium-salts, viz.:

$$Cu''Mg''(NH^4)^4(SO^4)^4.12H^2O \text{ and } Cu''Mg''K^4(SO^4)^4.12H^2O.$$

All these salts crystallise in monoclinic prisms and tables, isomorphous with the magnesium double salts (p. 602). Further, by mixing the solutions of three or four of these double salts, other salts of still more complex constitution may be formed, but still isomorphous with the preceding: *e.g.*, $Cu''Mn''Mg''K^6(SO^4)^6.18H^2O$, $Cu''Zn''Mg''(NH^4)^6(SO^4)^6.18H^2O$, and the corresponding potassium-salt; also $Cu''Co''Zn''Mg''K^8(SO^4)^8.24H^2O$. (Vohl, Ann. Ch. Pharm. xciv. 57; Jahresb. 1855, p. 311.)

Cobaltoso-cupric sulphate, $Cu''Co''^2(SO^4)^3.36H^2O$, obtained by evaporating a mixed solution of the component salts, crystallises like sulphate of cobalt. (Liebig.)

Ferroso-cupric Sulphate, also called *Salzburg Vitriol*, *Adlervitriol*, *Cuprum sulphuricum medium*.—It has already been mentioned that ferrous and cupric sulphates, though they crystallise separately in different forms, and with different quantities of crystallisation-water, are nevertheless capable of crystallising together in the form of ferrous sulphate—the cupric, like the ferrous salt, then taking up 7 at. water. Such composite salts (not true double salts) are obtained in bluish-green crystals in the preparation of cupric sulphate from ferruginous materials. The proportion between the copper and iron is very variable. A common proportion is that represented by the formula $CuFe^2(SO^4)^3.21H^2O$. The so-called Salzburg vitriol, prepared at Buxweiler in Alsace, is (according to Lefort) $CuFe^2(SO^4)^4.28H^2O$. In Admont vitriol the quantity of iron is to that of copper as 5 : 1; in double Admont vitriol, as 4 : 1; in Bayreuth vitriol, as 7 : 1.

Magnesio-cupric sulphate, $CuMg(SO^4)^2.14H^2O$, crystallises by spontaneous evaporation, in beautiful sky-blue tables and prisms. (Vohl.)

Sodio-cupric sulphate, $Cu''Na^2(SO^4)^2.2H^2O$(?)—A solution of blue vitriol and Glauber's salt deposits each of the salts separately; a solution of blue vitriol and acid sodic sulphate also yields blue vitriol and Glauber's salt separately at first, but afterwards small crystals of the double salt, united into a crust, and apparently containing 2 at. water. The double salt is easily dehydrated, melts at a commencing red heat without losing acid, and on cooling solidifies to a blue mass, which does not decrepitate like the potassic double salt. The sodio-cupric salt deliquesces slowly in the air, and is resolved by water into the two simple salts. (Graham, Phil. Mag. [3], li. 352.)

Zinco-cupric sulphate, $Cu''Zn''^3(SO^4)^4.28H^2O$, improperly called *Cyprian vitriol*, is prepared at Chessy near Lyons, from zinciferous copper-ores, and crystallises in blue rhombic prisms. (Lefort, Compt. rend. xxvi. 185.)

β. *Cuprous sulphate*, $\acute{Cu}^2SO^4 = Cu^2O.SO^3$, is (according to Berzelius) the black powder which remains undissolved when copper is heated with strong sulphuric acid; it dissolves in nitric acid, with evolution of nitric oxide. According to Mène, on the other hand, this insoluble residue is a mixture of cuprous and cupric sulphide with cupric oxide.

Sulphate of Didymium, $Di''SO^4$, is obtained by dissolving the oxide or carbonate in dilute sulphuric acid. (For the methods of separating it from sulphate of lanthanum, see LANTHANUM, iii. 468.) The solution is rose-coloured, and yields, by spontaneous evaporation, dark rose-coloured shining crystals having the form of oblique rhomboïdal prisms (Mosander), and cleaving readily and distinctly in a direction parallel to the base. They contain $3DiSO^4.8H^2O$ (Marignac), and are isomorphous with the similarly constituted hydrated sulphates of cadmium and yttrium (Rammelsberg, Pogg. Ann. cxv. 579). At 200°, they give off the whole of their water, leaving an anhydrous powder, which may be heated to redness without further alteration. Sulphate of didymium is more soluble in cold than in hot water. Its solution when heated, especially to the boiling-point, deposits a crystalline precipitate, containing $DiSO^4.2H^2O$. The anhydrous sulphate dissolves in water more readily than either of the hydrates. The following table exhibits the quantities of anhydrous sulphate in 100 pts. of water, in solutions formed by dissolving the anhydrous sulphate and the two hydrates in water at different temperatures (Marignac):

	Quantity of anhydrous salt to 100 pts. water in solution of		
Temperature.	anhydrous salt.	$DiSO^4.2H^2O$.	$3DiSO^4.8H^2O$.
12° C.	43·1		
14	39·3		
18	25·8	16·4	
19			11·7
25	20·6		
38	13·0		
40			8·8
50	11·0		6.5
100			1.7

The anhydrous sulphate exposed to the heat of an intense charcoal-fire, gives off two-thirds of its acid, and leaves a *tribasic sulphate*, $3DiO.SO^3$, or $DiSO^4.2DiO$. (Marignac). The same salt is obtained as a light-bluish rose-coloured hydrate, $3DiO.SO^3.8H^2O$, by precipitating a solution of the neutral sulphate with excess of ammonia. (Hermann, Jahresb. 1861, p. 197.)

Sulphate of didymium forms double salts with the sulphates of the alkali-metals.—The *ammonium-salt*, $\overset{\prime\prime\prime}{Di}{}^2(NH^4)^2(SO^4)^4.8H^2O$, dissolves in 18 times its weight of water.—The *potassium-salt*, $\overset{\prime\prime\prime}{Di}{}^2K^2(SO^4)^4.2H^2O$, dissolves in 63 pts. of cold water.—The *sodium-salt*, $Di'''^2Na^2(SO^4)^4$, is anhydrous, requires 200 pts. of water to dissolve it, and is still less soluble in solution of sodic sulphate. (Marignac.)

Sulphate of Erbium has, according to Marignac (Jahresb. 1864, p. 198), the composition $3Eb''SO^4.8H^2O$, and is isomorphous with sulphate of didymium.

Sulphates of Glucinum.—The *neutral salt*, $G''SO^4.4H^2O$, or $\overset{\prime\prime\prime}{Be}{}^2(SO^4)^3.12H^2O$ (ii. 849), is obtained by dissolving glucina or its carbonate in a slight excess of cold sulphuric acid, and crystallises, by spontaneous evaporation, in large quadratic octahedrons. Alcohol precipitates it from solution as a crystalline powder. It is very soluble in pure water, somewhat less soluble in acidulated water, insoluble in absolute alcohol. According to Debray, water at 15° takes up nearly its own weight of the crystals. The crystals effloresce in warm air, melt with strong intumescence when heated, and leave a residue of pure glucina. At 35° they give off 4 at. water and crumble to powder; between 100° and 110°, they retain only 1 at. water, which is regarded by Weeren as constitutional water. The solubility of the salt is not much diminished by dehydration; it does not give off any acid at 150°—200° (Weeren).—A *tribasic sulphate*, $3G''O.SO^3 = G''SO^4.2G''O$, or $Be^2O^3.SO^3$, is obtained, as a gummy opaque mass, by boiling the solution of the neutral salt with glucinic carbonate, as long as carbonic dioxide is given off, and leaving the solution to evaporate without previous dilution. If, on the other hand, the solution be diluted before evaporation, it deposits a *hexbasic salt*, $6GO.SO^3.3H^2O$, or $2Be^2O^3.SO^3.3H^2O$, in the form of a white powder; and the liquid filtered therefrom yields on evaporation a gummy mass, consisting of the *dibasic salt*, $2G''O.SO^3$, or $2Be^2O^3.3SO^3$.

Sulphates of Iridium.—*Iridic sulphate*, $Ir^{iv}O^2.SO^3 = Ir^{iv}(SO^4)^2.Ir^{iv}O^2$, is obtained by dissolving sulphide of iridium in nitric acid, and driving off the excess of acid by heat, as a thick yellow syrup, exhibiting no signs of crystallisation. It dissolves easily in water and in alcohol, forming orange-yellow solutions, which are not precipitated by alkalis. On drying the salt, half the acid is expelled, and a more highly basic salt, $2IrO^2.SO^3$, remains.—*Iridious sulphate*, $Ir''SO^4$, is produced by dissolving iridious hydrate in sulphuric acid, and separates, on evaporation at a gentle heat, as a brownish-green, shining, amorphous mass, which dissolves in water with dark yellow-green colour.

Sulphates of Iron.—*a. Ferric Salts.*—The *normal* (or *neutral*) *salt*, $\overset{'''}{Fe}{}^2(SO^4)^3 = Fe^2O^3.3SO^3$, occurs as a hydrate containing 9 at. water, at Coquimbo in Chile, in six-sided pyramids, and as a fine-grained mass, forming a layer several feet thick (see COQUIMBITE, ii. 83). It is produced artificially by heating brown hæmatite for some time with strong sulphuric acid, and then expelling the excess of acid by a gentle heat;—or, more generally, by adding 1 at. sulphuric acid to a solution of 2 at. ferrous sulphate, and then adding nitric acid by small portions as long as nitrous vapours are evolved:

$$2Fe''SO^4 + H^2SO^4 + O = \overset{'''}{Fe}{}^2(SO^4)^3 + H^2O.$$

According to Levol, this salt (and not ferrous sulphate) is formed when metallic iron is heated with strong sulphuric acid.—According to Bussy and Lecanu, the white deposit, formed during the concentration of the acid in sulphuric acid works, consists almost wholly of ferric sulphate, formed most probably by the accidental dropping of ferruginous substances into the acid.—The *anhydrous salt*, $\overset{'''}{Fe}{}^2(SO^4)^3$, is formed, according to P. Hart, on introducing ferrous sulphate into boiling concentrated sulphuric acid, and separates on cooling in very small crystalline scales. The same salt is described by Ulrich (Jahresb. 1859, p. 211) as occurring in the platinum-vessel used for concentrating sulphuric acid, at the vitriol-works of Oker in the Harz, in small, shining, peachblossom-coloured spangles, appearing under the microscope as rhombic octahedrons with truncated summits.

The red solution of ferric sulphate, obtained as above, leaves on evaporation a light-yellow deliquescent mass, consisting of the hydrated salt, still retaining a slight excess of acid. In this state it redissolves easily in water, but if it be gently heated till the water and excess of acid are expelled, the remaining anhydrous salt dissolves but very slowly in water, forming a reddish-yellow solution. The anhydrous salt is also nearly insoluble in hydrochloric acid, and quite insoluble in strong sulphuric acid, which indeed precipitates it from its solution.—The anhydrous salt is decomposed at a red heat, and is recommended by Berzelius for the preparation of sulphuric anhydride by dry distillation.

Basic Ferric Sulphates.—The *sesquibasic salt*, $Fe^2O^3.2SO^3 = 2Fe^2(SO^4)^3.Fe^2O^3$, is obtained (according to Maus) by digesting a concentrated solution of the normal salt with ferric hydrate, as a dark-red solution, which on boiling, or on dilution with water, is resolved into the soluble normal salt and an insoluble basic salt. The same salt is formed (according to Wittstein, Rep. Pharm. [3], i. 185), by the action of the air on ferrous sulphate, and constitutes the yellow crust, $Fe^2O^3.2SO^3.H^2O$, with which the crystals of this salt become covered after a while. It is resolved by water into the neutral and the *dibasic salt*, $2Fe^2O^3.3SO^3.8H^2O = Fe^2(SO^4)^3.Fe^2O^3.8H^2O$. According to H. Rose, this dibasic salt occurs, together with coquimbite, in yellowish-green, silky, fibrous masses.—Another *basic salt*, containing $2Fe^2O^3.5SO^3.18H^2O$, likewise occurs encrusting coquimbite. (H. Rose.)

The *tribasic salt*, $Fe^2O^3.SO^3 = Fe^2(SO^4)^3.2Fe^2O^3$, is produced, as a reddish-yellow powder, containing about 3 at. water, by dissolving the basic double salt of potassic sulphate and sesquibasic ferric sulphate (p. 597) in water, and heating the solution. (Soubeiran.)

The *hexbasic salt*, $2Fe^2O^3.SO^3 = Fe^2(SO^4)^3.5Fe^2O^3$, is, (according to **Berzelius**) the yellow precipitate which gradually forms in a solution of ferrous sulphate exposed to the air, according to the equation:

$$10(FeO.SO^3) + O^5 = 2Fe^2O^3.SO^3 + 3(Fe^2O^3.3SO^3);$$

but the composition of the precipitate most probably varies with the concentration of the solution.

The *nonobasic salt*, $2(3Fe^2O^3.SO^3).9H^2O = 2[Fe^2(SO^4)^3.8Fe^2O^3].27H^2O$, separates (according to Scheerer) as a brownish-yellow deposit, on evaporating an oxidised solution of ferrous sulphate, or when a neutral solution of ferric sulphate is diluted with a large quantity of water and boiled; also (according to Berzelius,) when a solution of ferrous sulphate is mixed with chlorate of potassium.

A *dodecabasic salt*, $4Fe^2O^3.SO^3 = Fe^2(SO^4)^3.11Fe^2O^3$, is formed (according to Anthon) in preparing ferric acetate by decomposing acetate of barium with soluble basic ferric sulphate, being precipitated as a bulky brown powder, together with the last portions of baric sulphate, from which it may be separated by levigation.—Another basic salt, containing $2(7Fe^2O^3.SO^3).21H^2O$, is found (according to **Scheerer**) as a dark-brown amorphous mass, in the alum-slate of Modum in Norway.

Double Salts.—***Aluminio-ferric sulphate*** occurs native in the quicksilver mines of Idria, in yellowish-white crystalline masses, containing 37·0 per cent. SO^3, 8·4 Fe^2O^3, 11·5 Al^2O^3, 43·0 water, and 1·0 insoluble residue; which, if the two bases are regarded as isomorphous, may be represented by the formula $(Al^2O^3;Fe^2O^3).3SO^3.15H^2O$. (Fehling.)

Ammonio-ferric sulphate, or *Ammonia-iron-alum*, $Fe'''(NH^4)(SO^4)^2.12H^2O$, or $\left.\begin{matrix}Fe^2O^3.3SO^3\\(NH^4)^2O.SO^3\end{matrix}\right\}.24H^2O$, is produced by mixing the solutions of ammonic and ferric sulphates, adding a little free sulphuric acid, and leaving the solution to evaporate. It is more stable than the corresponding potassium-salt, and crystallises more readily than the latter, in large, colourless, regular octahedrons. It is prepared on the large scale, for use in dyeing, being always employed when a perfectly neutral ferric salt is required.

A *basic ammonio-ferric sulphate*, $\left.\begin{matrix}Fe^2O^3.2SO^3\\2[(NH^4)^2O.SO^3]\end{matrix}\right\}.6H^2O$, is prepared (according to **Maus**) in the same manner as the corresponding potassium-salt, which it resembles very closely in form and other properties. Marignac, however, found for the salt thus prepared the composition $3Fe^2O^3.5(NH^4)^2O.12SO^3.18H^2O$. Berzelius mentions another basic ammonio-ferric sulphate (composition not specified), which he obtained as an ochry precipitate on dissolving iron in dilute sulphuric acid mixed with a little nitric acid, the ammonia being produced by the mutual action of the nitric acid and the water.

Cuprico-ferric sulphate, $\overset{\prime\prime\prime}{Fe}{}^2Cu''(SO^4)^4.24H^2O$, separates from a mixture of the component salts in equivalent proportions, containing a slight excess of sulphuric acid, on evaporating till a crystalline film begins to form, in bluish-green, microscopic, warty crystallisations (Bastick).—The corresponding *magnesium-salt* forms a warty mass; the corresponding *zinc-salt* crystallises in colourless prisms. (**Bastick.**)

Potassio-ferric sulphate, or *Potash-iron-alum*, $Fe''K(SO^4)^2.12H^2O$, or $\left.\begin{matrix}Fe^2O^3.3SO^3\\K^2O.SO^3\end{matrix}\right\}.24H^2O$, separates from a slightly acid mixture of the component salts, by spontaneous evaporation, in octahedral crystals, which in form and taste are undistinguishable from common alum. They are sometimes colourless, but often have an amethyst tint, arising (according to Heintz) from a trace of ferric acid. The salt does not, however, crystallise so readily as ammonia-iron-alum. To obtain large crystals, **Heintz** (Ann. Ch. Pharm. xliv. 271) triturates 10 pts. of crystallised ferrous sulphate with 4 pts. of saltpetre, then gradually adds 4 pts. of strong sulphuric acid, and heats gently as long as nitrous vapours continue to escape. The residue is thus dissolved in 3 or 4 pts. of water at 80°, and the filtered solution is left to crystallise at a temperature which is very slowly lowered to 0°.

Potash-iron-alum is not very stable, soon becoming covered with a yellow powder when exposed to the air at temperatures above 0°. Between 80° and 100° it is resolved into a basic potassio-ferric sulphate, neutral ferric sulphate, and free sulphuric acid:

$$\begin{aligned}2[(Fe^2O^3.3SO^3).(K^2O.SO^3).24H^2O] &= [(Fe^2O^3.2SO^3).2(K^2O.SO^3]\\ &\quad + (Fe^2O^3.3SO^3) + H^2O.SO^3 + 47H^2O.\end{aligned}$$

The aqueous solution likewise decomposes in the same manner when heated to 80°; but after keeping for some time, especially on addition of free sulphuric acid, it again yields, by spontaneous evaporation, crystals of the normal double salt. A solution of iron-alum, mixed with a large quantity of free sulphuric acid, does not decompose when evaporated over the water-bath, but deposits crystalline crusts containing $2Fe'''K(SO^4)^2.3H^2O$, and, on further concentration, a white powder, composed of $2Fe'''K(SO^4)^2.H^2O$. (Heintz.)

If potash be added to a concentrated solution of ferric sulphate or iron-alum till the precipitate no longer redissolves, the filtered solution yields, by spontaneous evaporation, olive-green or yellow six-sided tables of the basic salt $(Fe^2O^3.2SO^3).2(K^2O.SO^3).6H^2O$ (Maus).—Another *basic double salt*, $3(Fe^2O^3.2SO^3).2(K^2O.SO^3).22H^2O$, is produced (according to Soubeiran) on dropping carbonate of potassium into a solution of ferric oxide till the precipitate begins to become permanent, and mixing the clear solution with alcohol.—A third *basic double salt*, $4(Fe^2O^3.SO^3).(K^2O.SO^3).9H^2O$, occurs (according to Rammelsberg) as an ochre-yellow insoluble mass, in the lignite of Kaloforuk in Bohemia. (Handw. d. Chem. vii. 528.)

A *basic sodio-ferric sulphate*, $4(Fe^2O^3.SO^3).(Na^2O.SO^3).9H^2O$, analogous to the last-mentioned potassium-salt, occurs, as a light-yellow stalactitic mass, in the alum-slate of Modum in Norway.

β. Ferrous Sulphate, $Fe''SO^4.7H^2O$. *Green Vitriol. Copperas. Couperose. Eisenvitriol.*—This salt occurs native, sometimes in crystals, but more frequently massive and pulverulent, at Goslar in the Harz, at Hurlet near Paisley, in several of the Saxon and Hungarian mines, and at various localities in the United States, being formed by the oxidation of iron-pyrites. It may be obtained pure by dissolving 1 pt. iron or 1½ pt. ferrous sulphide in 1½ pt. sulphuric acid diluted with 4 pts. water. The solution, if quickly filtered, deposits the salt in beautiful, transparent, bluish-green, crystals, containing 7 at. water. The large quantities of ferrous sulphate consumed in the arts are however prepared, simultaneously with alum, by the decomposition of aluminous schists containing iron-pyrites (p. 580).

Ferrous sulphate forms well-defined monoclinic crystals, of prismatic or tabular character (*figs.* 285, 287, 289, 294, 298, 299, 308, 309, and 310: CRYSTALLOGRAPHY, ii. 152—156). Axes, $a:b:c = 0\cdot8476:1:1\cdot267$. Angle $b:c = 75°\ 40'$; $\infty P : \infty P$ (orthod.) $= 97°\ 39'$; $[P\infty] : [P\infty]$ (clinod.) $= 69°\ 15'$; $+P\infty : c = 43°\ 32'$; $-P\infty : c = 32°\ 36'$; $-\frac{1}{3}P\infty : c = 55°\ 20'$; $oP : \infty P = 80°\ 37'$. Cleavage perfect parallel to oP; less distinct parallel to ∞P. It is isomorphous with the heptahydrated sulphates of magnesium, zinc, cobalt, nickel, copper, &c. (p. 578).

The crystals of ferrous sulphate effloresce slightly in dry air, and if at all moist, absorb oxygen, and become covered with a reddish-yellow crust of basic ferric sulphate (p. 596); but if crushed, and deprived of hygrometric moisture by strong pressure between folds of cotton-cloth or filter-paper, they may be preserved in a bottle without change from oxidation (Graham). Ferrous sulphate, precipitated from its aqueous solution by alcohol, forms a bluish-white powder, which does not absorb oxygen unless exposed to very moist air. Another method of preserving it is to mix the pulverised crystals with an equal weight of gum-arabic, dissolve the whole in distilled water, evaporate over the water-bath to the consistence of an extract, pour the still hot mass upon porcelain plates, complete the desiccation in an oven at 30°, and preserve the dried salt in closely-stoppered bottles. (Parvesi, J. Pharm. [4] iii. 40.)

Crystallised ferrous sulphate gives off 6 at. water at 114°, but retains the last atom even at 280°; by very careful heating, however, it may be rendered perfectly anhydrous without appreciable loss of acid. The anhydrous salt is also obtained, in very small crystalline scales, by immersing the hydrated crystals in strong boiling sulphuric acid, and leaving the liquid to cool. At a red heat it decomposes, giving off sulphurous oxide, and leaving a basic ferric sulphate, which, when more strongly heated, ultimately leaves pure ferric oxide, known as *Colcothar vitrioli* or *Caput mortuum*.

The salt was observed by Mitscherlich to crystallise at 80° from a solution saturated at the boiling heat, with 4 at. water, in monoclinic prisms, isomorphous with the corresponding sulphate of manganese. When its solution, containing an excess of acid, is evaporated by heat, a saline crust is deposited, which (according to Kühn) contains $3H^2O$. Lastly, a dihydrate, $Fe''SO^4.2H^2O$, having the crystalline form and sparing solubility of gypsum, is obtained (according to Mitscherlich), by dissolving the ordinary crystals in strong sulphuric acid. A solution of the salt mixed with excess of sulphuric acid, and left to evaporate in a vacuum, first deposits the ordinary heptahydrated crystals, then greenish-blue crystals of a pentahydrate, $Fe''SO^4.5H^2O$, belonging to the triclinic system, and lastly crystals of the tetrahydrated salt. (Marignac.)

Ferrous sulphate dissolves easily in water, but is insoluble in alcohol. According to Brandes and Firnhaber, 1 pt. of the heptahydrated salt dissolves in the following quantities of water at the particular temperatures indicated above each quantity:—

10°	14°	25°	32·5°	46°	60°	84°	90°	100° C.
1·64	1·43	0·87	0·66	0·44	0·38	0·37	0·27	0·30

The solution has a slight bluish-green tint, or is colourless if very dilute. When exposed for some time to the air, it deposits a yellowish sediment of basic ferric sulphate, which is used in porcelain-painting. As soon, however, as a certain quantity of this salt is deposited, the oxidation ceases, and the solution remains almost unaltered. The partially oxidised solution may be reconverted into pure ferrous sulphate by boiling with metallic iron.

The solution of ferrous sulphate absorbs nitric oxide gas, assuming a dark-brown colour, which affords a very characteristic test for nitric acid (iv. 83). The brown solution has a powerful attraction for oxygen: if heated in close vessels, it gives off the gas for the most part unchanged; but when it is heated in contact with air, nitric acid is formed in the liquid, and converts the ferrous into a ferric salt.

Ferrous sulphate is largely used in dyeing and in tanning, and for the manufacture of ink and Prussian-blue. It is also very useful as a reducing agent in chlorimetry and other operations of analytical chemistry.

Ferrous sulphate forms, with the sulphates of potassium and ammonium, double salts containing 6 at. water isomorphous with the corresponding salts formed by the sulphates of zinc, copper, manganese, &c. The formula of the potassium-salt is $Fe''K^2(SO^4)^2.6H^2O$. The solution of this salt evaporated at 50°, yields a crystalline crust containing $Fe''K^2(SO^4)^2.2H^2O$. (Marignac.)

Ferrico-ferrous (or *Ferroso-ferric*) *sulphate*, $\overset{''}{Fe}{}^2\overset{'''}{Fe}{}^2(SO^4)^4$. or $(Fe''O.SO^3).(Fe^2O^3.3SO^3)$, is produced when a solution of ferrous sulphate is exposed to the air, till no more basic ferric sulphate is deposited. The solution, which is yellowish-red, does not crystallise, but yields black oxide of iron when precipitated by an alkali (Berzelius). Abich obtained a crystalline ferroso-ferric sulphate, containing $(3FeO.SO^3).2(Fe^2O^3.3SO^3)4H^2O$, or $\overset{''}{Fe}{}^3\overset{'''}{Fe}{}^4(SO^4)^9.4H^2O$, by heating a moderately strong solution of 16 pts. pure crystallised ferrous sulphate to the boiling-point with an equal weight of strong sulphuric acid, then adding 1 pt. of strong nitric acid, and a concentrated solution of 5 or 6 pts. alum. This solution, evaporated at a temperature below 70°, deposits a dark-brown crystalline powder, the solution of which, in water acidulated with sulphuric acid, yields the salt on evaporation, in nearly black shining crystals, which are combinations of the cube and regular octahedron. According to Barreswil, a salt having the same composition as Abich's, but of a dark-blue colour, is formed by mixing the solutions of 3 at. ferrous and 2 at. ferric sulphate, and slowly dropping sulphuric acid into the liquid as long as any blue precipitate is produced (Handw. d. Chem. vii. 532).—A *basic ferroso-ferric sulphate*, containing $(3FeO.2SO^3).3(Fe^2O^3.2SO^3).36H^2O$, is found in the copper-mines of Fahlun, in large red stalactites composed of small transparent crystals. (Berzelius.)

Magnesio-ferrous sulphate, $Fe''Mg''(SO^4)^2 14H^2O$, crystallises from a solution of the component salts, by spontaneous evaporation, in large sea-green crystals. (Vohl.)

Sodio-ferrous sulphate, $Fe''Na^2(SO^4)^2.4H^2O$, obtained by evaporation at 55°, is permanent in the air, and does not decompose at 100°; but on redissolving it, and leaving the solution to evaporate, the sodic and ferrous salts crystallise out separately.

Thallio-ferrous sulphate, $Fe''Tl^2(SO^4)^2.6H^2O$, has a pale-green colour, and is isomorphous with the corresponding potassium-salt. (Werther.)

Zinco-ammonio-ferrous sulphate, $Fe''Zn''(NH^4)^4(SO^4)^4.12H^2O$, and the corresponding *potassium-salt*, crystallise readily in large, greenish, oblique rhombic prisms and tables, which turn yellow in the air, from absorption of oxygen.

Sulphate of Lanthanum, $La''SO^4$, is prepared as described under LANTHANUM (iii. 468), and separates by spontaneous evaporation in small prismatic crystals containing $La''SO^4.3H^2O$. It gives off its water at a low red heat, and half its acid at a full red heat. It is much less soluble in hot than in cold water.—*Ammonio-lanthanic sulphate*, $\overset{''}{La}{}^3(NH^4)^2(SO^4)^4.8H^2O$, is obtained, by spontaneous evaporation of a dilute solution of lanthanum-sulphate mixed with a slight excess of ammonium-sulphate, in colourless, sparingly soluble, monoclinic crystals. (Marignac.)

Potassio-lanthanic sulphate, $La''K^2(SO^4)^2$, is formed as a white precipitate on mixing the solution of a lanthanum-salt with sulphate of potassium. (Hermann, Jahresb. 1861, p. 194.)

Sulphate of Lead, $Pb''SO^4 = Pb''O.SO^3$.—This compound occurs native as *Anglesite*, in large and beautiful crystals, at Pary's mine in Anglesea, Leadhills in Scotland, Wanlockhead in Derbyshire, and at Clausthal, Zellerfield, and Giepenbach in the Harz; also in Prussia, in the Black Forest, at Badenweiler in the Breisgau, in the

Island of Sardinia, and in the United States; also massive in Siberia, in Andalusia, and on Alston Moor in Cumberland. In Algeria it occurs (according to Marcel de Serres, Compt. rend. liv. 743), in kidney-shaped lumps enclosing a nucleus of galena, by the oxidation of which it has been formed.

The crystals of anglesite are trimetric and isomorphous with those of heavy spar (iii. 137), exhibiting generally the same faces, but with $\infty \breve{P} 2$ mostly predominant. Axes, $a : b : c :$ = 0·6089 : 1 : 0·7756. Angle $\infty P : \infty P$ (macr.) = 62° 40′; $\infty\breve{P}2 : \infty\breve{P}2$ (macr.) = 101° 13′; $\breve{P}\infty : \breve{P}\infty$ (basal) = 75° 35′; $\bar{P}\infty : \bar{P}\infty$ (basal) = 103° 43′. Cleavage imperfect parallel to $\infty\breve{P}\infty$ and $\bar{P}\infty$. Hardness = 2·75 to 3. Specific gravity = 6·295 to 6·298. Lustre highly adamantine in some specimens, in others inclining to vitreous and resinous. Colour white, tinged with yellow, grey, green, and sometimes blue. Streak uncoloured. Transparent to opaque. Fracture conchoïdal. Very brittle.

Sulphate of lead also occurs, combined with carbonate of lead, as *Lanarkite* (iii. 467), and as *Leadhillite* (iii. 560); also, with carbonate of lead and carbonate of copper, as *Caledonite* (i. 372).

Sulphate of lead may be artificially crystallised by fusing chloride of lead with sulphate of potassium, and boiling out the soluble salts with water; it then remains as a heavy white crystalline powder, which, even under a low magnifying power, is seen to consist of tabular crystals having the form of the native sulphate (Manross). It is usually obtained, as a heavy white crystalline powder, by precipitating a soluble lead-salt with sulphuric acid or a soluble sulphate; and on the large scale, as a secondary product, in the preparation of aluminic acetate by precipitating alum with acetate of lead. It is also produced by oxidising sulphide of lead with strong nitric acid.

Sulphate of lead is nearly insoluble in pure *water*; according to Rodwell (Chem. News, xi. 50), 1 pt. of it dissolves in 31,062 pts. water at 15°; also in dilute *sulphuric acid*, somewhat more easily in strong sulphuric acid; also in *nitric* and *hydrochloric acids*. According to Rodwell (Chem. Soc. Qu. J. xv. 59), 1 pt. of lead-sulphate dissolves in the following quantities of hydrochloric and nitric acids of various strengths:—

Hydrochloric acid.	Specific gravity.	HCl per cent.	Nitric acid.	Specific gravity.	N^2O^5 per cent.
681·89	1·0519	10·602	303·10	1·079	11·55
281·73	1·0800	16·310	173·75	1·123	17·50
105·65	1·1070	22·010	127·48	1·250	34·00
47·30	1·1359	27·525	10282·78	1·420	60·00
35·03	1·1570	31·602			

On dilution, all the hydrochloric acid solutions, except the first, deposit needles of plumbic chloride. The nitric acid solutions yield by evaporation octahedrons of plumbic nitrate. The sulphate, digested for three or four days with nitric acid containing 60 per cent. N^2O^5, is almost wholly converted into octahedrons of the nitrate.

It is dissolved in larger quantity by some *ammoniacal salts—e.g.*, by the sulphate, nitrate, acetate, and tartrate, and easily by caustic potash or soda. When boiled with a strong solution of *potassic* or *sodic carbonate* (best with the acid carbonates), it is decomposed like sulphate of barium, yielding a solution of alkaline sulphate and a deposit of carbonate of lead. According to Löwe (Jahresb. 1859, p. 685), sulphate of lead dissolves in aqueous *hyposulphite of sodium*, in consequence of the formation of sodio-plumbic hyposulphite. This reaction may be rendered available for separating sulphate of lead from sulphate of barium. According to Field (Chem. Soc. Qu. J. xvi. 28), nitrate of lead produces no precipitate in a mixture of sodic sulphate and hyposulphite. According to Städel (Jahresb. 1863, p. 245), 1 pt. lead-sulphate dissolves in 12·2 pts. of *calcic acetate* (in very dilute solution). It is slightly soluble also in *triplumbic acetate*, insoluble in *diplumbic acetate*.

Sulphate of lead melts at a red heat, without decomposition, unless in contact with silica or clay. On *charcoal* before the blowpipe, it is reduced to metallic lead, with evolution of sulphurous oxide. The products obtained by heating it with charcoal vary, however, according to the proportions used: thus—

$$2PbSO^4 + C = 2PbO + CO^2 + 2SO^2$$
$$PbSO^4 + C = Pb + CO^2 + SO^2$$
$$PbSO^4 + C^4 = PbS + 4CO.$$

When heated with *sulphide of lead*, as in the process of lead-smelting (iii. 482), it yields metallic lead, or a mixture of the metal and the protoxide, with evolution of sulphurous oxide:

$$PbSO^4 + PbS = 2SO^2 + Pb^2$$
$$2PbSO^4 + PbS = 3SO^2 + 2PbO + Pb.$$

Heated to redness in a stream of *hydrogen*, it is reduced to metallic lead, according to the equation,

$$2PbSO^4 + 7H^2 = Pb^2 + SO^2 + H^2S + 6H^2O.$$

The reduction of the sulphate by *carbonic oxide* is much more difficult, and requires a much higher temperature; in consequence of which a portion of the sulphide of lead formed at first, as represented by the equation

$$2PbSO^4 + 6CO = Pb + PbS + SO^2 + 6CO^2,$$

acts upon the undecomposed sulphate as above, and thus complicates the reaction. (Rodwell, Chem. Soc. Qu. J. xvi. 42.)

Iron and *zinc*, in contact with water, reduce sulphate of lead to a spongy mass of metallic lead. When triturated with a solution of *potassic chromate*, it yields chrome-yellow. Like all other lead-salts, it is blackened by *sulphydric acid*.

Sulphate of lead, as commonly prepared, is not adapted for painting, on account of its crystalline character and transparency; but by mixing litharge to a paste, with water containing a small quantity of acetate of lead, and gradually adding sulphuric acid, the sulphate may be obtained in the amorphous state, and mixed with a large excess of oxide of lead. In this state it has considerable body, and may be used instead of ordinary white lead. (Richardson.)

A *basic sulphate of lead*, $2PbO.SO^3 = PbSO^4.PbO$, is obtained (according to Kühn) by digesting the recently precipitated normal sulphate with aqueous ammonia.

Ammonio-plumbic sulphate, $Pb''(NH^4)^2(SO^4)^2$, is produced by precipitating a moderately concentrated solution of plumbic acetate with excess of sulphuric acid, neutralising the liquid with ammonia, and heating it to the boiling-point. If a sufficient quantity of ammoniacal salt is present, the precipitate dissolves completely, and the solution on cooling deposits the double salt, in slender, shining, transparent crystals. If no crystals separate, the liquid must be again heated till a precipitate begins to form; the liquid will then deposit crystals on cooling. Water decomposes the double salts, extracting 39·4 per cent. ammonium-sulphate, and leaving 60·6 per cent. plumbic sulphate. The crystals when heated yield a sublimate of ammonium-sulphite. (Wöhler.)

A compound of *sulphate* and *chloride of lead* was obtained by Becquerel (Ann. Ch. Pharm. lxxxiv. 199), in needle-shaped crystals, together with other products, by the action of galena on a solution of cupric sulphate and sodic chloride, continued for seven years.

Sulphate of Lithium, $Li^2SO^4.H^2O$.—This salt may be prepared by decomposing the carbonate or chloride with sulphuric acid,—or, better (according to Fuchs), from triphyllin. 8 pts. of this mineral, finely pounded, are stirred up with 6 pts. of water; 3½ pts. of nitric acid (of specific gravity 1·20) and 1½ pts. of strong sulphuric acid are then added; the whole is evaporated to dryness; the dry mass exhausted with water; the solution precipitated with ammonia and sulphide of ammonium, and then with oxalate of ammonium; the filtrate evaporated to dryness; and the residue ignited. The aqueous solution of the residue yields the salt in crystals. Sulphate of lithium crystallises in flat prisms or tables containing 1 at. water. It melts easily, and dissolves in water and in alcohol. Respecting the expansion of the aqueous solution by heat, see Kremers (Jahresb. xiv. 61).

Potassio-lithic sulphate, $Li^2K^4(SO^4)^3$, forms crystals belonging to the hexagonal system (Schabus).—*Sodio-lithic sulphate* crystallises, (according to Mitscherlich) in acute rhombohedrons.

Sulphate of Magnesium, $Mg''SO^4.7H^2O$. *Bitter Salt. Epsom, Seidlitz*, or *Saidschütz Salt. Epsomite. Sal amarum, s. anglicum, s. catharticum.*—This salt is very widely diffused in nature, occurring sometimes in the solid state, but much more abundantly in solution in sea-water and saline springs. It occurs as *Epsomite*, or *Hair-salt*, in silky fibres and fibrous crusts, at Idria in Carniola, at the gypsum quarries of Montmartre near Paris, in Fitou, Dept. of the Aude (France), in Arragon and Catalonia, in the Cordillera of St. Juan in Chile, and in a grotto in South Africa, where it forms a layer 1½ inch thick. The floors of the limestone caves in Kentucky, Tennessee, and Indiana are in many instances covered with minute crystals of epsomite mingled with the earth. In the Mammoth Cave, Kentucky, it adheres to the roof in loose masses, like snowballs. It is said to occur also in California and at Marmora in Canada West. (Dana.)

A monohydrated sulphate of magnesium, called *Kieserite*, occurs, mixed with the anhydrous sulphite, in the salt-beds of Stassfurth, forming granular lumps.

Sulphate of magnesium constitutes the purgative principle of bitter-waters, as those of Epsom in Surrey, and of Seidlitz, Saidschütz, and Püllna in Bohemia. It is often produced by the mutual action of magnesic carbonate and gypsum, as when a solution of gypsum remains for a long time in contact with a magnesian limestone. At Saidschütz, Seidlitz, and Püllna it is obtained by digging pits in the marl; in these the bitter-water gradually collects, in consequence of the reaction just mentioned, and on subsequently leaving the water to evaporate in shallow pans, the sulphate of magnesium crystallises out.

Sulphate of magnesium is prepared in considerable quantities from sea-water and saline springs, either by precipitating the magnesia with lime, and then dissolving it in sulphuric acid; or by first crystallising out the greater part of the common salt, and then treating the mother-liquor, which contains chloride of magnesium, either with sulphuric acid or with ferrous sulphate, whereby sulphate of magnesium and ferrous chloride are obtained, the latter remaining in solution when the liquor is further evaporated, while the sulphate of magnesium crystallises out. Respecting Balard's improved process for obtaining sulphate of magnesium and chloride of potassium from the mother-liquors of sea-water, see POTASSIUM-SALTS (iv. 717); also Richardson and Watts's *Chemical Technology* (vol. i. pt. iii. pp. 157, 538).

Sulphate of magnesium is also produced in considerable quantities by treating native carbonate of magnesium or dolomite with sulphuric acid; the gypsum formed in the latter case, being much less soluble than the magnesian sulphate, is easily separated from it. Sometimes the dolomite is burnt, the lime dissolved out by pyroligneous acid, and the residual magnesia treated with sulphuric acid (Henry). Serpentine, which is composed of hydrate and silicate of magnesium, may also be used as a source of magnesic sulphate. In the neighbourhood of Genoa, the serpentine of the locality, which is intersected with veins of iron and copper pyrites, is roasted, then exposed to the air for a long time, and lixiviated. From the liquor thus obtained, the copper is precipitated by iron; the ferrous oxide is peroxidised by chlorine; the resulting ferric oxide is precipitated by burnt lime or dolomite; and the clarified solution, which contains sulphate of magnesium, is evaporated to the crystallising-point.

Sulphate of magnesium crystallises on cooling, from a hot moderately concentrated solution, in large, four-sided, right rhombic prisms, containing 7 at. water, and isomorphous with the heptahydrated sulphates of zinc and nickel, also with chromate of magnesium. The most common form is the combination $\infty P . \frac{P}{2}$—that is to say, a vertical prism terminated by dome-shaped summits placed in opposite directions above and below (*fig.* 281, ii. 150). Axes $a : b : c = 0·989 : 1 : 0·5703$. Angle $\infty P : \infty P = 89° 22'$. Cleavable parallel to $\infty\breve{P}\infty$. The commercial salt is usually crystallised in small needles, obtained by rapid crystallisation from a very strong solution. The crystals are not efflorescent, but the commercial salt sometimes becomes moist in contact with the air, from adhering chloride of magnesium.

A boiling concentrated solution, if transferred while still hot to a well-closed vessel, often remains liquid and in a state of supersaturation, for a long time after cooling; but if exposed to a low temperature, it solidifies entirely to a crystalline mass. Sometimes, however, such a solution, after keeping for weeks or months, deposits milk-white prisms containing 6 at. water, and sometimes crystals containing 7 at. water, but differing in form from the ordinary crystals (Löwel, Ann. Ch. Phys. [3], xliii. 405; Jahresb. 1855, p. 345). These heptahydrated crystals were formerly supposed, according to Marignac's determinations (Jahresb. 1857, p. 150), to be rhombohedral (oR . + R . + R . − 2R); but Kopp has shown (Ann. Ch. Pharm. cxxv. 369; Jahresb. 1863, p. 192) that they are monoclinic prisms $\infty P . oP . +P\infty$, rendered tabular by predominance of $+P\infty$. The heptahydrated salt appears, therefore, to be dimorphous, a property which is further illustrated by the existence of the monoclinic double salt, $Fe''Mg''(SO^4)^2.14H^2O$, or $Fe''SO^4.7H^2O + Mg''SO^4.7H^2O$, and others of similar composition (pp. 594, 598).

A solution of magnesic sulphate, concentrated till a crystalline film begins to form upon it, and then left to crystallise at 30°, deposits the hexhydrated salt, $Mg''SO^4.6H^2O$, in small monoclinic crystals, isomorphous with the corresponding hydrated sulphates of zinc and nickel. Axes, $a : b : c = 0·7123 : 1 : 1·1841$. Angle $b : c = 81° 26'$; $\infty P : \infty P$ (orthod.) $= 108° 28'$; $oP : \infty P = 85° 0'$. Ordinary combination, $oP . \infty P$, with $-P$, $+\frac{1}{2}P$ and $+2P$, &c. subordinate.—A solution, crystallised at a temperature several degrees below 0°, deposits (according to Fritzsche) large crystals containing 12 at. water, of which, however, 5 at. are given off as soon as the temperature rises to 0°.

The ordinary heptahydrated crystals melt in their water of crystallisation when heated, and give off 6 at. water at 150°, but retain the seventh atom even at 200°. This last atom of water, designated by Graham as "constitutional water," may be replaced by various salts, giving rise to double salts. The anhydrous salt is a white mass, which melts at a red heat, but is only partially decomposed at very high temperatures.

Sulphate of magnesium is very soluble in water. 100 pts. of water dissolve 25·76 pts. of the anhydrous salt at 0°, and 0·47816 pts. for every degree beyond (Gay-Lussac). One pt. of the heptahydrated salt dissolves in 0·790 pts. water at 18·75.

forming a liquid of specific gravity 1·2932 (Authon). The following table exhibits the quantities of magnesic sulphate contained in solutions of different specific gravities, as determined by Schiff (Ann. Ch. Pharm. cviii. 336):

Specific gravity at 23°.	Per cent. of $MgSO^4.7aq$.	Per cent. of $MgSO^4$.	Specific gravity at 23°.	Per cent. of $MgSO^4.7aq$	Per cent. of $MgSO^4$.

Sulphate of magnesium is insoluble in absolute alcohol, moderately soluble in hydrated alcohol. According to Schiff (Ann. Ch. Pharm. cxviii. 365):

A solution (saturated at 15°) in alcohol of:		Contains per cent. of
Specific Gravity	Per cent. by weight.	$MgSO^4aq$.
1·000	0	50·8
0·986	10	39·3
0·972	20	21·3
0·939	40	1·62

(See, further, Storer's *Dictionary of Solubilities*, vol. iii. pp. 609—612.)

Sulphate of magnesium may be used, in localities where it occurs native, as a substitute for sulphuric acid in the decomposition of common salt. When 2 pts. of the ordinary crystallised sulphate are heated with 1 pt. of common salt, hydrochloric acid is evolved, and a residue is obtained, consisting chiefly of sulphate of magnesium and sulphate of sodium (Ramon de Luna). Respecting Clemm's process for preparing sulphuric acid from kieserite, ($MgSO^4.H^2O$), or from common sulphate of magnesium, and for decomposing common salt and chloride of potassium with kieserite, see Richardson and Watts's *Chemical Technology*, vol. i. pt. v. p. 266. A mixture of common salt, peroxide of magnesia, and sulphate of magnesium may be used for the preparation of chlorine. (De Luna.)

An *acid sulphate of magnesium*, $Mg''H^2(SO^4)^2$, is produced by dissolving the anhydrous neutral sulphate in hot concentrated sulphuric acid. The perfectly saturated syrupy solution deposits the acid salt on standing, in shining six-sided tables, which, however, rapidly absorb water and are thereby decomposed. (Schiff, Ann. Ch. Pharm. cvi. 115.)

Double Salts.—Sulphate of magnesium unites with the sulphates of ammonium, potassium, and thallium, forming double salts, which contain 6 at. water, and, as already observed, may be regarded as formed from the heptahydrated sulphate by the substitution of 1 at. K^2SO^4, &c. for 1 at. H^2O. They crystallise in monoclinic prisms, isomorphous with the corresponding ferrous salts, &c. (pp. 593, 598). The several salts of this isomorphous group do not exhibit exactly the same angles, but the differences are but small. As an average, the ratio of the axes, $a : b : c = 1·4 : 1 : 0·67$. Angle

$b : c = 74° 30'$. The crystals generally exhibit the faces $\infty P . oP . + P . + 2P\infty . P\infty$; often also $[\infty P2]$ and $\infty P\infty$, but mostly subordinate; also $- P$, &c. They are usually prismatic in the direction of the principal axis, or tabular from predominance of oP; rarely pyramidal or rhombohedral.

Potassio-magnesic sulphate $Mg''K^2(SO^4)^2.6H^2O$, is obtained, as a secondary product, in the preparation of common salt from sea-water and brine-springs (iv. 717), separating from the mother-liquors when concentrated to 34° Baumé in large hard crystals, which may be purified by recrystallisation. It also separates from a solution of its component salts, by cooling or evaporation. It is nearly as soluble as sulphate of magnesium.

Sulphate of magnesium also unites directly with other heptahydrated sulphates of diatomic metals, forming salts containing $14H^2O$, which, as they are formed without replacement of any portion of the water by another salt, may for distinction be called coupled or composite salts (*gepaarte Salze*: Vohl)—*e.g.*, *Magnesio-ferrous sulphate*, $Mg''Fe''(SO^4)^2.14H^2O$. (p. 598); and these composite salts are further capable of uniting with alkaline sulphates, forming double salts in which 2 at. water out of the 14 are replaced by 2 at. of an alkaline sulphate—*e.g.*, $Mg''Cu''K^4(SO^4)^4.12H^2O$.

Potassio-ferroso-magnesic sulphate, $Mg''Fe''K^4(SO^4)^4.12H^2O$, and the corresponding *ammonium-salt* crystallise in large, greenish, oblique, rhombic prisms and tables, which turn yellow on exposure to the air. (Vohl.)

Potassio-calcio-magnesic sulphate, $Mg''\overset{\prime\prime}{Ca}{}^2K^2(SO^4)^4.2H^2O$, occurs in the salt-beds of Stassfurth, and other localities, forming the mineral called polyhalite (iv. 687, 718).

Sodio-magnesic sulphate, $Mg''Na^2(SO^4)^2.6H^2O$, separates in rhombohedral crystals, from the liquors obtained in the preparation of Epsom-salt. It dissolves in 3 pts. of cold water, is permanent in the air, decrepitates when heated, and gives off its water without melting. A sodio-magnesic sulphate with 8 at. water, is found (according to Munoz y Luna) in the form of efflorescences, on the bottoms of numerous lakes which dry up in summer, in the province of Toledo, between Madrid and the Mediterranean. It forms large, transparent, regular, prismatic crystals.

Sulphates of Manganese.—α. *Manganic Sulphate*, $\overset{\prime\prime\prime}{Mn}{}^2(SO^4)^3 = \overset{\prime\prime\prime}{Mn}{}^2O^3.3SO^3$.—This salt does not crystallise, and was formerly known only in solution; but, according to Carius, it may be obtained in the solid state by triturating very finely-divided manganic peroxide (prepared by passing chlorine into a solution of sodic carbonate in which manganous carbonate is suspended) to a thin paste with strong sulphuric acid, heating the mass very gradually to about 138° (at which temperature it exhibits a deep green colour), then placing it on a warm plate of pumice to absorb the excess of sulphuric acid, triturating it in a warm porcelain mortar with strong nitric acid, afterwards absorbing this acid by pumice, and repeating this treatment six or eight times—finally heating the mass in a porcelain dish to 130°, till all the nitric acid is driven off, and quickly transferring the product to dry glass vessels.

Manganic sulphate thus prepared is a deep green perfectly amorphous powder. It may be heated with sulphuric acid to the boiling-point of the latter without decomposition; but on continued boiling, it gives off oxygen, and gradually dissolves as manganous sulphate. It is insoluble in nitric acid; but strong hydrochloric acid dissolves it, forming a brown solution, which gives off chlorine when heated. It absorbs moisture rapidly from the air, and small quantities of it deliquesce instantly to a clear violet viscid solution, which, however, soon becomes turbid from separation of manganic hydrate. It is quickly decomposed by water, and by dilute acids. With organic bodies it reacts like a mixture of manganic peroxide and sulphuric acid, but much more quickly. When heated with a large quantity of sulphuric acid, and a small quantity of water, it is converted into a red-brown basic manganic sulphate. (Carius, Ann. Ch. Pharm. xcviii. 54.)

Manganic sulphate unites directly with the *sulphates of potassium and ammonium*, forming alums.—The *potassium-salt*, $Mn'''K(SO^4)^2.12H^2O$, obtained by mixing the concentrated red solution of manganic sulphate with a saturated solution of potassic sulphate, and evaporating to a syrup at a gentle heat, crystallises on cooling in dark-violet octahedrons. It is resolved by water into its component salts.—The *ammonium-salt* resembles it exactly in external appearance.

β. *Manganous sulphate*, $Mn''SO^4$, is occasionally found native together with ferrous sulphate and zinc-sulphate. It is prepared by dissolving manganous carbonate in dilute sulphuric acid, or by heating any of the higher oxides of manganese (generally the native peroxide) with strong sulphuric acid, till the evolution of oxygen ceases, and the mass has become dry. This residue, after being then strongly ignited to decompose the iron-salt present, yields, by lixiviation with water, a solution of manganous sulphate free from iron. A process, much used on the large scale, consists in igniting manganic peroxide in a gas retort with about one-tenth of its weight of pounded coal, and dissolving the manganous oxide thus obtained in sulphuric acid, adding a little hydrochloric acid at the last, to reduce any remaining portion of the higher oxides of manganese.

Manganous sulphate crystallises, though with some difficulty, from a solution evaporated and left to itself, the proportion of water contained in the crystals varying with the temperature at which they are deposited. Below + 6°, crystals are formed containing 7 at. water, and isomorphous with ordinary ferrous sulphate; but those deposited between 7° and 20° contain 5 at. water, and are isomorphous with cupric sulphate. The heptahydrated salt melts at 18°, and the liquid, if further evaporated, deposits a salt containing $2H^2O$. The heptahydrate effloresces in dry air at 10° to 12°, and is converted into the hexhydrate $MnSO^4.6H^2O$, which at 18° gives off 2 at. more of water, leaving the tetrahydrate. The heptahydrated salt covered with absolute alcohol, and exposed for some days to a temperature of 10°, is converted into a powder containing 5 at. water, but at 20° into a powder containing only 4 at. water (**Brandes**). Between 20° and 30° a solution of manganous sulphate yields the tetrahydrate $MnSO^4.4H^2O$, in monoclinic prisms, isomorphous with tetrahydrated ferrous sulphate, and exhibiting the combination, $\infty P . \infty P2 . [\infty P\infty]$, with oP and $[P\infty]$ at the ends. Axes, $a : b : c : = 1{\cdot}157 : 1 : 0{\cdot}6783$. Angle $b : c + 89° 7'$; $\infty P : \infty P$ (orthod.) $= 81° 40'$; $\infty P2 : \infty P2$ (orthod.) $= 46° 44'$; $[P\infty] : [P\infty]$ (basal) $= 119° 10'$; $oP : \infty P = 89° 20'$.—These crystals give off 3 at. water at 115°, but retain the last at 200°. According to Kühn, a strongly acid and concentrated solution of manganous sulphate yields, by evaporation, a granular salt containing 1 at. water. Of all these hydrates, that containing 4 at. water is of most frequent occurrence. The crystals of manganous sulphate are colourless, or have a faint amethyst-red tint, due probably to a trace of manganic salt. The anhydrous salt dissolves, according to Brandes, in 2 pts. water at 15°, and in 1 pt. at 50°; at higher temperatures it is more soluble.

It is insoluble in absolute alcohol, moderately soluble in weak spirit.

Ammonio-manganous sulphate, $Mn''(NH^4)^2(SO^4)^2.6H^2O$, prepared by mixing the solutions of the component salts, and evaporating, forms deliquescent monoclinic crystals, isomorphous with the corresponding magnesium-salt. (**Mitscherlich.**)

Potassio-manganous sulphate, $Mn''K^2(SO^4)^2.6H^2O$, is obtained (according to **Mitscherlich**,) in like manner, and crystallises in similar form. **Marignac**, on the other hand (Ann. Min. [5] ix. 1; Jahresb. 1856, p. 381), by mixing equivalent quantities of manganous sulphate and potassic sulphate, and evaporating the solution in a vacuum at 10° to 12°, or by cooling a solution saturated at ordinary temperatures to 0°, never obtained the hexhydrated salt, but always the tetrahydrate, $Mn''K^2(SO^4)^2.4H^2O$, in monoclinic crystals,—a result confirmed by v. **Hauer** (J. pr Chem. lxxiv. 431; Jahresb. 1858, p. 170). The tetrahydrated salt was also previously obtained by **Pierre** (Ann. Ch. Phys. [3], xvi. 239). The same solution, left for some time at 40° to 50°, yields pale-red triclinic crystals of the dihydrate $Mn\ K^2(SO^4)^2.2H^2O$. (**Marignac.**)

Sodio-manganous sulphate, $Mn'Na^2SO^4$, crystallises by spontaneous evaporation in monoclinic crystals, containing $4H^2O$; and at 40° to 50°, in triclinic crystals with 2 at. water. (**Marignac**, *loc. cit.*) The dihydrated salt was previously obtained in a similar manner by **Arrott** (Ann. Ch. Pharm. lii. 243). It is not efflorescent, and bears a temperature of 100° without decomposition.

Ammonio-ferroso-manganous sulphate, $Mn''Fe''(NH^4)^4(SO^4)^4.12H^2O$, and the corresponding *potassium-salt*, also the corresponding *zinco-manganous salts*, crystallise in monoclinic prisms and tables; the zinc-salts are colourless; the ferrous salts have a tinge of green, and oxidise on exposure to the air. (**Vohl.**)

Sulphates of Mercury.—*a. Mercuric Salts.*—The *neutral salt*, $Hg''SO^4$ or $Hg''O.SO^3$, is prepared by boiling 4 pts. of mercury with 5 pts. of strong sulphuric acid, till sulphurous oxide is no longer evolved, and the whole is converted into a dry saline mass; or by dissolving 2 pts. of finely pulverised mercuric oxide in 1 pt. sulphuric acid diluted with 4 to 6 pts. water, and evaporating with constant stirring. Eissfeldt obtained it, in crystals containing 1 at. water, by heating mercury with sulphuric acid, as above, till the mass no longer became moist on exposure to the air; then spreading it out in a thin layer, and just covering it with water; the hydrated salt then separated, in the course of an hour, in colourless quadratic prisms, several lines long. The 1 at. water is given off at 100°.

Mercuric sulphate has a sharp, saline, disgusting metallic taste. It bears an incipient red heat without alteration, but melts at a higher temperature to a brown liquid, and volatilises completely to a white crystalline sublimate—a small portion, however, suffering decomposition. When heated in hydrochloric acid gas, it is converted into mercuric chloride, and is decomposed in like manner by dry hydriodic and hydrocyanic acids. In the wet way it is decomposed by all hydracids. By water it is resolved into a soluble acid salt, and an insoluble basic salt.—The *acid salt*, $Hg''O.3SO^3 = Hg''SO^4.2SO^3$, is obtained, by evaporating the filtered solution, in white needle-shaped crystals which absorb moisture from the air.—The *basic salt*, $3Hg''O.SO^3 = Hg''SO^4.2Hg''O$, formerly called *mineral turpethum*, or *turbith mineral*, is prepared by boiling the neutral salt with water, or by precipitating a hot dilute solution of mercuric nitrate with sulphate of sodium. It forms a lemon-yellow powder, which turns grey on exposure to the air, is very slightly soluble in cold, somewhat more in hot water. When heated, it is resolved into mercuric oxide and the neutral salt.

Both the neutral and the basic sulphate are converted by aqueous ammonia into sulphate of tetramercurammonium, or ammoniacal turpethum, $(N^2Hg^4) SO^4.2H^2O$ (iii. 928).

Ammonio-mercuric sulphate, $3Hg''(NH^4)^2(SO^4)^2.2H^2O$ [?], obtained by mixing the solution of the component salts, is slightly soluble in water, more soluble in excess of ammonia, and crystallises in large, oblique, rhombic prisms, which blacken on exposure to light. It appears to be analogous in composition to the potassium-salt, but its analysis could not be made with accuracy, as the crystals were covered with a fine powder of ammoniacal turpethum. (Hirzel, Zeitschr. f. Pharm. 1850, p. 17; Jahresb. 1850, p. 332.)

Potassio-mercuric sulphate, $3Hg''K^2(SO^4)^2.2H^2O$, is produced by dissolving 1 pt. of dry mercuric sulphate in warm sulphuric acid, adding a solution of 1 pt. potassic sulphate, digesting till the whole is dissolved, and gradually adding boiling water till a permanent cloud just begins to form. By slow cooling, it crystallises in large, colourless, monoclinic prisms. (Hirzel.)

Mercuric sulphato-iodide, $Hg''SO^4.Hg''I^2$, is produced by dissolving mercuric iodide, with aid of heat, in concentrated sulphuric acid, and separates from the solution in white confused crystals, which may be washed with alcohol, but are decomposed by water. (Souville, J. Pharm. xxvi. 174.)

Mercuric sulphato-phosphide, $2(3Hg''O.SO^3).Hg^3P$, is obtained, by passing phosphoretted hydrogen-gas into a solution of mercuric sulphate containing free sulphuric acid, as a heavy white powder, which, after drying in a vacuum, contains 4 at. water, but becomes anhydrous and yellow when gently heated. It dissolves easily in nitromuriatic acid. (H. Rose, Pogg. Ann. xl. 75.)

Mercuric sulphato-sulphide, $2Hg''SO^4.Hg''S$, discovered by Rose, is produced, by imperfect precipitation of mercuric sulphate with sulphydric acid, as a white flocculent precipitate, acquiring a yellowish tinge when dried at 100°. (Jacobsen, Pogg. Ann. lxviii. 411.)

β. *Mercurous Sulphate*, $Hg^2SO^4 = Hg^2O.SO^3$, is obtained by heating 1 pt. of mercury with 1½ pt. strong sulphuric acid, till the whole is converted into a white powder, but no longer; care must also be taken that the heat does not rise to the boiling-point of the acid, as in that case mercuric sulphate will also be formed. The mass is to be washed with cold water, as long as the water acquires a sour taste. According to Mohr, it may be obtained as a sublimate, by heating mercuric sulphate to redness in a retort. It is also precipitated as a white crystalline powder, on mixing a solution of mercurous nitrate with sulphuric acid or sulphate of sodium.

Mercurous sulphate is sparingly soluble in water, requiring 500 pts. of cold and 300 pts. of warm water to dissolve it. It separates from the solution in rhombic prisms, also from solution in boiling dilute sulphuric acid. Caustic alkalis, added in small quantity to a boiling solution of this salt, throw down a basic mercurous sulphate; when added in excess, they precipitate pure mercurous oxide.

A *mercuroso-mercuric sulphate*, $Hg^2SO^4.2Hg''SO^4$, is produced, according to Brooke, by heating mercuroso-mercuric nitrate with sulphate of sodium. It is insoluble in cold water.

Sulphates of Molybdenum.—*Molybdous sulphate*, $Mo''SO^4 = MoO.SO^3$, prepared by dissolving molybdous hydrate in sulphuric acid, forms a nearly black solution. By triturating the dry hydrate with strong sulphuric acid, a pitch-black viscid compound is obtained, which is neutral if a sufficient quantity of the hydrate has been used. Water decomposes it into a soluble acid salt and an insoluble basic salt. (Berzelius.)

Molybdic sulphate, $Mo^{iv}(SO^4)^2$, $= MoO^2.2SO^4$ is produced by dissolving molybdic hydrate in sulphuric acid, or by decomposing molybdic chloride with that acid. It is red solution, black in the dry state, or blue if dried at a higher temperature. (Berzelius).

Permolybdic sulphate, $Mo^{vi}(SO^4)^3.2H^2O = Mo^{vi}O^3.3SO^3.2H^2O$, forms (according to Berzelius) a yellow solution, which dries up to a lemon-yellow mass. According to Anderson, it may be obtained in crystals, by decomposing molybdate of barium with excess of sulphuric acid, and evaporating the filtered solution in the exsiccator. It deliquesces on exposure to the air. On boiling the solution with excess of molybdic trioxide, the liquid becomes turbid, gelatinises on cooling, and deposits a light-yellow flocculent body, probably a basic salt, somewhat soluble in water, but insoluble in alcohol.

Sulphate of Nickel, $Ni''SO^4 = Ni''O.SO^3$, is obtained by dissolving metallic nickel in dilute sulphuric acid mixed with a little nitric acid, or by dissolving the hydrate or carbonate of nickel in dilute sulphuric acid. The solution, concentrated by evaporation, yields crystals containing 6 or 7 at. water, according to the temperature at which they separate. Below 15°, the salt $NiSO^4.7H^2O$ separates in emerald-green crystals, isomorphous with sulphate of magnesium; but between 15° and 20°, emerald-green, quadratic octahedral crystals are deposited, containing $Ni''SO^4.6H^2O$, exhibiting the combinations P . oP (*fig.* 228, ii. 136); P . ½P . oP (*fig.* 229); P . ½P . oP . P∞ (*fig.* 230); P . ½P . ⅓P . oP; also P . ½P . ⅓P . oP . P∞ . ∞P∞ (*fig.* 231), and ∞P∞ . P∞ . oP . P . ½P. Length of principal axis = 1·888. Angle P : P in the terminal edges = 97° 4′; in the lateral edges = 138° 56′; ½P : ½P (terminal) = 111° 4′ (lateral) = 106° 20′. Cleavage very distinct parallel to oP, less distinct parallel to ∞P∞. The former crystals, when exposed for some days to a gentle heat, are converted into aggregates of the latter, losing their transparency at the same time; sometimes also, when broken, they exhibit in their interior aggregates of the quadratic crystals (Mitscherlich). The hexhydrated salt is moreover dimorphous, a solution kept at a temperature of 50° to 70°, depositing monoclinic crystals with 6 at. water, and isomorphous with the 6-hydrated crystals of magnesic sulphate (p. 601), cobaltous sulphate, and zinc-sulphate. These crystals gradually become opaque and bluish at ordinary temperatures. (Marignac.)

Sulphate of nickel dissolves in 3 pts. of water at 10°, but is insoluble in alcohol and in ether. The crystals effloresce in dry air, and crumble to a white powder. When heated, they give off their water, the last atom being, however, retained more strongly than the rest. The anhydrous salt is yellow, and gives off part of its acid at a red heat.

A *basic nickel-sulphate* is obtained, as a light-green insoluble powder, by imperfect precipitation of the neutral salt with potash; also (according to Tupputi) by gently heating the neutral salt.

Ammoniacal Sulphates of Nickel.—Anhydrous sulphate of nickel absorbs ammonia-gas with rise of temperature, forming the pale-violet compound, $NiSO^4.6NH^3$ (H. Rose). A warm saturated solution of nickel-sulphate in aqueous ammonia, left to cool and evaporate in a vacuum, deposits (according to Erdmann,) light-blue prismatic crystals belonging to the trimetric system, and containing $NiSO^4.4NH^3.2H^2O$. This compound is very soluble in water, and is precipitated from the solution by alcohol. The solution is decomposed by boiling.

Sulphate of Nickel and Potassium, $Ni''K^2(SO^4)^2.6H^2O$, is a light-green salt forming crystals, isomorphous with the corresponding ferrous and magnesic salts, and exhibiting the combination ∞P . [∞P2] . [∞P∞]. oP . [P∞] . +P . +2P∞ (*fig.* 296, ii. 154), also without [∞P2] and [∞P∞] (*fig.* 297). It dissolves in 9 pts. of water. The corresponding *ammonium-salt,* $Ni''(NH^4)^2(SO^4)^2.6H^2O$, dissolves in 1⅛ pt. water.

Sulphate of Nickel and Zinc, $Ni''Zn''(SO^4)^2.6H^2O$, is formed (according to Mitscherlich) by digesting sulphate of nickel with metallic zinc, and separates on evaporation; in light-green efflorescent crystals, having the form of the 6-hydrated sulphate of nickel (which form ?).

The salt $Ni''Fe''K^4(SO^4)^4.12H^2O$, and the corresponding salts containing magnesium, manganese, or zinc in place of iron, and ammonium in place of potassium, crystallise in emerald-green prisms and tables, isomorphous with the salts of like composition already described. (Vohl.)

Sulphates of Osmium.—*Osmic sulphate,* $Os^{iv}(SO^4)^2 = OsO^2.2SO^3$, is produced by dissolving sulphide of osmium in excess of nitric acid, and remains after the excess of nitric acid and the osmic tetroxide simultaneously formed have been removed by distillation, as a dark yellowish-brown syrup, showing no tendency to crystallise. The yellow aqueous solution has an astringent taste, reddens litmus strongly, and is not precipitated by alkalis.—*Osmious sulphate,* $Os''SO^4$, obtained by treating sulphide of osmium with an insufficient quantity of nitric acid, or by dissolving osmious hydrate in dilute sulphuric acid, is a yellowish-brown amorphous mass.

Sulphates of Palladium.—The *neutral sulphate,* $Pd''SO^4$, is obtained, according to Kane, by dissolving palladium in sulphuric acid mixed with a little nitric acid. The solution, evaporated to a syrup, deposits the salt on cooling, in brown irregular crystals containing 2 at. water. It has a sour and metallic taste, deliquesces in moist air, and is decomposed by a large quantity of water.—A *basic salt,* $Pd''SO^4.7Pd''O.6H^2O$, is formed when a solution of the neutral salt in a small quantity of water is diluted with a large quantity, and separates as a brown powder, which, when exposed to the air in the dry state, gradually takes up 4 at. water. (Kane.)

Sulphate of Palladammonium, $N^2H^6Pd''.SO^4$. See PALLADIUM-BASES (iv. 329).

Sulphates of Platinum.—*Platinic sulphate*, $Pt^{iv}(SO^4)^2$, is prepared by dissolving recently precipitated sulphide of platinum in fuming nitric acid, and evaporating at a gentle heat (E. Davy); or by mixing a concentrated aqueous solution of platinic chloride with sulphuric acid, and evaporating to dryness (Berzelius). The dry salt is nearly black, the solution dark-brown. It is decomposed by sal-ammoniac when evaporated to dryness therewith. (E. Davy, Phil. Trans. 1820; Schw. J. xxxi. 340.)

Bario-platinic sulphate is formed, as a precipitate insoluble in water, on mixing a solution of platinic sulphate with chloride of barium. It dissolves in boiling hydrochloric acid, and is not decomposed by alkalis. (E. Davy, *loc. cit.*)

Potassio-platinic sulphate is formed, by boiling a solution of platinic sulphate with potash, as a dark-brown precipitate, which is insoluble in water, dissolves in hydrochloric acid at the boiling heat, turns black on drying, and decomposes at a red heat. (E. Davy.)

Sodio-platinic sulphate is a similar double salt, containing 7·11 per cent. sodic sulphate, 84·16 platinum, and 8·73 water. (E. Davy.)

Platinous sulphate, $Pt''SO^4$, is obtained by saturating as olution of platinous oxide in potash with sulphuric acid, decanting the liquid, and dissolving the precipitated oxide in dilute sulphuric acid (Berzelius); also by digesting platinous chloride with strong sulphuric acid, as long as hydrochloric acid is thereby eliminated (Vauquelin). The solution is dark-brown, turns red on dilution, and leaves a black syrup when evaporated.

Respecting the *ammoniacal sulphates of platinum*, see PLATINUM-BASES (iv 675–677).

Sulphates of Potassium.—*a*. *Normal* or *Neutral Sulphate*, $K^2SO^4 = K^2O.SO^3$. *Tartarus vitriolatus. Arcanum duplicatum. Sal polychrestum Glaseri. Sal de duobus. Specificum purgans Paracelsi. Panacea holsatica. Panacea duplicata. Nitrum vitriolatum. Spiritus vitrioli coagulabilis.*—This salt occurs native, in delicate needle-shaped crystals, or as a crust, on many of the Vesuvian lavas, and is designated mineralogically as *Glaserite, Arcanite, Aphthitalite, Aphthalose*, or *Vesuvian salt*. It exists more abundantly, however, in solution in sea-water and spring-water, and in the bodies of plants and animals. It is obtained as a bye-product in several manufacturing processes, as in the preparation of nitric acid from nitrate of potassium, the acid sulphate usually obtained as a residue of this operation being converted into neutral sulphate by addition of potassic carbonate. The quantity thus produced is, however, not so great at present as formerly, in consequence of the substitution of sodic for potassic nitrate as a source of nitric acid. Sulphate of potassium is also obtained when the residue left on treating crude potash with cold water (iv. 710) is dissolved in a small quantity of boiling water. It likewise crystallises out from the mother-liquors of sea-water and salt-springs, and of the liquors obtained by lixiviating kelp and varec, when these mother-liquors are left to cool at a certain stage of the concentration (iv. 713–719). According to Payen, 300,000 kilogrammes of this salt are annually obtained in France from varec. Further, it may be formed directly by heating a solution of chloride of potassium with kieserite, $MgSO^4.H^2O$, or ordinary sulphate of magnesium, under a pressure of 10 atmospheres (Clemm, Jahresb. 1864, p. 764); and from felspar by calcining that mineral with lime and sulphate of calcium or barium. (Tilghmann, iv. 719.)

Sulphate of potassium crystallises in four-sided prisms, or double six-sided pyramids, belonging to the trimetric system (*figs.* 269–275, CRYSTALLOGRAPHY, ii. 148, 149); also in twins like *fig.* 331 (ii. 162). Cleavage parallel to $\infty\breve{P}\infty$ and $\infty\bar{P}\infty$. Axes $a : b : c = 0·7464 : 1 : 0·5727$. Angle $P : P$ (brach.) $= 131° 8'$; $\infty P : \infty P$ (macr.) $= 73° 28'$; $\infty\breve{P}2 : \infty\breve{P}2 = 112° 22'$; $\breve{P}\infty : \breve{P}\infty$ (basal) $= 59° 36'$. The salt was formerly supposed, under certain circumstances, to form crystals belonging to the hexagonal system; but these crystals are now known to consist of sodio-potassic sulphate (p. 609). The crystals of potassic sulphate are colourless, very hard, anhydrous, and unalterable in the air; they decrepitate when heated, and melt at a bright red heat. Specific gravity = 2·662 (Kopp); 2·572. (Buignet.)

Sulphate of potassium has a saline bitter taste, and is one of the least soluble of potassium-salts. According to Kopp (Ann. Ch. Pharm. xxxiv. 361), 100 pts. of water dissolve 8·36 pts. of it at 0°, and 0·1741 pt. for every degree above 0°. According to Kremers (Pogg. Ann. xcv. 120), the specific gravity of the solution varies with its strength, as follows:

Specific gravity of aqueous solution at 19·5° (specific gravity of water at 19·5° = 1).	Quantity of K^2SO^4 in 100 pts. of solution.	Quantity of K^2SO^4 in 100 pts. of water.
1·0193	2·401	2·46
1·0385	4·744	4·98
1·0568	6·968	7·49
1·0763	9·264	10·21
1·0909	10·945	12·29

A saturated solution boils at 103°. (Kremers.)

Sulphate of potassium is insoluble in potash-ley of specific gravity 1·35 (Liebig), but more soluble in the aqueous solutions of other salts (as the sulphates of sodium, magnesium, and copper) than in puro water (Pfaff, Ann. Ch. Pharm. xcix. 227). It is insoluble in absolute alcohol, but soluble in dilute spirit. According to Schiff (Ann. Ch. Pharm. cxviii. 365):

A solution (saturated at 15°) in spirit of:		Contains per cent. of K^2SO^4.
Specific gravity.	Per cent. by weight.	
1·000	0	10·4
0·986	10	3·9
0·972	20	1·46
0·958	30	0·55
0·939	40	0·21

Most of the stronger acids abstract half the potash from neutral sulphate of potassium, and convert it into the acid sulphate.

With nitric and with phosphoric acid, however, it forms definite compounds. A solution of the salt in *nitric acid*, first deposits crystals of acid sulphate and nitrate of potassium, and afterwards the compound $K^2SO^4.HNO^3$, in oblique four-sided prisms, which have a specific gravity of 2·381, melt at 150°, and are decomposed by water and by alcohol. The compound $K^2SO^4.H^3PO^4$ crystallises, on cooling, from a solution of neutral potassic sulphate in *ordinary phosphoric acid*, in six-sided prisms, which have a specific gravity of 2·296, and melt at 240°. Both compounds are decomposed by water and by alcohol. (Jacquelain, Ann. Ch. Phys. [2], lxx. 311.)

β. Acid Sulphates.—Hydro-monopotassic sulphate, $KHSO^4$ or $K^2SO^4.H^2SO^4$, commonly called *Bisulphate of potash*, occurs native as *Misenite*, in white silky fibres, in the hot tufa cavern of Miseno near Naples. It may be produced by melting 13 pts. of the neutral sulphate with 8 pts. of strong sulphuric acid, and is obtained as residue in the preparation of nitric acid by distilling 1 at. nitrate of potassium with 1 at. sulphuric acid (iv. 78). It dissolves in about half its weight of boiling water, and crystallises from a concentrated solution on cooling, in rhombic octahedrons and combinations thereof, often very much like those of native sulphur. Axes $a : b : c$ = 0·8611 : 1 : 1·9347. Angle P : P (brach.) = 103° 36′; P : P (macr.) = 88° 12′; P : P (basal) = 142° 44′; P∞ : P∞ (basal) = 132·0; ½P∞ : ½P∞ = 96° 38′. The crystals often exhibt the simple form P (like *fig.* 260, ii. 144); often also oP . P, tabular from predominance of oP, and with the above-mentioned brachydiagonal domes subordinate. They have a specific gravity of 2·163, melt at 197°; and the fused salt solidifies on cooling in large monoclinic crystals, very much like those of felspar. The salt is therefore dimorphous. At higher temperatures it gives off water and afterwards sulphuric anhydride, leaving the neutral salt. It is decomposed by alcohol and by a large quantity of water into sulphuric acid and neutral potassic sulphate. It is often used in mineral analysis, especially for the decomposition by fusion of aluminous minerals, and of niobic and tantalic compounds.

Hydro-dipotassic sulphate, $K^4H^2(SO^4)^3 = 2K^2SO^4.H^2SO^4$ (sesquisulphate of potash), crystallises from a solution of the neutral sulphate in dilute sulphuric acid, together with the preceding salt, in asbestos-like threads (Phillips, Phil. Mag. i. 429). Jacquelain succeeded only once in preparing this salt.

Hydro-tripotassic sulphate, $K^3H(SO^4)^2$, or $3K^2SO^4.H^2SO^4$, is produced, according to Marignac (Jahresb. 1856, p. 320), by dissolving hydromonopotassic sulphate in excess of water, concentrating the solution by heat, till it yields a small quantity of crystals on cooling, then concentrating the mother-liquor again, and leaving it to crystallise, and so on. The solution then deposits, first the neutral sulphate, afterwards the hydrotripotassic, and finally the hydromonopotassic salt. The hydrotripotassic salt forms six-sided tables or acute rhombohedrons, both belonging to the monoclinic system.

γ. Anhydrosulphate, $K^2S^2O^7 = K^2SO^4.SO^3 = K^2O.2SO^3$ (anhydrous bisulphate of potash), is formed, according to Jacquelain (Ann. Ch. Phys. [2] lxx. 311) by dissolving 1 at. of the neutral salt and 1½ at. sulphuric acid in water, and leaving the solution to evaporate; also when the neutral salt is heated in a platinum-crucible with half its weight of sulphuric acid, till that acid is no longer given off at a commencing red heat. It crystallises in prismatic needles, of specific gravity 2·277, which melt at 210°. These crystals, when left immersed in water for several days, gradually disappear, and the solution yields large crystals of hydromonopotassic sulphate. The anhydrosulphate dissolves very easily in hot water, and crystallises unaltered on cooling, but is decomposed by a quantity of water larger than that required to dissolve it.

8. *Double Salts.—Sodio-tripotassic sulphate*, $K^3Na(SO^4)^2$, technically called *plato-sulphate of potash*, and formerly regarded as neutral sulphate of potassium, is deposited, on cooling, from the aqueous extract of kelp, when this liquid is concentrated to commencing crystallisation, and is obtained in cakes of greater thickness, by repeatedly pouring fresh quantities of warm saturated liquor on the separated salt. Its crystallisation, especially when the temperature of the liquid has sunk to 38°, is accompanied by vivid flashes of light, which may be increased by triturating the separated salt under the liquid, or by breaking the saline crusts formed on the surface, touching the warm saturated liquid with a crystalline mass already cooled, &c. On recrystallising it, however, no light is emitted (Penny, Phil. Mag. x. 401; Jahresb. 1855, p. 332). A solution of 1 at. Na^2SO^4 and 3 at. K^2SO^4 first deposits crystals of pure potassic sulphate, and afterwards crystals of the double salt (v. Hauer, Jahresb. 1860, p. 117). The crystals of this salt belong to the hexagonal system, exhibiting the tabular combination oR . R, or prismatic ∞R . oR . +R . −R (like *fig.* 240, ii. 139). For R, the length of the principal axis is 1·284. Angle R : R (terminal) = 88° 13′; for the pyramid composed of +R and −R, angle R : R (terminal) = 131° 2′; (basal) = 112° 0′. (Mitscherlich, Pogg. Ann. lviii. 468; v. Hauer, J. pr. Chem. lxxxiii. 356; Jahresb. 1861, p. 170.—Kopp's *Krystallographie*, 2te Aufl. 1862, p. 218.)

Sodio-pentapotassic sulphate, $K^5Na(SO^4)^3$, is produced, according to Gladstone, (Chem. Soc. Qu. J. vi. 106), by fusing the neutral or acid sulphate of potassium with common salt, or the neutral sulphate with sulphate of sodium. It crystallises from the hot solution in six-sided prisms with pyramidal summits.

Strontio-potassic sulphate, $Sr''K^2(SO^4)^2$, separates, according to H. Rose, in microscopic prisms, from a solution of the strontium-salt mixed with excess of neutral potassic sulphate.

Sulphate of Rhodium, $\overset{\prime\prime\prime}{Rh}{}^2(SO^4)^3 = Rh^2O^3.3SO^3$, is prepared by dissolving precipitated rhodium-sulphide in fuming nitric acid. It is a brown powder, soluble with red colour in water. (Berzelius.)

Potassio-rhodic sulphate is formed, according to Berzelius, when finely-divided rhodium is heated to low redness with acid sulphate of potassium. The cooled mass is yellow, or rarely rose-coloured, and dissolves in water, forming a yellow solution, from which alkalis and sulphydric acid throw down only part of the rhodium.—Another *potassio-rhodic sulphate*, probably $Rh'''K(SO^4)^2$, is obtained by treating potassio-rhodic chloride with sulphurous acid, and separates from the solution as a white powder, nearly insoluble in water, and only slightly soluble in sulphuric acid.

Sulphates of Rubidium.—The *anhydrosulphate*, $Rb^2S^2O^7 = Rb^2SO^4.SO^3$, melts, like the corresponding potassium-salt, at commencing redness, and when more strongly heated, gives off sulphuric anhydride, and is converted into the neutral salt Rb^2SO^4. The latter separates from aqueous solution in large, hard, vitreous crystals, isomorphous with sulphate of potassium, and exhibiting the combination P . 2P∞. Axes, $a : b : c = 0·5723 : 1 : 0·7522$. Angle P : P (brach.) = 131° 6′; P : P (macr.) = 87° 8′; P : P (basal) = 113° 6′; ∞P : ∞P (macr.) = 73° 54′; ∞P2 : ∞P2 (macr.) = 112° 46′; P∞ : P∞ (basal) = 59° 34′. The crystals are anhydrous, permanent in the air, decrepitate and become opaque when heated.

Sulphate of rubidium forms, with *sulphate of aluminium*, an alum containing $Al'''Rb(SO^4)^2.12H^2O$; and with the *sulphates of nickel, cobalt, magnesium*, &c., hexhydrated double salts, isomorphous with the corresponding potassium-compounds. (Kirchhoff and Bunsen, Pogg. Ann. cxv. 584; Jahresb. 1861, p. 177.)

Sulphate of Ruthenium, $Ru^{iv}(SO^4)^2 = RuO^2.2SO^3$, is obtained by the action of nitric acid on the sulphide of ruthenium precipitated from the trichloride by sulphydric acid. It forms an orange-yellow solution, which, when evaporated to dryness, leaves a yellow-brown, amorphous, deliquescent mass, having a sour astringent taste. The finely-divided dry powder resembles mosaic gold. The aqueous solution yields a yellow-brown precipitate with alkalis only on heating, and is coloured blue by sulphydric acid. (Claus.)

Sulphate of Silver, $Ag^2SO^4 = Ag^2O.SO^3$. *Silver-vitriol.*—This salt is produced either by dissolving silver in boiling sulphuric acid, or by precipitating a solution of the nitrate with sulphate of sodium. It is a white inodorous powder, having a disagreeable metallic taste, melts at a rather low temperature, and decomposes at a higher temperature, leaving metallic silver. When exposed to light, it gradually turns green. It dissolves in 200 pts. of cold and 88 pts. of boiling water, and crystallises on cooling in anhydrous shining needles. According to Mitscherlich, the best crystals are obtained by slow evaporation of a solution of the salt in nitric acid. They are trimetric and isomorphous with anhydrous sulphate of sodium, exhibiting the combination $P \,.\, \infty\breve{P}\infty \,.\, \infty P \,.\, \frac{1}{3}P$. Axes, $a : b : c = 0{\cdot}4614 : 1 : 0{\cdot}8078$. Angle $P : P$ (brach.) $= 136° 20'$; $P : P$ (macr.) $= 72° 32'$; $P : P$ (basal) $= 125° 11'$. Cleavage parallel to P and $\infty\breve{P}\infty$.

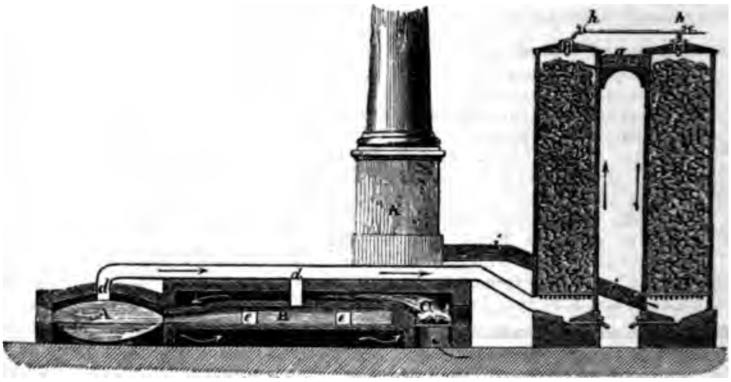
A *sulphato-sulphide of silver* is formed by digesting the sulphide with nitric acid, as a brown-yellow powder, which when boiled with excess of nitric acid, is completely converted into sulphate. Boiling water dissolves out the sulphate of silver and leaves the sulphide. (Berzelius.)

Sulphate of Argentammonium, $(NH^3Ag)^2SO^4$, is formed by saturating the dry sulphate with ammonia-gas (H. Rose). Mitscherlich obtained the compound $Ag^2SO^4.4NH^3 = [N^2H^4(NH^4)^2Ag^2]''(SO^4)$, by dissolving recently precipitated argentic sulphate in warm strong ammonia: it separated on cooling in colourless crystals, tolerably permanent in the air.

Silver-alum, $Al'''Ag(SO^4)^2.12H^2O$, has already been described.—A basic *argento-ferric sulphate*, $18(2Ag^2O.SO^3).(2Fe^2O^3.SO^3)$, is obtained, according to Lavini, by leaving a solution of argentic and ferric sulphates for some time in a closed vessel, and separates in rust-brown crystalline crusts, soluble in 100 pts. of water.

Sulphates of Sodium.—*a.* The *Normal* or *Neutral Salt*, $Na^2SO^4 = Na^2O.SO^3$. *Glauber's Salt. Sal mirabile Glauberi. Natrum sulphuricum crystallisatum.*—This salt was discovered and described in 1658 by Glauber, who prepared it from the residue obtained in the preparation of hydrochloric acid from common salt and sulphuric acid. It occurs rather abundantly in nature, either anhydrous, as *Thénardite*, crystallised in right rhombic prisms, or with 10 at. water, as Glauber's salt, in monoclinic prisms. Thénardite is found at Tarapaca in Peru, and at Espartinas near Madrid. Glauber's salt occurs in crystals, or more frequently in efflorescent crusts, at Ischl and Hallstadt in Austria; also in Hungary, Switzerland, Italy, &c.; it is abundantly deposited at the hot springs of Karlsbad; in large quantity also in a cavern in Hawaii, being formed by the action of volcanic heat and gases on salt-water; and effloresces with other salts in the limestone below the Genesee Falls, Rochester, New York; also near the Sweetwater river, Rocky Mountains. It occurs more abundantly in combination with calcic sulphate, as *glauberite* or *brongniartin* (ii. 845). Sulphate of sodium is also a constituent of seawater and of most brine springs, and exists in large quantity in many salt lakes of Russia, and in many mineral waters, as those of Karlsbad and Püllna.

FIG. 795.



Sulphate of sodium is prepared in enormous quantities by the action of sulphuric acid on common salt as a preliminary step in the manufacture of carbonate of sodium. The operation is performed in a reverberatory furnace connected with an apparatus for condensing the hydrochloric acid. One of the best forms of furnace is represented in *fig.* 795, the arrangement of the flues being, however, somewhat different.

A, the smaller of the two compartments which compose the furnace, is of cast iron;

In this (the *decomposer*) from 5 to 6 cwt. of common salt is introduced, and an equal weight of sulphuric acid (of specific gravity 1·6) is gradually mixed with it, a gentle heat being applied to the outside; enormous volumes of hydrochloric acid are disengaged, and pass off by the flue *d*, to the condensing towers E and F. These towers are filled with fragments of coke or stone, over which a continuous stream of water is caused to trickle slowly from *h h*. A steady current of air is drawn through the furnace and condensing towers, by connecting the first tower with the second, as shown at *g*, and the second tower with the main chimney (E) of the works. In the first bed of the furnace, about half the chlorine is expelled as hydrochloric acid from the common salt, and the pasty mass thence resulting is pushed through a door into the roaster, or second division (B) of the furnace. In this state it consists of a mixture of acid sodic sulphate and undecomposed sodic chloride:

$$2NaCl + H^2SO^4 = NaCl + NaHSO^4 + HCl.$$

In the second stage, a higher temperature is required, the acid sulphate then reacting on the unchanged chloride, in such a manner as to convert the whole of the sodium in to normal sulphate:

$$NaCl + NaHSO^4 = HCl + Na^2SO^4.$$

The fused sulphate of sodium thus obtained is called salt-cake. The hydrochloric acid gas, as it is liberated from B, passes through the flue *d*, and is carried on to the condensing towers. Heat is applied to the outside of the roaster B; the smoke and products of combustion circulate in separate flues round the chamber, in the direction indicated by the arrows, but never come into contact with the salt-cake in B. (Miller's *Elements of Chemistry*, 3rd edition, part ii. p. 420.)

For further details, see Richardson and Watts's *Chemical Technology*, vol. i. part. iii. pp. 204—215, and part v. pp. 235—244.

Sulphate of sodium is likewise obtained as a residue in many chemical operations as: (*a*) in the preparation of nitric acid with sulphuric acid and Chilè saltpetre; (*b*) of, sal-ammoniac from sulphate of ammonium and chloride of sodium; (*c*) of *magnesia alba* from sulphate of magnesium and carbonate of sodium.—(*d*) Considerable quantities are also obtained from the panstone and mother-liquors in the preparation of common salt from sea-water and salt-springs (p. 333). The panstone, which often consists mainly of a mixture of common salt and anhydrous calcio-sodic sulphate, is lixiviated with water, which dissolves out the sulphate of sodium; the non-saturated solutions are poured upon fresh panstone, and the saturated solutions into large receivers, in which the sulphate of sodium crystallises out in winter. From the mother-liquor of brine-springs and of sea-water, sulphate of sodium is separated by fractional crystallisation, the liquor being exposed during winter to a freezing temperature. The sulphate of sodium partly exists in these mother-liquors ready-formed, and is partly produced by the mutual action of the magnesic sulphate and sodic chloride contained in them, so that the mother-liquor left after the separation of the sodic sulphate contains chiefly chloride of magnesium. The crude salt is dissolved in water at 33°, and separates from the solution on cooling in large tolerably pure crystals (Richardson and Watts's *Chemical Technology*, vol. i. part iii. pp. 157, 545).—*e*. By the decomposition of ferrous sulphate with chloride of sodium, a mixture of these two salts depositing sulphate of sodium when exposed to a winter temperature. It may also be formed by heating iron-pyrites or green vitriol with common salt in a reverberatory furnace, hydrochloric acid then going off, and the iron being partly volatilised as chloride, partly remaining in the form of ferric oxide. At Fahlun, in Sweden, Glauber's salt is obtained from the mine-water, and from the mother-liquor of green vitriol, by mixing these liquids with the requisite quantity of common salt, evaporating to dryness, igniting, and dissolving the residue in hot water.

Sulphate of sodium is obtained, as an anhydrous mass, by leaving ordinary Glauber's salt (the decahydrate) to effloresce, or by heating it to redness, and in anhydrous crystals by heating a solution saturated at 33° to 40°, some degrees higher; according to Mitscherlich, it separates even at 40°. These crystals, which have the same form as thénardite, are rhombic octahedrons ismorphous with sulphate of silver, and with the selenates of sodium and silver, and exhibit the combination $P . \frac{1}{3}P . \infty P . \infty\breve{P}\infty$. Axes $a:b:c = 0{\cdot}4734 : 1 : 0{\cdot}8005$. Angle P : P (brach.) = 135° 41′; P : P (macr.) = 74° 18′; P : P (basal) = 123·43°. Cleavage parallel to P. and $\infty\breve{P}\infty$. The salt melts at a strong red heat to a thin liquid, and solidifies on cooling to a transparent crystalline mass. Specific gravity of the crystals = 2·73 (Cordier); 2·645 (Thomson); of the solid fused salt = 2·693 (Karsten; Schröder). By ignition with charcoal, it is converted into monosulphide of sodium.

Sulphate of sodium crystallises from solution at ordinary temperatures, in large, colourless, striated, monoclinic prisms, containing $Na^2SO^4.10H^2O$, and isomorphous with chromate and selenate of sodium containing corresponding quantities of water. Axes $a : b : c = 0·8962 : 1 : 1·109$. Angle $b : c = 72° 15'$; ∞P : ∞P (orthod.) = 93° 29′; [P∞] : [P∞] (clinod.) = 80° 38′; [2P∞] : [2P∞] (clinod.) = 45° 58′; +P∞ : c = 49° 50′; +½P∞ : c = 75° 19′; − ½P : c = 47° 56′; oP : ∞P = 77° 56′. The ordinary combination is ∞P . ∞P∞ . oP . [P∞]. +P. +P∞. The crystals are almost always prismatically elongated in the direction of the orthodiagonal, and cleave very distinctly parallel to ∞P∞. They effloresce readily on exposure to the air, melt in their water of crystallisation at 33°, and give off the whole of it below 100°.

The salt has a bitter and cooling taste, and is used as a purgative. 100 pts. of water dissolve 12 pts. of it at 0°; 48 pts. at 18°; 100 pts. at 25°; 322·6 pts. at 33°; 263 pts. at 50° (Gay-Lussac), and 244 pts. at 100° (Brandes and Firnhaber). Hence it appears that there is a maximum of solubility at about 34°.

When a solution saturated at the point of greatest solubility is left to cool in a closed vessel and at perfect rest, it remains supersaturated at ordinary temperatures, and does not crystallise; but on agitating it in contact with the air, or dropping a crystal of the salt into it, the whole solidifies, with rise of temperature, to a mass of crystals of ordinary Glauber's salt. If, however, the supersaturated solution be cooled below 12°, without agitation, crystals are sometimes formed containing 7 at. water and much harder than the decahydrated crystals. If now the temperature be again raised above 15°, or the crystals touched, they become milk-white, and are converted, with considerable rise of temperature, into a mixture of the anhydrous and the decahydrated salt. (Ziz; Faraday; Löwel.)

The heptahydrated salt, $Na^2SO^4.7H^2O$, crystallises in rhombic prisms, ∞P . ∞$\bar{P}$3 . ∞$\breve{P}$∞, terminated by the faces, $\breve{P}$∞ . ⅓$\breve{P}$∞. Axes $a : b : c = 0·955 : 1 : 0·966$. ∞P : ∞P (macr.) = 87° 20′ : ∞$\bar{P}$3 : ∞$\bar{P}$3 = 35° 18′; $\breve{P}$∞ : $\breve{P}$∞ (basal) = 88° 0′; ⅓P∞ : ⅓P∞ (basal) = 35° 40′.

According to Löwel (Ann. Ch. Phys. [3], xlix. 32; Jahresb. 1856, p. 321), sulphate of sodium may exist in solution in three different states—viz., as anhydrous salt, or as the ordinary decahydrate, or as the heptahydrate. When the ordinary decahydrated crystals are melted in their water of crystallisation, then heated till the liquid boils, and the vessel immediately closed, a crystalline powder of the anhydrous salt is deposited. If the liquid be frequently agitated as it cools, the anhydrous salt dissolves more and more, till the temperature has fallen to 18°. On further cooling, crystals of the salt $Na^2SO^4.7H^2O$ are deposited on the still undissolved residue, and below 18°, the anhydrous salt is gradually but completely converted into the heptahydrate. The solutions of the anhydrous sulphate remain as such at ordinary temperatures only in closed vessels; in contact with the air, or a crystal of Glauber's salt, they immediately deposit crystals of the decahydrated salt. The solubility of the anhydrous salt diminishes as the temperature rises; but that of the ordinary decahydrate increases up to about 34°, at which temperature it is converted into the anhydrous salt. At 34°, the decahydrated crystals gradually melt in their water of crystallisation. As long as the saturated liquid remains in contact with a large excess of the unaltered crystals, it retains an amount of salt corresponding to that in a solution of the decahydrated salt saturated at 34°—that is to say, 55 pts. of anhydrous salt to 100 pts. water. If, however, the fusion be continued further, the anhydrous salt begins to separate; and when all the crystals are fused, the solution ultimately contains 49·53 pts. of anhydrous salt to 100 pts. water, an amount corresponding to that of a solution of the anhydrous salt saturated at 34°. Hence the apparent maximum in the solubility of sodic sulphate at 34°, arises from the fact that the salt, under ordinary circumstances, dissolves in water up to the temperature of 34°, as $Na^2SO^4.10H^2O$, the solubility of which increases with the temperature; but above 34°, it dissolves as anhydrous salt, the solubility of which diminishes as the temperature rises up to 103·7°, the boiling-point of the saturated solution. (Löwel.)

Saturated solutions of the salt $Na^2SO^4.7H^2O$ are obtained, for higher temperatures, by removing, at a lower temperature, a portion of the mother-liquor which covers the crystals, and then warming the crystals with the rest of the liquid. When a liquid containing an excess of the crystals of this heptahydrate is heated to 27°, these crystals behave just like those of the decahydrate at 34°—that is to say, they melt, and the liquid deposits the anhydrous salt. (Löwel.)

The following table exhibits the variations of solubility of anhydrous sodic sulphate, and of the two hydrates; in the two latter cases, also, the quantity of anhydrous salt equivalent to the hydrated salt dissolved at each temperature is given:—

Quantities of Sodic Sulphate dissolved in 100 pts. of Water in the state of Saturated Solution.

Temperature.	Na^2SO^4, Anhydrous.	$Na^2SO^4 + 10H^2O$.		$Na^2SO^4 + 7H^2O$.	
		Anhydrous.	Hydrate.	Anhydrous.	Hydrate.
0°C.	. .	5·02	12·16	19·62	44·84
10	. .	9·00	23·04	30·49	78·90

70·61	44·35				
84·42	42·96				
103·17	42·65				

Sulphate of sodium is insoluble in alcohol, but somewhat soluble in dilute spirit; strong alcohol heated with the ordinary crystals, abstracts part of their water of crystallisation. According to Schiff (Ann. Ch. Pharm. cxviii. 365):

A solution (saturated at 15°) in alcohol of:		Contains per cent. of
Specific gravity.	Per cent by weight.	$Na^2SO^4.10H^2O$.
1·000	0	25·6
0·976	10	14·35
0·972	20	5·6
0·939	40	1·3

Alcohol precipitates it from the cold aqueous solution.—[On the solubility of sodic sulphate in various liquids, see further, Storer's *Dictionary of Solubilities*, iii. 623—628.]

Strong hydrochloric acid poured upon crystallised Glauber's salt, produces considerable depression of temperature.

β. Acid Sulphates of Sodium.—Hydro-monosodic sulphate, $NaHSO^4$ or $Na^2SO^4.H^2SO^4$, commonly called *hydrated bisulphate of soda*, is obtained, in large transparent triclinic crystals, by dissolving equivalent quantities of the neutral sulphate and sulphuric acid in water, and evaporating by heat. From a solution saturated at the boiling heat, it separates on cooling in oblique rhombic prisms containing 2 at. water, according to Mitscherlich, 3 at. according to Wittstein. The crystals, when exposed to the air, graduallly, absorb water without deliquescing, and are resolved into the neutral salt and free sulphuric acid. The same decomposition takes places on dissolving them in 4 pts. of hot water or pouring alcohol upon them.

Hydro-trisodic sulphate, $Na^3H(SO^4)^2$, is obtained, according to Mitscherlich, when the neutral sulphate is treated with half the quantity of sulphuric acid required to convert it into the preceding salts; it crystallises by evaporation in beautiful oblique rhombic prisms. H. Rose always obtained it from a solution of hydromonosodic sulphate, and in one preparation it was deposited in small crystals with a somewhat different amount of water. Its aqueous solution always yields crystals of neutral sodic sulphate with 2½ at. water (H. Rose). Mitscherlich sometimes also obtained crystals containing $Na^3H(SO^4)^2$.

The *anhydrosulphate*, $Na^2S^2O^7 = Na^2SO^4.SO^3 = Na^2O.2SO^3$, or *anhydrous bisulphate of soda*, is obtained by covering 1 at. of the dry neutral sulphate with 1 at. sulphuric acid, and heating till the mass fuses tranquilly at a low red heat. When heated to full redness, it gives off sulphuric anhydride (p. 569).

Sulphate of Strontium, $Sr''SO^4. = SrO.SO^3$, occurs native as cœlestin, sometimes in large trimetric crystals, sometimes sparry or fibrous (i. 1069.) Manross, by fusing sulphate of potassium with excess of chloride of strontium, obtained sulphate of strontium in crystals having the form and specific gravity of cœlestin. By precipitating a soluble strontium-salt with sulphuric acid, it is obtained as a white powder which, according to Fresenius, is soluble in 6,895 pts. of cold and 9,638 pts. of boiling water, but much less soluble in water containing hydrochloric or sulphuric acid, of which it requires 11,800 parts. The aqueous solution is used as a reagent for distinguishing barium from strontium (p. 436). According to H. Rose, sulphate of strontium dissolves very perceptibly in hydrochloric acid at ordinary temperatures. Water containing common salt dissolves it slowly but completely. Virck (Chem. Centr. 1862, p. 402) has determined the solubility of sulphate of strontium in certain saline solutions with the following results:—

Quantity of salt in solution.	Quantity of $SrSO^4$ dissolved.	Quantity of salt in solution.	Quantity of $SrSO^4$ dissolved.
NaCl 22·17	0·1811	$MgCl^2$ 13·63	0·2419
„ 15·54	0·2186	„ 4·03	0·2057
„ 8·44	0·1653	„ 1·59	0·1986
KCl 18·08	0·2513	$CaCl^2$ 33·70	0·1706
„ 12·54	0·1933	„ 16·51	0·1853
„ 8·22	0·1925	„ 8·67	0·1756

Sulphate of strontium melts to a vitreous mass at a strong red heat, and is reduced on charcoal before the blowpipe to sulphide of strontium. With an equivalent quantity of sodic carbonate, it forms an easily fusible mass, which, on cooling, becomes opaque, and like mother-of-pearl.

Sulphate of Tellurium, $Te^{iv}(SO^4)^2 = TeO^2.2SO^3$?—When pulverised tellurium is triturated to a thin paste with strong sulphuric acid, and the mass gently heated, it assumes a fine purple-red colour, arising, according to Magnus, from the solution of the tellurium as such, and not in the oxidised state. The purple colour remains as long as there is any liquid left, whilst the undissolved portion of the tellurium becomes oxidised at the expense of the sulphuric acid, and disappears as soon as all the acid is decomposed, the whole being then converted into a white mass. If this mass be gently heated till the excess of acid is just driven off, there remains a white, earthy, amorphous substance, which produces a sense of dryness on the tongue, and after a while a metallic taste. When heated it melts, gives off sulphuric anhydride, and leaves a yellow liquid, which solidifies on cooling to a transparent vitreous mass, consisting of a basic salt, which, when heated in an open crucible, gives off its sulphuric acid, and leaves opaque tellurous oxide. Sulphate of tellurium dissolves in warm hydrochloric or nitric acid, and crystallises therefrom in granules on cooling. Water decomposes it, dissolving out sulphuric acid with a small quantity of tellurium, and separating tellurous oxide (Magnus, Pogg. Ann. x. 491). See further Gmelin's *Handbook*, iv. 406.

Sulphate of Terbium, $3Tb''SO^4.8H^2O$, is isomorphous with sulphate of didymium (Delafontaine, Jahresb. 1864, p. 198; 1865, p. 179). According to Mosander, it effloresces at 50°; Delafontaine, however, only once observed an imperfectly crystallised specimen to effloresce completely at ordinary temperatures. (See TERBIUM.)

Sulphates of Thallium.—*a. Thallious sulphate*, $Tl^2SO^4 = Tl^2O.SO^3$, is obtained by evaporating a solution of the chloride or nitrate with sulphuric acid (Lamy), or by heating metallic thallium with sulphuric acid (Crookes). It is soluble in 21·1 pts. of water at 15° and in 5·4 pts. at 100° (Crookes), and crystallises from the solution in anhydrous rhombic prisms, isomorphous with sulphate of potassium, and exhibiting the combination $\infty\breve{P}\infty \,.\, \infty\breve{P}2 \,.\, \infty P \,.\, \infty\bar{P}\infty \,.\, P \,.\, \breve{P}\infty$; the crystals are prismatically elongated in the direction of the principal axis, and the faces $\infty\breve{P}\infty$ greatly predominate (v. Lang, Phil. Mag. [4] xxv. 348). In presence of sulphate of ammonium, it separates in long striated crystals resembling sulphocyanate of potassium. (Crookes, Chem. News, viii. 243.)

Thallious sulphate forms, with sulphate of potassium, the salt, $TlAl'''(SO^4)^2.12H^2O$, isomorphous with common alum (Lamy); and with the sulphates of magnesium, nickel, &c., double salts containing 6 at. water, and isomorphous with potassio-magnesic sulphate, &c. (G. Werther, Bull. Soc. Chim. [2] ii. 272; Jahresb. 1864, p. 248).—The *nickel-salt*, $Tl^2Ni''(SO^4)^2.6H^2O$, separates from a solution containing a slight excess of nickel-sulphate, in green prisms, which are permanent in the air, give off their water at 120°, and decompose at a red heat.—The *ferrous salt*, $Tl^2Fe''(SO^4)^2.6H^2O$, obtained in like manner, is pale-green; the *zinc-salt*, $Tl^2Zn''(SO^4)^2.6H^2O$, is colourless, and has a glassy lustre; the magnesium-salt, $Tl^2Mg''(SO^4)^2.6H^2O$, resembles it, but is more soluble.

β. Thallic sulphate, $\overset{'''}{Tl}{}^2(SO^4)^3.7H^2O = \overset{'''}{Tl}{}^2O^3.3SO^3.7H^2O$, separates by evaporation from a solution of thallic oxide in dilute sulphuric acid, in thin colourless laminæ, which are decomposed by water, even in the cold, with separation of brown thallic oxide. It gives off 6 at. water at 220°, and is reduced at a stronger heat to thallious sulphate. (Strecker, Ann. Ch. Pharm. cxxxv. 207.)

According to Willm (Ann. Ch. Phys. [4] ix. 5; Jahresb. 1865, p. 253), a solution of thallic oxide in moderately concentrated sulphuric acid, prepared with aid of heat, first deposits slender needles of the basic salt, $\mathrm{Tl^2O^3.2SO^3.5H^2O}$; afterwards a *thalloso-thallic sulphate*, in transparent prismatic crystals, together with an amorphous pulverulent salt containing $\mathrm{Tl^2O^3.2SO^3.3H^2O}$. A solution of thallious sulphate heated with baric or plumbic peroxide and sulphuric acid, then filtered and concentrated by evaporation, deposits crystals of anhydrous thallic sulphate, $\mathrm{Tl^2O^3.3SO^3}$. (Willm.)

Potassio-thallic sulphate, $\overset{'''}{\mathrm{Tl}}{}^2\mathrm{K^4(SO^4)^5} = \overset{''}{\mathrm{Tl}}{}^2\mathrm{(SO^4)^2.2K^2SO^4}$, separates, on mixing a solution of the preceding salt with a strong solution of potassic sulphate, as a hard, colourless, crystalline crust, which is coloured brown on the surface by water, and is but slightly soluble in dilute sulphuric acid.—*Sodio-thallic sulphate*, $\mathrm{Tl\,Na(SO^4)^2}$, is formed in like manner, and separates in colourless needles. (Strecker.)

Sulphate of Thornium, $\mathrm{Th^{iv}(SO^4)^2 = ThO^2.2SO^3}$.*—Obtained as a white powder by dissolving thorina in strong sulphuric acid and expelling the excess of acid by evaporation (Berzelius). Delafontaine (N. Arch. Ph. Nat. xviii. 343; Jahresb. 1863, p. 197) prepares it by mixing finely pulverised thorite or orangite with strong sulphuric acid to a semi-fluid paste (the mass becoming strongly heated, and part of the excess of acid volatilising), and heating the residue to 400°—500°, as long as acid fumes are evolved; then gradually introducing the dry and cooled mass into cold water, with constant stirring, and heating the filtered solution to 100°. The sulphate of thorinum then separates, and may be purified by repeated solution in cold water and precipitation by heat.

Sulphate of thorinum thus obtained is a heavy white curdy precipitate, made up of interlaced needles, and consisting, according to Delafontaine, of $\mathrm{2Th^{iv}(SO^4)^2.9H^2O}$. By slow evaporation of an aqueous solution at ordinary temperatures (10°—15°), a salt separates containing double this amount of water, viz., $\mathrm{Th^{iv}(SO^4)^2.9H^2O}$ (Delafontaine. Chydenius, Pogg. Ann. cxix. 48; Jahresb. 1863, p. 196). Berzelius, by spontaneous evaporation of a solution containing a little free sulphuric acid, obtained a hydrate containing 10 at. water, 6 at. of which were given off at a somewhat higher temperature, leaving the salt $\mathrm{Th^{iv}(SO^4)^2.4H^2O}$, which also separated from the solution on evaporation at higher temperatures. These two hydrates were probably the same as those above mentioned, containing 9 and 4½ at. water.

The hydrate, $\mathrm{Th(SO^4)^2.9H^2O}$, crystallises, according to Chydenius, in translucent, efflorescent, monoclinic prisms, exhibiting the combination $\infty P \,.\, [P\infty] \,.\, \infty P\infty \,.\, [\infty P\infty] \,.\, oP$. Axes, $a : b : c = 1 : 0{\cdot}5981 : 0{\cdot}6584$. Angle $b : c = 81° 50'$; $\infty P \,.\, \infty P$ (clinod.) $= 118° 50'$; $[P\infty] : [P\infty]$ (over the pole) $= 149° 25'$. Delafontaine, by leaving the salt precipitated from a hot solution, in contact with a quantity of water not sufficient to dissolve it, obtained six or eight-sided, pointed, monoclinic crystals, the composition of which is not stated, but which, according to Marignac's determinations, exhibit the same faces as those just described, with addition of $[8P\infty]$ and $[\infty P\infty]$ and nearly the same value of the angle $\infty P : \infty P$, viz. 119° 0'; also $oP : \infty P\infty = 98° 20'$; $\infty P : oP = 97° 6'$; $[P\infty] : oP = 124° 28'$; $[6P\infty] : oP = 96° 27'$; $[\infty P\infty] : oP = 94° 51'$. Hence they were probably also $\mathrm{Th(SO^4)^2.9H^2O}$.

A slightly acidulated aqueous solution of sulphate of thorinum yields, when boiled, a flocculent precipitate which redissolves on cooling, and contains $\mathrm{Th(SO^4)^2.3H^2O}$, or from somewhat dilute solutions, $\mathrm{Th(SO^4)^2.H^2O}$. The solution, evaporated at 25°, yields without formation of crystals, a white saline mass consisting of $\mathrm{Th(SO^4)^2.2H^2O}$. The 9-hydrated salt gives up half its water at 100°, and the rest at a stronger heat (at 400° to 450°, according to Delafontaine). The anhydrous salt hisses when dissolved in water (Chydenius). The salt is insoluble in alcohol, and gives off all its acid at a red heat (Berzelius).—A *basic salt* is obtained on adding ammonia to the solution of the neutral salt as long as any precipitate is formed.

Potassio-thorinic sulphate, $\mathrm{Th^{iv}K^4(SO^4)^4.2H^2O = Th^{iv}(SO^4)^2.2K^2SO^4.2H^2O}$, separates, according to Berzelius, as a crystalline powder, when a crust of potassic sulphate is suspended in a solution of thorinic sulphate. It is easily soluble in water, insoluble in alcohol and in sulphate of potassium. From a boiling aqueous solution, it crystallises on cooling in rectangular prisms, which give off their water at a gentle heat, but without disintegrating (Berzelius). According to Chydenius, the salt, $\mathrm{Th^{iv}K^8(SO^4)^6.2H^2O}$, separates in slender crystals when solid sulphate of potassium is immersed in a solution of thorinic sulphate at 60°—70°.

Sulphates of Tin.—*Stannic sulphate*, $\mathrm{Sn^{iv}(SO^4)^2 = Sn^{iv}O^2.2SO^3}$, is formed by dissolving stannic hydrate in sulphuric acid, or by heating tin with excess of the acid. It forms an acid uncrystallisable syrup.

---

* Th = 137.

Stannous sulphate, $Sn''SO^4 = Sn''O.SO^3$, is obtained, by heating an excess of tin with concentrated or slightly diluted sulphuric acid, as a saline mass, which dissolves with brown colour in boiling water, and separates in needle-shaped crystals on cooling; also in nacreous laminar crystals, by dissolving stannous hydrate in warm dilute sulphuric acid; and as a crystalline precipitate, by adding sulphuric acid to a concentrated solution of stannous chloride. The anhydrous salt is obtained by distilling stannous sulphide with mercuric oxide. It bears a red heat without decomposition, whereas the hydrated salt when ignited leaves a residue of stannic oxide. Stannous sulphate dissolves very easily in water, but the solution, after some time, deposits a white basic salt.

Potassio-stannous sulphate separates, on mixing a solution of stannous sulphate with sulphate of potassium in fine silky needles, containing $\acute{S}nK^2(SO^4)^2$, or $Sn''K^2(SO^4)^2$ (Marignac). A mixture of hot concentrated solutions of stannous chloride and sulphate of potassium, deposits the compound $4Sn''K^2(SO^4)^2.Sn''Cl^2$, in small, shining, hexagonal crystals, which may be recrystallised without decomposition. (Marignac.)

Sulphates of Titanium.—*Titanic sulphate*, $Ti^{iv}(SO^4)^2 = Ti^{iv}O^2.2SO^3$, is prepared by digesting finely pulverised titanic oxide with sulphuric acid diluted with half its weight of water till all the water is driven off. On expelling the excess of acid by a stronger heat, titanic sulphate remains as a saline mass, which dissolves completely in lukewarm water; the diluted solution, however, deposits titanic oxide when boiled (H. Rose). From a solution of acid potassic titanate in hydrochloric acid, sulphuric acid throws down a compound consisting of $9TiO^2.SO^3.9H^2O$ (H. Rose).—*Potassio-titanic sulphate*, $Ti^{iv}K^2(SO^4)^3$, is obtained, according to Warren (Jahresb. 1857, p. 175), in small sparingly soluble crystals, by fusing titanic oxide with acid sulphate of potassium, digesting the resulting vitreous mass with strong sulphuric acid, expelling the greater part of the latter by a gentle heat, and dissolving out the excess of acid potassic sulphate with water.

Titanous sulphate, $Ti^2O^3.3SO^3$, according to Ebelmen, is formed by dissolving trichloride of titanium in sulphuric acid, and separates on evaporating the solution in a vacuum over lime, in violet, deliquescent, crystalline masses. Its solution, when boiled, deposits titanic oxide.

Sulphate of Tungsten separates, on dropping a solution of alkaline tungstate into dilute sulphuric acid, as a heavy white precipitate, soluble in pure water.

Sulphates of Uranium.—*Uranic sulphate*, $U^2O^3.SO^3$, or *Sulphate of Uranyl*, $(U^2O^2)''SO^4$, is obtained by dissolving uranoso-uranic oxide in strong sulphuric acid, diluting the solution with water, and oxidising with nitric acid; also by decomposing a solution of uranic nitrate with sulphuric acid, expelling the excess of acid by heat, dissolving the residue in water, evaporating the solution to a syrup, and leaving it to crystallise. It forms small lemon-yellow prisms containing 3 at. water (Berzelius; Péligot); 3½ at. (Ebelmen). According to Berzelius, the salts $U^2O^3.2SO^3$ and $U^2O^3.3SO^3$, are obtained by dissolving the monosulphate in sulphuric acid; but Péligot denies their existence (see URANIUM).—Uranic sulphates of various composition, called *uranium-ochre* and *uranium-vitriol*, are found in small flattened monoclinic crystals, of a bright emerald-green colour, near Joachimsthal in Bohemia, also at Johanngeorgenstadt. (Rammelsberg's *Mineralchemie*, p. 279.)

Potassio-uranic sulphate, $(U^2O^2)''K^2(SO^4)^2.2H^2O$, forms lemon-yellow crystalline crusts, very soluble in water, and becoming anhydrous at 100°.—*Ammonio-uranic sulphate*, of similar composition, forms sparingly soluble, lemon-yellow prisms. There is also a crystalline *sodio-uranic sulphate*.—Basic *cupro-uranic sulphates*, called *uranium-green*, are found at Joachimsthal. (Rammelsberg's *Mineralchemie*, p. 295.)

Uranous sulphate, $U''SO^4 = U''O.SO^3$, may be prepared by dissolving uranoso-uranic oxide in hot oil of vitriol, diluting with water, and evaporating in a vacuum; or by dissolving hydrated uranous oxide in dilute sulphuric acid; or by decomposing a concentrated solution of uranous chloride with sulphuric acid. It crystallises with 2 and with 4 at. water.—A *dibasic uranous sulphate*, $U''SO^4.U''O.3H^2O$, is obtained by treating the normal salt with a large quantity of water; by exposing the alcoholic solution of that salt to the sun's rays; by careful addition of ammonia to its aqueous solution; and by boiling that solution with green uranoso-uranic oxide. It forms a light-green powder having a silky lustre.

Ammonio-uranous sulphate, $U''(NH^4)^2(SO^4)^2$, forms easily soluble, dark-green, warty groups of crystals: its solution, when heated, deposits a basic sulphate.

Potassio-uranic sulphate, $\acute{U}^2K^2(SO^4)^2.H^2O$, forms green, slightly soluble saline crusts.

Uranoso-uranic sulphate, $U''(U^2O^2)''(SO^4)^2$, obtained by dissolving uranoso-uranic oxide in warm oil of vitriol, and evaporating the excess of acid by heat, forms a light-green, soluble mass, which at a red heat gives off sulphurous anhydride, and is converted into uranic sulphite (Ebelmen, (Ann. Ch. Phys. v. 189). On the sulphates of uranium, see further Gmelin's *Handbook*, iv. 174.)

Sulphates of Vanadium.—*Vanadi sulphate*, $Vd^{vi}(SO^4)^3 = VdO^3.3SO^3$, is produced by dissolving vanadic oxide in hot sulphuric acid diluted with half its weight of water, and evaporating the excess of acid at as low a temperature as possible. It forms small red-brown crystalline scales, quickly deliquescing to a rusty-brown syrup, which is not rendered turbid either by water or by alcohol. The aqueous solution becomes turbid on boiling, and the liquid separated from the precipitate contains an *acid salt*, which dries up to a red syrup. A *basic salt*, $VdO^3.2SO^3$, formed by dissolving neutral vanadious sulphate in nitric acid, forms a red, deliquescent, soluble, saline mass (Berzelius). *Potassio-vanadic sulphate*, $Vd^{vi}K^2(SO^4)^4$, separates from a solution of potassic vanadate mixed with a little sulphuric acid, and left to evaporate, in yellow grains, composed of microscopic crystals. It is slightly soluble in water, insoluble in alcohol. (Berzelius.)

Vanadious sulphate, $Vd^{iv}(SO^4)^2 = VdO^2.2SO^3$, is prepared by dissolving the di- or tri-oxide of vanadium, obtained by igniting vanadate of ammonium, in sulphuric acid, and passing sulphurous acid gas through the solution, or heating it with oxalic acid, to complete the reduction of the vanadic tri-oxide. The solution, when evaporated, yields sky-blue crystals, probably consisting of an acid vanadious sulphate, which, when purified by washing with absolute alcohol, gradually swells up, and is converted into a loose sky-blue powder, consisting of the neutral salt. This salt, after being washed with alcohol, and dried over oil of vitriol, may be obtained in the crystalline form by allowing it to deliquesce, and then leaving it for some time in a dry atmosphere. It usually crystallises in groups of prisms, but sometimes in separate, short, rhombic prisms, having a fine blue colour, and consisting of $Vd^{iv}(SO^4)^2.4H^2O$. It dissolves very slowly in cold water, and when ignited, leaves vanadic tri-oxide (Berzelius). A *basic salt* is produced, according to Berzelius, by digesting a strong solution of the neutral sulphate with vanadious hydrate. It dries up to a blue transparent mass, which gives off water and turns brown at 100°. *Potassio-vanadious sulphate*, $Vd^{iv}K^2(SO^4)^3$, is a light blue gummy mass.

Sulphates of Yttrium. The *neutral sulphate*, $Y''SO^4$, crystallises very easily in small four- or six-sided, colourless, or faintly rose-coloured prisms, which do not effloresce, but remain transparent, even at 80°, but at higher temperatures give off water and become milk-white; they dissolve very slowly in water (Berzelius). A solution of yttria in sulphuric acid saturated in the cold, becomes turbid at 30°—40°, from separation of the sulphate, and at the boiling heat the whole is precipitated as a crystalline powder, containing $2Y''SO^4.5H^2O$; it has a faint reddish-colour, which it loses at 180°, together with its water of crystallisation. The anhydrous salt dissolves easily in cold water (Popp, Ann. Ch. Pharm. cxxxi. 179; Jahresb. 1864, p. 203). By evaporation over oil of vitriol at 6°—10°, crystalline crusts are obtained, consisting of $3Y''SO^4.8H^2O$, isomorphous with the corresponding hydrated sulphates of cadmium and didymium (Popp; Delafontaine, Jahresb. 1864, p. 198.) The anhydrous salt gives off $\frac{2}{3}$ of its sulphuric anhydride at a red heat, leaving the tribasic salt $3YO.SO^3 = Y''SO^4.2YO$; and by very strong and prolonged ignition, the whole of the sulphuric anhydride may be expelled, leaving pure yttria. The basic salt is likewise obtained by precipitating the neutral salt with ammonia. (Berzelius.)

Potassio-yttric sulphate, $Y''K^2(SO^4)^2$, is obtained, by evaporation of the solution of its component salts, as white crystalline crust (Berzelius); or by covering the solution with a layer of alcohol, in crystals, which, on exposure to the air, give off about 6 per cent. of water (Popp). The salt dissolves in 16 pts. of cold water, and in 10 pts. of a solution of potassic sulphate (Berzelius). The aqueous solution saturated in the cold, deposits sulphate of yttrium when heated. (Popp.)

Sulphate of yttrium may be combined by fusion with sulphate of sodium, but does not unite with sulphate of *magnesium*. (Popp.)

Sulphates of Zinc.—The *normal* or *neutral sulphate*, $Zn''SO^4$, also called *white vitriol* or *zinc-vitriol*, is produced by dissolving oxide or carbonate of zinc in dilute sulphuric acid; and on the large scale, by roasting the native sulphide, lixiviating with water, and concentrating the solution by addition of fresh roasted ore. It separates from solution at ordinary temperatures, in right rhombic prisms, containing $Zn''SO^4.7H^2O$, isomorphous with sulphate of magnesium, and exhibiting the combinations $\infty P . P$. (fig. 264, ii. 147), and $P . \bar{P}\infty . \infty P . \infty\breve{P}\infty$; also the hemihedral form $+\frac{P}{2} . -\frac{P}{2} . \infty P . \infty\breve{P}\infty$. (fig. 282, ii. 148). The crystals have a rough metallic taste, and effloresce slightly in dry air. Like the other heptahydrated magnesian sulphates, they give off 6 at. water at about 100°, but the seventh only at a higher temperature (about 260°); indeed it is difficult to obtain the salt perfectly anhydrous without loss of acid. At a bright red heat, the anhydrous salt is completely decomposed, leaving pure oxide of zinc.

The heptahydrated crystals dissolve in about 2⅓ pts. of cold, and in somewhat less than their own weight of boiling water; the solution has an acid reaction. According to Poggiale, 100 pts. of water dissolve at different temperatures the following quantities of zinc-sulphate:—

Temperature. C.	Crystallised $ZnSO^4.7H^2O$.	Anhydrous $ZnSO^4$.
10°	138·21	48·36
20°	161·50	53·10
30°	191·00	58·50
50°	263·80	68·75
100°	653·60	95·60

The salt is insoluble in absolute alcohol. According to Schröder (Ann. Ch. Pharm. cix. 45), a supersaturated solution of zinc-vitriol contained in a glass tube, closed by a plug of cotton-wool, deposits a modification of the heptahydrated salt more soluble than the ordinary salt. The supernatant liquid still remains supersaturated, and, in contact with the air, yields crystals of the ordinary salt, together with crystals of the more soluble modification.

A solution of zinc-sulphate left to crystallise at 30°, yields monoclinic hexhydrated crystals, $Zn''SO^4.6H^2O$, isomorphous with the corresponding magnesium- and nickel-salts. The same hydrate is obtained by heating the ordinary crystals to 52°. A *pentahydrated salt*, $Zn''SO^4.5H^2O$, is obtained, according to Kühn, by boiling the pulverised heptahydrated salt with alcohol of specific gravity 0·856. It also crystallises, according to Pierre and Schindler, from solution between 35° and 50°. A granular *dihydrate*, $Zn'SO^4.2H^2O$, is obtained by boiling the finely pulverised heptahydrate with absolute alcohol; it also separates on adding strong sulphuric acid to a concentrated solution of zinc-sulphate (Kühn). The *monohydrate*, $Zn''SO^4.H^2O$, remains when the heptahydrated salt is dried in the air at 100°, or in a vacuum over oil of vitriol at 20° (Schindler, Graham); it also separates in crystalline grains during the cooling of a boiling saturated solution of zinc-sulphate (Graham). It retains its water at 205°, but gives it up at 238°. (Graham.)

Sulphate of zinc is chiefly used in calico-printing. It also serves as an addition to oils in the manufacture of varnishes; for the preparation of many other zinc-compounds, as of zinc-white; and in medicine for the composition of eye-washes, &c.

Basic Zinc-sulphates.—The *dibasic salt*, $2ZnO.SO^3 = Zn''SO^4.Zn''O$, is produced by digesting a strong solution of zinc-vitriol with oxide or hydrate of zinc as long as anything is dissolved: it does not crystallise (Schindler).—The *tetrabasic salt*, $4Zn''O.SO^3 = Zn''SO^4.3Zn''O$, crystallises from a solution of the preceding by spontaneous evaporation in long flexible needles, containing 10 at. water (Schindler). The same salt is precipitated on adding a small quantity of potash to the solution of the neutral sulphate, as a white bulky powder insoluble in cold water, and separates from a boiling aqueous solution on cooling, in small unctuous crystals, which, according to Kane, contain 2 at. water. It is also formed by heating the neutral sulphate till it is partially decomposed, and boiling the residue with water, or by boiling a solution of the neutral sulphate with zinc-oxide or metallic zinc; in that case also the solution, on cooling, deposits the dihydrated compound $Zn''SO^4.3Zn''O.2H^2O$. (Kühn, Schindler.)

The *hexbasic salt*, $6Zn''O.SO^3.10H^2O = Zn''SO^4.5Zn''O.10H^2O$, is obtained, according to Kane, as a white powder, by treating sulphate of zinc-ammonium with water.—The *octobasic salt*, $8Zn''O.SO^3.2H^2O = Zn''SO^4.7Zn''O.2H^2O$, is precipitated in white bulky flocks on diluting a solution of the dibasic salt with a large quantity of water. The precipitates formed by caustic potash in a solution of zinc-vitriol, are basic salts, varying in composition according to the quantity of alkali used.

All these basic zinc-sulphates, when heated nearly to redness, give off their chemically combined water, without change of appearance; but at a bright red heat, they are decomposed in such a manner that water afterwards extracts from them the neutral salt, leaving zinc-oxide.

Ammoniacal Sulphates of Zinc.—There are several of these compounds, varying in composition according to the quantity of ammonia added to the sulphate of zinc. When ammonia-gas is passed into a hot saturated solution of neutral zinc-sulphate till the precipitate at first formed is redissolved, *sulphate of zinc-ammonium*, $Zn''SO^4.2NH^3.H^2O = (N^2H^6Zn)''SO^4.H^2O$, separates on cooling in fine semi-crystalline starch-like granules. The water may be expelled by prolonged fusion. If the ammoniacal solution just mentioned be left to evaporate at ordinary temperatures, it yields crystals of the compound $Zn''SO^4.4NH^3.4H^2O$ or $[N^2.H^4(NH^4)^2Zn]''SO^4.4H^2O$, which give off 2 at. water in drying, and quickly effloresce. Above 27° they give off another atom of water, leaving the compound $Zn''SO^4.4NH^3.H^2O$; and this when carefully melted yields a gummy mass of zincammonium-sulphate, $Zn''SO^4.2NH^3.H^2O$, and ultimately the same compound in the anhydrous state (Kane). The compound, $Zn''SO^4.5NH^3$, is produced by the action of dry ammonia-gas on zinc sulphate, and forms a white powder which is dissolved by water with partial separation of zinc-oxide (H. Rose).—When zinc-sulphate supersaturated while hot with ammonia, is boiled till the odour of free ammonia is no longer perceptible, a precipitate is formed, consisting of $(4ZnO.SO^3).4NH^3.4H^2O$. (Schindler.)

Double Salts.—*Ammonio-zincic sulphate*, $Zn(\overset{''}{N}H^4)^2(SO^4)^2.6H^2O$, and the corresponding *potassium-salt*, are isomorphous with the corresponding magnesium-salts.

Sodio-zincic sulphate, $Zn''Na^2(SO^4)^2.4H^2O$, is produced, according to Graham, by mixing the concentrated solutions of zinc-sulphate and acid sodic sulphate, and evaporating to the crystallising point. It is very deliquescent.

Magnesio-zincic sulphate, $Zn''Mg''(SO^4)^2.14H^2O$, crystallises, according to Pierre, at ordinary temperatures, in fine rhombic prisms; it retains 2 at. water at 200°. The salt crystallised above 35° contains only 10 at. water.

Zinco-aluminic sulphate or *zinc-alum* is analogous in composition to common alum. (Kane.)

Sulphates of Zirconium.—The *neutral* or *normal sulphate*, $Zr^{iv}(SO^4)^2 = Zr^{iv}O^2.2SO^3$, is obtained by dissolving oxide or hydrate of zirconium, free from potash, in an excess of sulphuric acid; evaporating the solution to dryness; and heating the residue for a quarter of an hour to a temperature just below redness. The salt loses the whole of its acid at a full red heat. A neutral solution of the salt yields on evaporation, a gummy mass, which, when further dried, becomes white and full of fissures. If, however, the solution contains free acid, hydrated crystals are obtained, which may be freed from adhering acid by means of alcohol. The crystals fuse when heated, giving off their water, and swelling up like alum.

The anhydrous salt dissolves very slowly but completely in cold, and rapidly in hot water. Ammonia added in excess to the solution, precipitates pure zirconia free from sulphuric acid. Alcohol throws down a mixture of the normal and tribasic sulphates, which, after being washed for a considerable time with alcohol, is entirely converted into the tribasic sulphate. (Berzelius.)

The *dibasic sulphate*, $Zr^{iv}O^2.SO^3 = Zr^{iv}(SO^4)^2.Zn^{iv}O^2$, is formed by, saturating a concentrated solution of the normal salt with hydrate of zirconium. On evaporating the liquid, a mass of salt is obtained which is gummy and fissured at first, but when further dried becomes white and opaque. The salt, when heated, swells up like alum, and parts with its water, but a white heat is required to expel the acid. It dissolves in a very small quantity of water. By a larger addition of water, the solution is resolved into the tribasic salt, which is precipitated, and the normal salt, which remains in solution. (Berzelius.)

The *tribasic sulphate*, $3ZrO^2.2SO^3 = Zr(SO^4)^2.2ZrO^2$, is obtained by precipitating the normal salt with alcohol, and washing the precipitate first with alcohol and then with water; or by diluting a solution of the dibasic salt with a large quantity of water. It forms white flakes, insoluble in water, but soluble in hydrochloric acid. (Berzelius.)

A *hexbasic salt*, $3ZrO^2.SO^3 = Zn(SO^4)^2.5ZnO^3$, is produced by saturating a solution of a zirconium-salt at the boiling heat with sulphate of potassium, or by mixing the zirconium-solution with a hot saturated solution of sulphate of potassium. It separates as a white precipitate, and by saturating the supernatant liquid with carbonate of potassium, the whole of the zirconium may be brought into the precipitate (Berzelius, Hermann). According to Berzelius, the precipitate always contains small quantities of potash, probably chemically combined, inasmuch as it is produced only by sulphate of potassium, and not by sulphate of sodium. It is insoluble in a solution of potassic sulphate, but dissolves partially in pure water, and the water with which it is washed becomes turbid (Berzelius). Sulphate of ammonium reacts with zirconium-salts in the same manner as sulphate of potassium. (Berzelius.)

Zirconia fused with acid sulphate of potassium forms a double salt, which, in the fused state, is perfectly transparent. Water dissolves only the potassium-salt, leaving the sparingly soluble zirconium-salt just mentioned (Berzelius). Warren (Pogg. Ann. cii. 449; Jahresb. 1857, p. 158), by precipitating a solution of neutral zirconic sulphate with neutral and acid sulphate of potassium, has obtained some double salts of complicated and very doubtful composition.

ALCOHOLIC SULPHATES. SULPHURIC ETHERS.

Alcohols treated with strong sulphuric acid, yield acid sulphuric ethers represented by the general formula, $\frac{R}{H}SO^4$:

$$\left.\begin{matrix}R\\H\end{matrix}\right\}O + \left.\begin{matrix}H\\H\end{matrix}\right\}SO^4 = H^2O + \left.\begin{matrix}R\\H\end{matrix}\right\}SO^4.$$

Alcohol. Sulphuric acid. Acid ether.

There are also a few neutral sulphuric ethers represented by the formula $\left.\begin{matrix}R\\R\end{matrix}\right\}SO^4$; they are formed, not by the action of sulphuric acid upon alcohols, but of sulphuric anhydride upon neutral ethers (alcoholic oxides).

Allyl-sulphuric Acid, $C^3H^6SO^4 = \left.\begin{matrix}C^3H^4S^2\\H\end{matrix}\right\}SO^4 = \left.\begin{matrix}(SO^2)''\\C^3H^5\\H\end{matrix}\right\}O^2$. (Cahours and Hofmann, Chem. Soc. Qu. J. x. 316).—When allylic alcohol is added by drops to about an equal volume of strong sulphuric acid, the mixture becomes heated without blackening: and in adding seven or eight times the volume of water, and neutralising with carbonate of barium, the liquid yields, by evaporation, white shining crystals of baric allyl-sulphate $(C^3H^5)^2Ba''(SO^4)^2$.

Amylsulphuric acid, $(C^5H^{11})HSO^4$. *Sulphamylic acid.* (Cahours, Ann. Ch. Phys. [2], lxx. 86.—Kekulé, Ann. Ch. Pharm. lxxv. 275.)—A mixture of equal parts of amylic alcohol and oil of vitriol, after standing for some time, till water no longer separates amylic alcohol from it, is diluted with water; the resulting crude amyl-sulphuric acid is saturated with carbonate of barium; the solution filtered from the sulphate of barium is evaporated; and the crystals of amylsulphate of barium obtained after cooling are freed from the mother-liquor upon filter-paper; and purified by shaking up their aqueous solution with animal charcoal, and twice crystallising by spontaneous evaporation. The solution of these crystals, precipitated by the proper quantity of sulphuric acid, then filtered and evaporated, yields the pure acid. (Cahours). Kekulé prefers preparing the lead-salt and decomposing it with sulphuretted hydrogen, after which he carefully evaporates the colourless filtrate to a thin syrup.

Amyl-sulphuric acid is a colourless, thin syrup which sometimes deposits slender needles by spontaneous evaporation. (Kekulé did not obtain any crystals.) It tastes acid and bitter (sharply acid, according to Kekulé), and reddens litmus strongly. (Cahours.) It dissolves readily in water and in alcohol.

The concentrated aqueous acid decomposes spontaneously into amyl-alcohol and sulphuric acid, slowly in the cold and in a vacuum or when exposed to the air; quickly on boiling; the more quickly as it is more concentrated. It is decomposed by chlorine in the cold, and by nitric acid when heated.

The amylsulphates or sulphamylates $(C^5H^{11})MSO^4$, and $(C^5H^{11})^2M''(SO^4)^2$, are generally crystallisable, have a bitter taste and are soapy to the touch. The crystals generally contain water, and in that case are often efflorescent. When their aqueous solution is boiled, they are resolved into sulphate, free sulphuric acid and amylic alcohol. This decomposition takes place slowly at ordinary temperatures, even in the crystallised salts; nevertheless, these crystallised salts may generally be dehydrated at 100° before decomposition begins. All amylsulphates dissolve in water and in alcohol, very sparingly in ether. Most of them in the crystalline state or in aqueous solution are decomposed by prolonged contact with the air, giving off amylic alcohol and leaving a metallic sulphate; the decomposition is accelerated by heat. By dry distillation they leave metallic sulphate mixed with charcoal, and give off a combustible gas together with carbonic and sulphurous anhydrides, and an oil containing amylene, other hydrocarbons polymeric therewith, amylic ether $(C^5H^{11})^2O$, and probably also amylic sulphate $(C^5H^{11})^2SO^4$; at all events, the distilled product contains sulphur.

Amylsulphate of Aluminium forms a gelatinous mass, soluble in water, alcohol, and ether, very deliquescent, and easily decomposible.

Amylsulphate of Ammonium.—The filtrate obtained by precipitating the calcium-salt with carbonate of ammonia, yields by spontaneous evaporation, colourless, bitter crystalline scales, and by evaporation over the water-bath a nodular crystalline mass. The crystals give off nothing at 100°, begin to decompose at 140°, and burn away, leaving a residue of charcoal. They deliquesce slightly in damp air, and dissolve very readily in water, on which they move briskly about; they are less soluble in alcohol, and insoluble in ether.

The *barium-salt* $(C^5H^{11})^2Ba''(SO^4)^2.2H^2O$, prepared as above, crystallises by spontaneous evaporation, in large very flexible rhombic tables. The crystals effloresce in dry air and give off 6·66 per cent, (1 at.) water *in vacuo*. They begin to decompose at 95°, melting at the same time, if they have not been previously dried. They give off an oil somewhat above 200°, and leave sulphate of barium mixed with charcoal. Their aqueous solution is resolved by longer boiling, into amylic alcohol, sulphuric acid, and sulphate of barium. They dissolve very readily in water, more readily in warm than in cold alcohol, but are insoluble in ether.

The *calcium-salt*, $(C^5H^{11})^2Ca''(SO^4)^2.2H^2O$, obtained by saturating amyl-sulphuric acid with chalk, forms mammellated crystals, soft to the touch, very soluble in water, especially in hot water, soluble in alcohol, insoluble in ether. It has a bitter and pungent taste. An aqueous solution, saturated and limpid at ordinary temperatures, becomes turbid at the boiling heat. The crystals effloresce in dry air, give off the whole of their water (8·55 per cent.) in a vacuum, and are gradually decomposed by contact with the air. The salt, heated to 250° in a sealed tube with alcoholic ammonia, yields sulphate of calcium and sulphate of amylamine. (Berthelot, Compt. rend. xxxvi. 1098.)

The *cobalt-salt* is obtained, by precipitating the barium-salt with sulphate of cobalt, and evaporating the filtrate, in rose-coloured laminæ, very soluble in water.

Cupric salt, $(C^5H^{11})^2Cu''(SO^4)^2.2H^2O$.—The blue solution of carbonate of copper in the acid yields, when left over oil of vitriol, large elongated tables which are permanent in the air, dissolve readily in water and weak alcohol, less readily in absolute alcohol, and are insoluble in ether.

The *ferric salt*, obtained by dissolving ferric hydrate in the aqueous acid, forms small, yellow, easily decomposible, deliquescent, crystalline granules.—The *ferrous salt* is produced by dissolving metallic iron in the aqueous acid. The pale green, sweetish-bitter solution reddens litmus, and when evaporated, deposits brown flakes of ferric oxide, together with pale green crystalline grains of the ferrous salt. These crystals quickly turn yellow on exposure to the air, dissolve in water and alcohol, and with green colour in ether.

The *lead-salt*, $(C^5H^{11})^2Pb''(SO^4)^2.H^2O$, obtained by saturating the acid with carbonate of lead, forms mammellated groups of small laminæ, very soluble in water, acid to test-paper, soluble in alcohol, insoluble in ether, and having a bitter-sweet taste. The solution decomposes slowly in contact with the air, rapidly at the boiling heat.

The *magnesium-salt*, $(C^5H^{11})^2Mg''(SO^4)^2.4H^2O$, is obtained by spontaneous evaporation in elongated rhomboïdal laminæ, which, have a fine nacreous lustre, and are with difficulty deprived of the whole of their water of crystallisation.

The *manganese-salt*, $(C^5H^{11})^2Mn''(SO^4)^2.4H^2O$, forms nearly colourless crystals, permanent in the air; the solution, however, gradually decomposes.

Mercuric salt.—The yellow solution of mercuric oxide in amylsulphuric acid yields, by evaporation in a vacuum, dark yellow crystalline nodules, soapy and glutinous to the touch, having an extremely sharp and bitter taste; they contain 2 at. water, decompose after keeping for some time, and deliquesce in damp air.

The *nickel-salt*, $(C^5H^{11})^2Ni''(SO^4)^2.2H^2O$, crystallises by evaporation in a vacuum, in nodules of green, elongated laminæ, which deliquesce in moist air.

The *potassium-salt*, $(C^5H^{11})KSO^4$, separates from its solution by spontaneous evaporation in colourless tufts of needles, having a very bitter taste, or in nodules composed of needles having a silky lustre. These crystals effloresce on exposure to the air, and turn slightly brown, giving off amylic alcohol and sulphuric acid. In a vacuum or at 100°, they give off 3·99 per cent. (1 at.) of water, without further decomposition, swell up strongly at 170°, then melt, and leave a black scum. The salt dissolves readily in water and in weak alcohol, less readily in strong alcohol, from the hot solution in which it crystallises in slender needles, and is insoluble in ether.

Silver-salt, $(C^5H^{11})AgSO^4$.—The solution of carbonate of silver in the slightly heated acid yields, by evaporation, colourless laminæ, which dissolve very easily in water, blacken on exposure to the air, and dissolve in alcohol but not in ether.

The *sodium-salt*, $(C^5H^{11})NaSO^4$, is obtained by precipitating the calcium-salt with carbonate of sodium, and spontaneous evaporation of the filtrate, in nodules set with small crystals. These swell up at 35° [135?] softening, and giving off water, and begin to undergo further decomposition at 145°. They dissolve abundantly in cold water, and in all proportions in hot water; from hot alcohol they crystallise in long radiated laminæ; they do not dissolve in ether.

The *strontium-salt*, $(C^5H^{11})^2Sr''(SO^4)^2.2H^2O$, forms white crystallised nodules, which turn brown in the air, leave 39·82 per cent. sulphate of strontium when ignited, dissolve readily in water and weak alcohol, with difficulty in absolute alcohol, and not at all in ether.

The *zinc-salt*, $(C^5H^{11})^2Zn''(SO^4)^2.2H^2O$, forms nacreous scales grouped in nodules, soluble in water and in alcohol, and decomposing at 110°.

Butyl-sulphuric acid. See TETRYL-SULPHURIC ACID.

Capryl-sulphuric acid. See OCTYL-SULPHURIC ACID.

Cetyl-sulphuric acid. $(C^{16}H^{33})HSO^4$.—*Sulphocetic acid*: (Dumas and Péligot, Ann. Ch. Phys. [2] lxii. 4.—Köhler, Jahresb. 1856, p. 579.—Heintz, Pogg. Ann. cii. 257; Jahresb. 1857, p. 445.)—The potassium-salt of this acid is produced by mixing ethal with strong sulphuric acid, at the temperature of the water-bath; dissolving the mass in alcohol; saturating with alcoholic potash; separating the liquid from the deposited sulphate of potassium; concentrating it; digesting the cetyl-sulphate of potassium, which separates with alcohol, to free it from excess of ethal; and purifying it by repeated crystallisation from boiling alcohol.

Cetyl-sulphate of potassium, $(C^{16}H^{33})KSO^4$, crystallises in soft nacreous laminæ, composed of interlaced needles; it is moderately soluble in hot alcohol, less soluble in boiling water, insoluble in ether, not fusible. Heated with cyanide of potassium, it yields cyanide of cetyl (i. 840).

Ethyl-sulphuric acid. $(C^2H^5)HSO^4$. *Sulphethylic acid. Sulphovinic acid.* (Dabit, Ann. Chem. xxxiv. 300; xliii. 101.—Sertürner, Gilb. Ann. lx. 53; lxiv. 6, 7.—A. Vogel, *ibid.* lxiii. 81.—Gay-Lussac, Ann. Ch. Phys. [2], xiii. 76.—Hennell, Phil. Trans. 1826, p. 240; 1828, p. 365.—Dumas and Boullay, Ann. Ch. Phys. xxxvi. 300.—Serullas, *ibid.* xxxix. 153.—Liebig and Wöhler, Ann. Ch. Pharm. i. 37.—Liebig, *ibid.* xiii. 27.—Magnus, *ibid.* vi. 52.—Marchand, Pogg. Ann. xxviii. 454; xxxii. 345; xli. 595.—Müller, Ann. Ch. Phys. [3], xix. 22.—Berthelot, Compt. rend. xxxvi. 1098.—Gm. viii. 415; x. 511).—This acid, produced by the action of strong sulphuric acid upon alcohol, ether, or ethylene, was first noticed by Dabit (in 1800), in the residues of the preparation of ether by heating alcohol with sulphuric acid; afterwards (1819) by Sertürner. Hennel, in 1826, announced that he had produced it by the direct combination of ethylene (olefiant gas) with sulphuric acid; but this result was for a long time doubted, the formation of the ethyl-sulphuric acid being attributed to the presence of alcohol or ether vapour in the olefiant gas. The more recent experiments of Berthelot, however, have confirmed Hennel's statement, and shown that ethyl-sulphuric acid may be formed by briskly agitating strong sulphuric acid with perfectly pure ethylene gas, obtained either from alcohol, or from coal-gas (by absorbing it with iodine, and decomposing the ethylenic iodide with potash), or produced by the direct combination of hydrogen with acetylene, (i. 112), or in various other ways from inorganic materials (ii. 565.)—On the formation of ethyl-sulphuric acid from alcohol, see Alcohol (i. 76).

Preparation.—A mixture of equal parts of strong sulphuric acid and strong alcohol is heated to about 100°, and after standing in a warm place for 24 hours, diluted with water, and saturated with carbonate of barium or carbonate of lead; the solution is then filtered from the precipitated sulphate of barium or lead; and the filtrate carefully evaporated to the crystallising point. The crystals of baric or plumbic ethylsulphate are then redissolved in water; the solution is decomposed with an exactly equivalent quantity of sulphuric acid—or better, in the case of the lead-salt, with sulphydric acid;—and the filtrate is concentrated in a vacuum over oil of vitriol or chloride of calcium.

Properties.—Ethyl-sulphuric acid, concentrated to the highest degree that it will bear without decomposition, is a limpid, oily, very sour liquid, of specific gravity 1·315 to 1·317 at 16°. It dissolves in all proportions in water and in alcohol, but is insoluble in ether.

The dilute acid decomposes gradually at ordinary temperatures, quickly on boiling, into alcohol and sulphuric acid. The concentrated acid is resolved at a moderate degree of heat into ether and sulphuric acid, but at a higher temperature it suffers more complete decomposition, giving off ethylene gas and sulphurous oxide, and leaving a carbonaceous residue. Heated with alcohol to 130°—140°, it yields ether and sulphuric acid, (i. 76):

$$(C^2H^5)HSO^4 + (C^2H^5)HO = (C^2H^5)^2O + H^2SO^4.$$

Heated with manganic peroxide or potassic chromate, it yields aldehyde. (Jacquemin and Liès.-Bodard, Jahresb. 1857, p. 345.)

Ethyl-sulphates or sulphovinates, $(C^2H^5)MSO^4$ and $(C^2H^5)^2M''(SO^4)^2$. Ethylsulphuric acid is a strong acid, which decomposes carbonates and sulphites, and neutralises bases completely. Some of the ethyl-sulphates are anhydrous; others contain water of crystallisation, which for the most part they give off in a vacuum over oil of vitriol. They are likewise dehydrated by heating to 100°, or in some cases to higher temperatures, with partial decomposition. They all dissolve easily in water, some also in alcohol, and a few, the ammonium-salt, for example, in ether. Most ethylsulphates are permanent in the air, but the ammonium-, lithium-, sodium-, and zinc-salts are very deliquescent. When dissolved in a small quantity of water, they produce a perceptible degree of cold.

The ethyl-sulphates may be prepared by saturating the acid with oxides or carbonates, or by decomposing the barium- or lead-salt with the corresponding sulphates;

the ethyl-sulphates of the alkali-metals, also by decomposing the barium- or lead-salt with an alkaline carbonate.

The ethyl-sulphates in aqueous solution are decomposed by ebullition, but the decomposition is completely prevented by adding a few drops of caustic potash. Some of them, especially the strontic, baric, plumbic, ferric, manganous, argentic, aluminic, and uranic salts, undergo spontaneous decomposition, while others may be kept for years without alteration. They are decomposed by dry distillation, first giving off ether and alcohol, together with their water of crystallisation, afterwards heavy oil of wine (probably a mixture of neutral ethylicsulphate and oily hydrocarbons), together with carbonic and sulphurous anhydrides, and olefiant gas, and leaving metallic sulphate mixed with charcoal. Heated in contact with the air, they burn with a faint bluish flame. Heated with strong *sulphuric acid*, they give off ether, and, with the dilute acid, alcohol. Heated with *hydrate of potassium*, they yield alcohol, and with *quicklime* they give off, first alcohol, afterwards heavy oil of wine and olefiant gas.—Heated with *mangaric peroxide* or *potassic chromate*, they yield aldehyde, together with wine-oil and other products of decomposition. (**Jacquemin** and **Liés-Bodard.**)

The ethyl-sulphates distilled with other salts yield compound ethers; for example:

$$\underset{\substack{\text{Potassic}\\\text{acetate.}}}{C^2H^3KO^2} + \underset{\substack{\text{Potassic}\\\text{Ethyl-sulphate.}}}{C^2H^5KSO^4} = K^2SO^4 + \underset{\substack{\text{Ethylic}\\\text{acetate.}}}{C^2H^3(C^2H^5)O^2}.$$

Compound ethers are often prepared by this method. According to **Nadler** (Ann. Ch. Pharm. cxvi. 173; Jahresb. 1860, p. 403), ethyl-sulphate of potassium distilled with *nitrate of potassium*, yields, not ethylic nitrate, but a heavy oily liquid consisting of aceto-ethyl-nitrate, $C^6H^{14}N^2O^7$, a compound of 2 at. ethylic-nitrate and 1 at. aldehyde ($2C^2H^5NO^3 + C^2H^4O$), the latter being produced from ethylic nitrate by elimination of NO^2H.

When a cold concentrated aqueous solution of an ethyl-sulphate is electrolysed with platinum-plates for electrodes, the inorganic base is separated at the negative pole, with evolution of hydrogen, whilst free sulphuric acid is eliminated at the positive pole, together with oxygen and carbonic dioxide, an odour of aldehyde being also perceptible. If the positive pole is formed of amalgamated zinc, it becomes coated with a film of ethyl-sulphate of zinc, but neither aldehyde nor sulphuric acid makes its appearance. (**Guthrie**, Ann. Ch. Pharm. xcix. 64.)

Ethyl-sulphate of Aluminium is gummy and deliquescent.

The *ammonium-salt*, $(C^2H^5)(NH^4)SO^4$, forms anhydrous crystals which melt at 62°, are very deliquescent, and very soluble in water, alcohol, and ether.

The *barium-salt*, $(C^2H^5)^2Ba''(SO^4)^2.2H^2O$, crystallises in monoclinic prisms, isomorphous with the methyl-sulphate, and exhibiting the combination ∞P . ∞P∞ . oP . −P∞ . +P. Axes, $a : b : c = 0{\cdot}8229 : 0{\cdot}9790 : 1$. Angle $b : c = 84° 39'$; ∞P : ∞P (orthod.) = 80° 20′; +P : +P = 96° 44′; oP : ∞P = 93° 26′; ∞P∞ : −P∞ = 121° 18′. Cleavage perfect, parallel to ∞P∞ (**Schabus**, *Bestimmung der Krystallgestalten, &c.*). The crystals contain 8·48 per cent. water of crystallisation, which they give off in a vacuum. The anhydrous salt does not alter at 100°, but the hydrated salt undergoes slight decomposition at that temperature. The hydrated salt dissolves in 0·92 pts. water at 17°; it is soluble also in alcohol of ordinary strength. Its aqueous solution, when boiled, becomes turbid and acid, and deposits sulphate of barium, and the filtered liquid, saturated with carbonate of barium, yields parathionate of barium, isomeric with the ethyl-sulphate (iv. 354).

The *cadmium-salt*, $(C^2H^5)^2Cd''(SO^4)^2.2H^2O$, forms long limpid prisms, very soluble in water and in alcohol, insoluble in ether, and giving off their water of crystallisation in a vacuum.

The *calcium-salt* $(C^2H^5)^2Ca''(SO^4)^2.2H^2O$, forms monoclinic crystals, apparently isomorphous with the barium-salt. Dominant faces ∞P, ∞P∞. Angle ∞P : ∞P (orthod.) = 80° 8′ (**Schabus**). The crystals are permanent in the air, and contain 11·7 per cent. water, which they give off in a vacuum, or when heated to 80°. One part of the salt dissolves in 1 pt. water at 8°, in 0·8 pt. at 17°, in 0·63 pt. at 30°, and in all proportions in boiling water. The salt is less soluble in alcohol, insoluble in ether. The anhydrous salt begins to decompose at about 120°.

The *cobalt-salt*, $(C^2H^5)^2Co''(SO^4)^2.2H^2O$, forms dark-red crystals, permanent in the air, very soluble in water and in alcohol, insoluble in ether.

The *cupric salt*, $(C^2H^5)^2Cu''(SO^4)^2.4H^2O$, crystallises in right rectangular prisms, or laminæ of a fine blue colour, very soluble in water and in alcohol, insoluble in ether.

The *ferric salt*, obtained by dissolving ferric hydrate in ethylsulphuric acid, crystallises with difficulty in yellow deliquescent tables, soluble in water and in alcohol, insoluble in ether.

The *ferrous salt*, obtained by dissolving metallic iron in the acid, crystallises in greenish prisms, which alter very quickly.

Lead-salts.—The *normal salt*, $(C^2H^5)Pb''(SO^4)^2.2H^2O$, crystallises in colourless transparent tables, very soluble in water and in alcohol, and having an acid reaction. They contain 7·28 per cent. water of crystallisation, which they give off in a vacuum, or when heated. They undergo gradual decomposition. The solution of this salt, digested with recently precipitated oxide of lead, yields an uncrystallisable basic salt, $(C^2H^5)^2Pb''S^2O^8.Pb''O$, soluble in water and in alcohol. By supersaturating the solution of the neutral salt with ammonia, evaporating, redissolving the residue in water, and again evaporating, scales are obtained containing lead and ammonia.

The *lithium-salt*, $C^2H^5LiSO^4.H^2O$, forms deliquescent crystals.

The *magnesium-salt*, $(C^2H^5)^2Mg''(SO^4)^2.4H^2O$, forms crystals very soluble in water, insoluble in alcohol and in ether, and containing 20·8 per cent. water of crystallisation, half of which goes off at 80°, the rest at 90°.

The *manganese-salt*, $(C^2H^5)^2Mn''(SO^4)^2.4H^2O$, forms roseate tables, permanent in the air, very soluble in water and in alcohol, insoluble in ether.

The *mercuric salt* is very unstable and deliquescent.

The *nickel-salt*, $(C^2H^5)^2Ni''(SO^4)^2.2H^2O$, forms green, very soluble, granular crystals.

The *potassium-salt*, $C^2H^5KSO^4$, crystallises easily in large, colourless, anhydrous tables or laminæ belonging to the monoclinic system, and exhibiting the combination $\infty P . oP . [P\infty]$. Axes $a : b : c = 0·5730 : 0·6149 : 1$. Angle $b : c = 80° 27$. $\infty P : \infty P$ (othod.) $= 86° 53'$; $[P\infty] : [P\infty] = 60° 30'$; $oP : \infty P = 96° 33'$. Cleavage perfect parallel to oP (Schabus). It has a sweetish saline taste, dissolves in 0·8 pts. water at 17°, deliquesces in moist air, is insoluble in absolute alcohol and in ether.

The *silver-salt*, $C^2H^5AgSO^4.H^2O$, forms shining scales, which dissolve in water and in alcohol, and do not give off their water of crystallisation till raised to a temperature at which they decompose.

The *sodium-salt*, $C^2H^5NaSO^4.H^2O$, crystallises in hexagonal plates, which contain 10·78 per cent. water of crystallisation, effloresce in warm air, and melt to a colourless liquid at 86°. The anhydrous salt does not melt or decompose till heated above 100°. It dissolves in 0·61 pts. water at 17°, and is even more deliquescent than the potassium-salt.

The *strontium-salt*, $(C^2H^5)^2Sr''(SO^4)^2$, forms anhydrous crystals very soluble in water.

The *uranic salt* is yellow, and decomposes between 60° and 70°.—The *uranous salt* crystallises with difficulty and is deliquescent.

The *zinc-salt*, $(C^2H^5)^2Zn''(SO^4)^2.2H^2O$, forms large colourless tables, very soluble in water and in alcohol, insoluble in ether.

DIETHYLIC OR NEUTRAL ETHYLIC SULPHATE, OR ETHYLIC ETHYLSULPHATE, $(C^2H^5)^2SO^4 = (C^2H^5)^2O.SO^3$. *Sulphuric ether.* (Wetherill, Ann. Ch. Pharm. lxvi. 117.)—This compound is produced by direct combination of ethylic oxide with sulphuric anhydride; also by the action of sulphuric anhydride on absolute alcohol, the alcohol being first dehydrated, and the ether thus produced uniting with another portion of sulphuric anhydride.

Preparation.—Vapour of sulphuric anhydride is passed into a flask containing ether and surrounded by a freezing mixture. The vapour, by its great density, sinks to the bottom of the flask and comes in contact with the ether, and the liquid after a while acquires a syrupy consistency, so that it requires to be shaken up with an equal bulk of ether and four times its bulk of water. It then separates into two layers, the upper of which, containing the ethylic sulphate, must be separated from the lower, which is strongly acid, and contains sulphuric, sulphurous, ethionic, and ethyl-sulphuric acids (p. 625), mixed, if the temperature has not been kept low enough, with black carbonaceous particles, and also with isethionic and methionic acids, resulting from the decomposition of the ethionic acid. The ethereal liquid is then shaken up with milk of lime to remove the sulphurous acid—whereby part of the colouring matter is at the same time removed—then washed with water, filtered, and the ether distilled off. In the retort there remains an oily liquid, containing a trace of ether, and having a slightly acid reaction, arising from the decomposition of part of the ethylic sulphate, which takes place, when the liquid is heated, by the action of the water taken up by the ether. The oil is then transferred from the retort into a basin, and washed with a small quantity of water, the last portions of which are carefully removed by strips of bibulous paper, after which the liquid is dried in a vacuum over sulphuric acid.

Properties.—Ethylic sulphate is an oily liquid, colourless when pure, but generally exhibiting a yellow tint. It has a sharp taste, and smells like oil of peppermint. Specific gravity 1·120. It makes greasy spots on paper, which however disappear after a while.

1. *Decompositions.*—This compound is very easily decomposed when heated in contact with the air, so that it can only be distilled in an atmosphere of carbonic

anhydride. At 100°, vapours begin to rise, which condense in small oily drops; between 110° and 120°, the oil passes over unchanged; but between 130° and 140°, the liquid blackens, gives off sulphurous anhydride and alcohol, and at a higher temperature, the same products mixed with olefiant gas.—2. Ethylic sulphate heated with *water*, forms, without separation of wine-oil, a very acid liquid, which gives off alcohol when boiled; and when treated with carbonate of barium, yields three soluble barium-salts—viz., methionate, ethylsulphate, and isethionate of barium. The first of these salts is, however, so small in quantity, that it can only be regarded as a secondary product. The formation of the other products may be represented by the following equation:

$$\underset{\substack{\text{Ethylic}\\\text{sulphate.}}}{3(C^2H^5)^2SO^4} + 3H^2O = \underset{\substack{\text{Ethylsulphuric}\\\text{acid.}}}{2(C^2H^5)HSO^4} + \underset{\substack{\text{Isethionic}\\\text{acid.}}}{(C^2H^4)H^2SO^4} + \underset{\text{Alcohol.}}{3(C^2H^5.H.O)}$$

3. Ethylic sulphate is decomposed by an excess of *sulphuric anhydride*, yielding ethylsulphuric acid, ethionic acid, and ethionic anhydride; hence the formation of these products in the preparation of the compound:

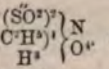
$$\underset{\substack{\text{Ethylic}\\\text{sulphate.}}}{2C^4H^{10}SO^4} + 5SO^3 = \underset{\substack{\text{Ethylsul-}\\\text{phuric acid.}}}{C^2H^6SO^4} + \underset{\substack{\text{Ethionic}\\\text{acid.}}}{C^2H^6S^2O^7} + \underset{\substack{\text{Ethionic}\\\text{anhydride.}}}{2C^2H^4S^2O^6}.$$

4. *Sulphydric acid* does not act on ethylic sulphate at ordinary temperatures, but *sulphydrate of potassium* decomposes it, forming mercaptan and sulphate of potassium:

$$(C^2H^5)^2SO^4 + 2KHS = 2(C^2H^5)HS + K^2SO^4.$$

5. *Chlorine* does not decompose ethylic sulphate at ordinary temperatures, but combines with it, forming a green liquid, which, on addition of water, yields the compound in its original state.—6. *Potassium* does not act on sulphuric ether at ordinary temperatures, but on the application of heat, decomposes it, with evolution of light and heat, forming mercaptan, together with other products.—7. Sulphuric ether dissolves in fuming *nitric acid*, and is precipitated from the solution by water. On adding caustic potash till the liquid is nearly neutral, and applying heat, *nitrous ether*, $C^2H^5NO^2$, is evolved.

SULPHETHAMIC ACID, $C^8H^{23}NS^2O^8 = 2C^4H^{10}SO^4.NH^3 =$



$$\left.\begin{matrix}(\overset{\prime\prime}{SO^2})^2\\(C^2H^5)^4\\H^3\end{matrix}\right\}\begin{matrix}N\\O^4\end{matrix}$$

(Strecker, Ann. Ch. Pharm. lxxv. 46.)—Ethylic sulphate absorbs ammonia-gas with rise of temperature; the product dissolves easily in water or in alcohol, and the solution yields, by evaporation, groups of crystalline laminæ, consisting of sulphethamate of ammonium. This salt, treated with oxide of lead, yields the sulphethamate of that base, which, when decomposed by sulphuretted hydrogen, yields the free acid. The solution of sulphethamic acid may be concentrated by evaporation; but at the boiling heat it decomposes, yielding free sulphuric acid.

Sulphethamate of Ammonium, $C^8H^{22}(NH^4)NS^2O^8$, deliquesces in moist air, melts below 100°, and burns at a stronger heat, with a faintly luminous flame, emitting an odour like that of ethylic sulphide. It dissolves easily in water and in alcohol, not in ether. The solution is neutral, and does not precipitate metallic salts. It is decomposed by alkalis in the cold, with evolution of ammonia. When mixed with chloride of barium and nitric acid, it does not yield an immediate precipitate of sulphate of barium, but the mixture becomes cloudy after long boiling.

When moist sulphethamate of ammonium is heated to 100°, or a little above, it quickly becomes acid, and its solution is then precipitated by barium-salts. If the ammonia be precipitated from a solution of the salt by platinic chloride and hydrochloric acid, and the liquid containing the excess of platinic chloride evaporated over the water-bath, crystals of chloroplatinate of ethylamine are obtained. It appears then that sulphethamic acid is decomposed by heat, under the influence of acids, into ethylamine and sulphuric acid, other products not yet examined being likewise produced. Possibly alcohol and isethionic acid are formed at the same time, according to the equation:

$$C^8H^{23}NS^2O^8 + 2H^2O = C^2H^7N + C^2H^6SO^4 + 2C^2H^6O + H^2SO^4.$$

A solution of the ammonium-salt evaporated over the water-bath with baryta, leaves nothing but sulphate of barium. On boiling it with carbonate of barium or oxide of lead, till all the ammonia is expelled, and then distilling with potash, ethylamine is obtained.

Sulphethamate of Barium is obtained by boiling the aqueous ammonium-salt for a short time with carbonate of barium, and remains on evaporation as a very soluble mass, crystallising with difficulty.—The *lead-salt*, prepared in like manner with oxide of lead, the excess of lead being removed by carbonic acid, crystallises in needles, very soluble in water and alcohol of ordinary strength, slightly soluble in absolute alcohol. (Strecker.)

Methylsulphuric Acid, $(CH^3)HSO^4$. *Sulphomethylic Acid.* (Dumas and Péligot, Ann. Ch. Phys. lviii. 54; lxi. 199.—Kane, Phil. Mag. vii. 397.)—Produced in large quantity by mixing 1 pt. of wood-spirit with 2 pts. of strong sulphuric acid, the mass becoming hot, and sometimes crystallising by spontaneous evaporation. It is obtained pure by completely decomposing a solution of its barium-salt with sulphuric acid; also (according to Liebig) by dissolving neutral methylic sulphate in boiling water, and leaving the solution to evaporate. It forms colourless needles, soluble in water and in alcohol, and very unstable.

The methylsulphates, CH^3MSO^4, are all very soluble in water. Those of the alkali-metals yield, by distillation, a large quantity of methylic sulphate, with a residue of alkaline sulphate:

$$2CH^3KSO^4 = (CH^3)^2SO^4 + K^2SO^4.$$

When distilled with other salts, they yield methylic ethers by double decomposition, just like the ethylsulphates.

The *barium-salt*, $(CH^3)^2Ba''(SO^4)^2.2H^2O$, obtained by saturating a mixture of sulphuric acid and wood-spirit with carbonate of barium, is deposited, by evaporation in a vacuum, in beautiful nacreous tables or laminæ, very soluble in water. The crystals are monoclinic, exhibiting the combination ∞P . ∞P∞ . [∞P∞] . oP . [P∞]. Axes, $a : b : c = 0·824 : 1·907 : 1$. Angle $b : c = 83° 30'$; ∞P : ∞P (clinod.) = 47° 0'; [P∞] : [P∞] = 79° 20'; oP : ∞P = 92° 35'. Cleavage perfect parallel to ∞P∞. (Schabus). By dry distillation, the salt yields sulphurous oxide, inflammable gas, water, and neutral methylic sulphate, leaving sulphate of barium slightly coloured with charcoal.—An isomer of this salt is obtained in very thin prisms, when wood-spirit which has absorbed the vapour of sulphuric anhydride is diluted with water and saturated with baryta-water.

The *calcium-salt*, $(CH^3)^2Ca''(SO^4)^2$, forms anhydrous, very deliquescent octahedrons.

The *lead-salt*, $(CH^3)^2Pb''(SO^4)^2$, crystallises in long prisms containing 1 at. water, or sometimes in tables containing 2 at. water. The crystals are very soluble and deliquescent.

The *potassium-salt*, $CH^3KSO^4.H^2O$, forms rhombic, very deliquescent, monoclinic tables, exhibiting the faces oP . −P . ∞P . [P∞]. Axes, $a : b : c = 0·742 : 0·779 : 1$. Angle $b : c = 86° 51'$; ∞P : ∞P (clinod.) = 87° 16'; −P : −P = 99° 15'; [P∞] : [P∞] = 40° 50'. (Schabus.)

The *uranic salt*, $(CH^3)^2(U^2O^2)''(SO^4)^2.H^2O$, obtained by precipitating the barium-salt with uranic sulphate, and evaporating the filtrate in a vacuum, is deposited after some time in very deliquescent crystals.

DIMETHYLIC or NEUTRAL METHYLIC SULPHATE, $(CH^3)^2SO^4$. *Methylsulphuric Ether.* (Dumas and Péligot, Ann. Ch. Phys. [2] lviii. 32.)—Produced by the direct combination of sulphuric anhydride and methylic oxide: $(CH^3)^2O + SO^3 = (CH^3)^2SO^4$; also in the dry distillation of methylsulphates.

It is most readily prepared by distilling 1 pt. of wood-spirit with 8 or 10 pts. of strong sulphuric acid, the mixture being kept in a state of gentle ebullition; washing the oily liquid which condenses in the receiver, with water; agitating it with chloride of calcium; and rectifying it several times over finely-pounded caustic baryta.

Methylic sulphate is a colourless oil, having an alliaceous odour and a density of 1·324 at 22° (Dumas and Péligot); 1·385 at ordinary temperatures (Bödeker, Jahresb. 1860, p. 17). It boils at 188°, under a pressure of 761 millimetres.

It is slowly decomposed by cold, rapidly by boiling *water*, into methylic alcohol and methylsulphuric acid.—When boiled with *alkalis*, it yields methylic alcohol and an alkaline sulphate.—By distillation with fused *chloride of sodium*, it yields methylic chloride and sulphate of sodium; with *benzoate of potassium*, methylic benzoate and sulphate of potassium; with *formate of sodium*, in like mannner, it yields methylic formate; and in contact with *sulphides of alkali-metal*, it is converted into methylic sulphide, $(CH^3)^2S$.

Ammonia converts it into methylic sulphamate (sulphamethylane) and methylic alcohol:

$$(CH^3)^2SO^4 + NH^3 = CH^5NSO^3 + (CH^3)HO.$$

This reaction is totally different from that of ethylic sulphate with ammonia (p. 625).

Octylsulphuric Acid, $(C^8H^{17})HSO^4$. *Caprylsulphuric* or *Sulphocaprylic Acid.* (Bouis, Compt. rend. xxxiii. 144; xxxviii. 935.)—Produced by gradually mixing 2 pts. of octylic alcohol with 1 pt. of strong sulphuric acid, keeping the mixture cool at first, but afterwards assisting the action by a gentle heat. It then separates into two layers, the upper of which, consisting chiefly of octylsulphuric acid, may be diluted with water, and neutralised with carbonate of barium, calcium, or lead.

The pure acid, obtained by decomposing the lead-salt with sulphydric acid, or the barium-salt with sulphuric acid, and evaporating in a vacuum over oil of vitriol, is a limpid, colourless, syrupy, strongly acid liquid, which dissolves very readily in water and alcohol, and dissolves zinc and iron with evolution of hydrogen. It blackens when heated, and its aqueous solution, when boiled, is resolved into octylic alcohol and sulphuric acid.

Octylsulphate of Barium, $(C^8H^{17})^2Ba''(SO^4)^2$, is obtained in fine, flexible, nacreous crystals containing 2 at. water, by cooling its solution, or leaving it over oil of vitriol; the crystals, merely freed from mother-liquor by pressure between filter-paper, contain 3 at. water. It is very soluble in water, has an extremely bitter taste, and leaves a strongly saccharine aftertaste. The solution is decomposed by boiling, and the dry salt by heating to 100°, or by prolonged keeping in a vacuum.

The *calcium-salt* crystallises in colourless tables, bitter and soapy to the touch.

The *neutral lead-salt* crystallises readily: its solution is acid to test-paper. By digestion with massicot, it yields a colourless alkaline solution, containing a *basic lead-salt*, which, on exposure to the air, becomes covered with pellicles of lead-carbonate, and is reconverted into the neutral salt.

The *potassium-salt*, $C^8H^{17}KSO^4.H^2O$, is white, nacreous, permanent in the air, very soluble in water and in alcohol. When heated, it begins to fuse, and burns with a bright flame without carbonisation. It decomposes at temperatures above 100°.

Phenylsulphuric Acid, $C^6H^6SO^4 = (C^6H^5)HSO^4$. *Sulphophenic* or *Sulphophenylic Acid*. (Laurent, Ann. Ch. Phys. [3], iii. 203.—Freund, Ann. Ch. Pharm. cxx. 76; Jahresb. 1861, p. 617.)—Prepared by treating phenol with excess of strong sulphuric acid; diluting with water after about twenty-four hours; saturating the solution with carbonate of barium; filtering, evaporating, and purifying the crystallised barium-salt thus obtained by recrystallisation from alcohol; and decomposing it with an equivalent quantity of sulphuric acid (Laurent).—Or the barium-salt may be converted into a cupric salt by double decomposition with cupric sulphate, and the cupric salt decomposed by sulphydric acid. (Freund.)

Phenylsulphuric acid may be obtained, by evaporation in a vacuum over oil of vitriol, in slender needle-shaped crystals (Laurent obtained it only as a syrup). The recently prepared solution yields, by distillation, first water containing phenol, then pure phenol, together with sulphurous anhydride; and leaves a carbonaceous residue, the acid being first resolved into phenol and sulphuric acid, ($C^6H^6SO^4 + H^2O = C^6H^6O + H^2SO^4$), which is subsequently reduced to sulphurous acid by the organic matter present. (Freund.)

Phenylsulphates, $C^6H^5MSO^4$ and $(C^6H^5)^2M''(SO^4)^2$.—The *ammonium-salt*, $2C^6H^5(NH^4)SO^4.H^2O$, crystallises in scales.—The *barium-salt*, $(C^6H^5)^2Ba''(SO^4)^2.3H^2O$, crystallises in spherical groups of microscopic needles, which give off their water of crystallisation at 100°, and yield phenol by dry distillation. (Laurent.)

The *cupric salt*, $C^{12}H^{10}Cu''S^2O^8$, separates from a concentrated aqueous solution on cooling, or by spontaneous evaporation, in greenish-blue permanent crystals containing 6 at. water; and the dark-green mother-liquor yields, by further concentration, crystals containing 4 at. water. The mother-liquor remaining after the hexhydrated crystals had separated by spontaneous evaporation, once yielded, after some time, probably in consequence of depression of temperature, well-defined efflorescent crystals having the colour of blue vitriol, and containing 10 at. water. (Freund.)

The *cobalt-salt*, $C^{12}H^{10}Co''S^2O^8.8H^2O$, forms beautiful crystals, having the colour of neutral cobalt-sulphate, permanent in the air, easily soluble in water and in alcohol, and giving up part of their water (19 per cent.) at 180°.—The *nickel-salt*, $C^{12}H^{10}Ni''S^2O^8.8H^2O$, forms emerald-green crystals, which are permanent in the air, dissolve in water and in alcohol, and acquire a canary-yellow colour when dehydrated. (Freund.)

The *magnesium-salt* forms white needle-shaped crystals, soluble in water and in alcohol.

The *potassium-salt*, $C^6H^5KSO^4.H^2O$, forms small silky crystals, soluble in water and in alcohol.

The *silver-salt*, dried over oil of vitriol, is anhydrous, very soluble in water and in alcohol, and crystallises indistinctly. (Freund.)

Paraphenylsulphuric Acid, $C^6H^6SO^4$, called *Oxyphenylsulphuric Acid* by R. Schmitt (Ann. Ch. Pharm. cxx. 129; Jahresb. 1861, p. 623.)—This acid is produced: 1. By passing a rapid stream of nitrous acid vapour into a hot saturated solution of phenylsulphamic (sulphanilic) acid (p. 477):

$$C^6H^7NSO^3 + HNO^2 = C^6H^6SO^4 + H^2O + N^2.$$

2. By heating diazophenylsulphurous acid to 80°:

$$C^6H^4N^2SO^3 + H^2O = C^6H^6SO^4 + N^2.$$

If this decomposition be allowed to take place in a vessel from which air is excluded, and the resulting liquid be concentrated over the water-bath, in a flask into which a stream of carbonic acid gas is continually passed, the acid is obtained as a light-brown uncrystallisable syrup. (Schmitt.)

Paraphenylsulphuric acid decomposes carbonates, and forms salts which are very soluble in water, and can be obtained in the crystalline state only by evaporating their solutions to dryness.—The *barium-salt*, $C^{12}H^{10}Ba''S^2O^8.xH^2O$, requires a strong heat to decompose it. When heated with solid potash, it forms sulphate of potassium, and gives off phenol.—The *silver-salt*, $C^6H^5AgSO^4$, bears in the dry state a tolerably high temperature without decomposition. Both these salts have a yellowish or brownish colour. (Schmitt.)

Dibromophenylsulphuric Acid, $C^6H^4Br^2SO^4$, is produced by boiling diazodibromophenylsulphurous acid (*infra*) with water. By saturating its aqueous solution with carbonate of ammonium, adding chloride of barium, and recrystallising the resulting precipitate, the barium-salt is obtained in needle-shaped crystals. (Schmitt.)

Appendix to Phenylsulphuric Acid.

PHENYLSULPHUROUS ACID, $(C^6H^5)HSO^3$.—To the description of this acid already given (p. 564), we have to add the following results obtained by Freund (Ann. Ch. Pharm. cxx. 76):—Pure benzene (prepared by distilling calcic benzoate), left in contact with frequently-renewed quantities of pure strong sulphuric acid at ordinary temperatures, and repeatedly shaken, dissolves completely, without evolution of sulphurous oxide; and the product diluted with water also dissolves perfectly, forming a clear liquid; and by neutralising this liquid with carbonate of barium, filtering, evaporating to dryness, redissolving in water, and again concentrating, pure *phenylsulphite of barium* is obtained, in transparent nacreous laminæ or tables, containing $C^{12}H^{10}Ba''S^2O^6.2H^2O$. This salt is slightly soluble in alcohol, and effloresces over oil of vitriol, but not on mere exposure to the air.—*Cupric phenylsulphite*, $C^{12}H^{10}Cu''S^2O^6.6H^2O$, prepared by decomposing the barium-salt with cupric sulphate, evaporating the filtrate to dryness, and redissolving in alcohol, crystallises from a hot concentrated alcoholic or aqueous solution, on cooling, in large, thin, tabular, light-blue crystals, permanent in the air; by spontaneous evaporation of the aqueous solution, also in well-defined crystals.—The *silver-salt*, $C^6H^5AgSO^3.8H^2O$, produced by precipitating the barium-salt with sulphate of silver, forms tabular crystals, soluble in water and in alcohol.

Phenylsulphurous acid, obtained by decomposing the cupric salt with sulphuretted hydrogen, crystallises by evaporation, in slender very deliquescent needles. The aqueous solution, when distilled, begins to decompose as soon as it attains a syrupy consistence, giving off sulphurous oxide, benzene, and sulphobenzide (p. 486), which condenses in the crystalline form; the distillate also contains sulphuric and undecomposed phenylsulphurous acids, while a black liquid, or a light, shining, carbonaceous mass, is left behind, according to the strength and duration of the heating. Phenylsulphurous acid is therefore decomposed by distillation, partly by assumption of 1 at. water, into benzene and sulphuric acid:

$$C^6H^6SO^3 + H^2O = C^6H^6 + H^2SO^4;$$

partly into sulphobenzide and sulphuric acid:

$$2C^6H^6SO^3 = C^{12}H^{10}SO^2 + H^2SO^4.$$

At the same time, a secondary decomposition takes place, attended with elimination of sulphurous acid and separation of carbon. (Freund.)

Paraphenylsulphurous Acid.—This name may be applied to an uncrystallisable modification of phenylsulphurous acid, obtained—according to R. Schmitt (Ann. Ch. Pharm. cxx. 129), by whom it is inappropriately termed "phenylsulphuric acid" (*Phenylschwefsäure*)—by heating diazophenylsulphurous acid (*infra*) with absolute alcohol under pressure.—Its *barium-salt*, $C^{12}H^{10}Ba''S^2O^6.xH^2O$, is soluble in water, slightly soluble in alcohol, gives off its water of crystallisation at 110°, and decomposes at a higher temperature.—The *lead-salt*, $C^{12}H^{10}Pb''S^2O^6.xH^2O$, is a colourless crystalline mass, easily soluble in water, very slightly soluble in alcohol.

Dibromophenylsulphurous Acid, $C^6H^4Br^2SO^3$ (Schmitt's *Dibromophenylschwefsäure*), is produced by boiling diazodibromophenylsulphurous acid with absolute alcohol under pressure. By evaporation it is obtained as a brown liquid, which solidifies after some time to a crystalline mass; and by precipitating its solution with acetate of lead, decomposing the lead-salt with sulphuretted hydrogen, and evaporating, it may be obtained in needle-shaped crystals containing 1 at. water; these crystals melt at 84°—86°, without loss of water, and decompose at a higher temperature.

The salts of this acid resemble the dibromosulphanilates (p. 478) in solubility.—The *barium-salt*, $C^{12}H^6Ba''Br^4S^2O^6.xH^2O$, obtained by precipitation, crystallises from hot water in long needles, sparingly soluble in cold water and in alcohol; it gives off its water at 100°, but does not decompose even at 200°. By dry distillation, it gives off water, sulphurous oxide, and an oil having the odour of bromobenzene.—The *lead-* and *silver-salts* crystallise in needles slightly soluble in water.—The *potassium-salt* forms easily soluble needles. (Schmitt, *loc. cit.*)

Diazophenylsulphurous Acid, $C^6H^4N^2SO^3$ (Schmitt, *loc. cit.*). *Diazophenylschwefelsäure.*—This acid is produced by the action of nitrous acid on sulphanilic acid (p. 478), $2C^6H^7NSO^3 + N^2O^3 = 2C^6H^4N^2SO^3 + 3H^2O$. It is insoluble in cold water, but dissolves easily in water at 60°—70°, and separates, by rapid cooling, in small colourless needles. It is insoluble in cold alcohol, and is decomposed by boiling alcohol, with evolution of nitrogen. Its aqueous solution is very unstable, and gives off nitrogen continuously. When heated to 100°, it decomposes with explosive violence, leaving a brown woolly substance. Gaseous ammonia decomposes it with explosion. It is decomposed by *hydriodic* and *hydrobromic acids*, with evolution of nitrogen; and by *sulphydric acid*, with evolution of nitrogen, separation of sulphur, and formation of sulphanilic acid:

$$2C^6H^4N^2SO^3 + 3H^2S = 2C^6H^7NSO^3 + S^3 + N^2.$$

When boiled with *alcohol* of 90 per cent., it yields aldehyde, paraphenylsulphurous acid, and paraphenylsulphuric acid; but when it is heated with absolute alcohol, under pressure, only the first two products are obtained, thus:

$$C^6H^4N^2SO^3 + C^2H^6O = C^6H^6SO^3 + C^2H^4O + N^2.$$

Diazodibromophenylsulphurous acid, $C^6H^2Br^2N^2SO^3$, is produced by the action of nitrous acid on bromosulphanilic acid (p. 479). It forms yellowish-white scales, which are permanent at 100°, but decompose with detonation at a higher temperature. It dissolves in alcohol, but not without detonation; is nearly insoluble in cold water, easily soluble in hot water; but decomposes in aqueous solution at the boiling heat, with evolution of nitrogen. Its reactions are similar to those of diazophenylsulphurous acid.

Tetrylsulphuric Acid, $(C^4H^9)HSO^4$. *Butylsulphuric Acid. Sulphobutylic Acid.* (Wurtz, Compt. rend. xxxv. 310.)—Produced by mixing tetrylic alcohol with an equal volume of strong sulphuric acid, taking care that the mixture does not become hot. After about twenty-four hours the action is complete, and a product is obtained perfectly soluble in water. The solution, saturated with carbonate of potassium, and evaporated to dryness over the water-bath, yields a mixture of sulphate and tetrylsulphate of potassium.

The tetrylsulphate, $C^4H^9KSO^4$, extracted from the mixture by boiling absolute alcohol, crystallises on cooling, in shining anhydrous laminæ, which when dry have a nacreous lustre, and are unctuous to the touch. The salt distilled with cyanate of potassium yields a mixture of tetrylic cyanate and cyanurate.

Tritylsulphuric Acid, $(C^3H^7)HSO^4$. *Propylsulphuric* or *Sulphopropylic Acid.* (Chancel, Compt. rend. xxxvii. 410.)—The potassium-salt of this acid, $C^3H^7KSO^4$, prepared from tritylic alcohol in the same manner as the preceding, crystallises on cooling from alcoholic solution, in anhydrous very slender needles, extremely soluble in water.

Hyposulphurous Compounds.

HYPOSULPHUROUS OR THIOSULPHURIC ACID, $H^2S^2O^3$; called also *Dithionous Acid*, and *Sulphuretted Sulphurous Acid.* (Gay-Lussac, Ann. Chim. lxxxv. 199.—Herschel, Ed. Phil. J. i. 8, 296; ii. 154.—Kessler, Pogg. Ann. lxxxiv. 274.—Vohl, Ann. Ch. Pharm. xciv. 237.—Slater, Chem. Gaz. 1856, p. 369.)—This acid is scarcely known in the free state, since, when liberated from any of its salts by the action of a stronger acid, it is almost immediately resolved into sulphurous acid and sulphur: $H^2S^2O^3 = H^2SO^3 + S$. According to H. Rose, however (*Traité de Chimie analytique*, i. 475), the decomposition is never complete unless the quantity of hyposulphite operated upon is very small; and the liquid, if filtered from the deposited sulphur, even after several weeks, still exhibits the reactions of hyposulphurous acid. According to Flückinger (J. Pharm. [3], xlvi. 453; Jahresb. 1863, p. 149), small quantities of this acid are often found in flowers of sulphur, in precipitated sulphur, in sulphur which has been crystallised from carbonic disulphide, and even in roll-sulphur. Flückinger finds also that it is produced by the action of aqueous sulphurous acid on pure sulphur, even at ordinary temperatures, but more readily at 80° or 90° in a sealed tube. When a mixture of finely-divided cadmium, sulphide of cadmium, and sulphur, moistened with absolute alcohol, was treated with sulphurous acid, sulphuretted hydrogen then passed into the filtrate after the sulphurous acid had evaporated, and the excess of sulphuretted hydrogen removed, the liquid after five months still exhibited the reactions of hyposulphurous acid,—a fact which confirms H. Rose's statement as to the stability of that acid in dilute solutions.

Hyposulphites.—These salts may for the most part be regarded either as analogous to the formates ($MHCO^2$), and represented by the formulæ $MHSO^2$ and $M''H^2S^2O^4$, or as hydrated thiosulphates, $\left.\begin{matrix}M^2\\ \text{or } M''\end{matrix}\right\}SO^3.H^2O$, derived from sulphates, $\left.\begin{matrix}M^2\\ \text{or } M''\end{matrix}\right\}SO^4$, by the substitution of S for O:

$$M^2S^2O^3.H^2O \quad = \quad 2MHSO^2$$
$$M''S^2O^3.H^2O \quad = \quad M''H^2S^2O^4.$$

The former view is in accordance with the fact established by H. Rose, that nearly all hyposulphites contain at least one atom of hydrogen; also with the formation of hyposulphites by the action of sodium, zinc, or iron on aqueous sulphurous acid, just as sodic formate is produced by the action of sodium on carbonic acid (ii. 683):

$$\underset{\substack{\text{Sulphurous}\\ \text{acid.}}}{2H^2SO^3} + Na^2 = \underset{\substack{\text{Sodic hypo-}\\ \text{sulphite.}}}{NaHSO^2} + \underset{\substack{\text{Acid sodic}\\ \text{sulphite.}}}{NaHSO^3} + H^2O.$$

$$\underset{\substack{\text{Carbonic}\\ \text{acid.}}}{2H^2CO^3} + Na^2 = \underset{\substack{\text{Sodic}\\ \text{formate.}}}{NaHCO^2} + \underset{\substack{\text{Acid sodic}\\ \text{carbonate.}}}{NaHCO^3} + H^2O.$$

But, on the other hand, hyposulphate of lead contains no water of crystallisation, and may be rendered completely anhydrous by heating to 100° (Pape, Jahresb. 1864, p. 57): it cannot, therefore, be regarded as analogous to a formate, but must be represented by the formula $Pb''S^2O^3$. The potassium-salt appears also to be capable of crystallising with less than 1 at. water. The dibasic formula M^2SO^3 is also more in accordance with the tendency of hyposulphurous acid to form double salts.

Hyposulphites are produced:—*α*. By passing sulphurous oxide through a solution of an alkaline sulphide, the reaction being accompanied by deposition of sulphur; *e.g.*:

$$2Na^2S + 3SO^2 = 2Na^2S^2O^3 + S$$
$$2Na^2S^5 + 3SO^2 = 2Na^2S^2O^3 + S^9;$$

or, better, by digesting or boiling sulphur with a solution of an alkaline sulphite; thus:

$$Na^2SO^3 + S = Na^2S^2O^3.$$

β. By boiling sulphur with a solution of alkaline hydrate, an alkaline pentasulphide being formed at the same time; thus with calcic hydrate:

$$3CaH^2O^2 + S^{12} = CaS^2O^3 + 2CaS^5 + 3H^2O.$$

By exposing the resulting solution to the air till it becomes colourless, the pentasulphide is further resolved into sulphur and hyposulphite:

$$CaS^5 + O^3 = CaS^2O^3 + S^3.$$

In this manner hyposulphites are obtained from gas-lime refuse and ball-soda refuse, which contain sulphide of calcium.

γ. By the action of certain metals on aqueous sulphurous acid (*supra*).

δ. According to Rathke and Zschiesche (J. pr. Chem. xcii. 141), hyposulphites are produced, together with hyposulphates (dithionates), when selenium is dissolved in an alkaline sulphite. By quickly evaporating such a solution, recently prepared and saturated, a crystalline mass is obtained, coloured red by separated selenium, and consisting mainly of alkaline sulphite mixed with hyposulphate; and the solution of these crystals, freed from selenium by filtration, and evaporated (even in an atmosphere of hydrogen), again deposits selenium, and afterwards a mixture of sulphite and hyposulphite. The mother-liquor of the first crystals also leaves, when evaporated, a certain quantity of selenium, and a crystalline mass consisting of a small quantity of sulphite, and a large quantity of hyposulphite together with separated sulphur.

The hyposulphites of the alkali-metals, alkaline earth-metals, and magnesium are soluble in water. That of barium, however, is only slightly soluble, and may be obtained, as a crystalline precipitate, by mixing the solutions of baric chloride and sodic hyposulphite.

Solutions of hyposulphites dissolve chloride, iodide and bromide of silver, mercurous chloride, iodide of lead, sulphate of calcium, and sulphate of lead. Mercuric iodide dissolves in cold aqueous hyposulphite of sodium, and the solution when heated deposits red sulphide of mercury free from iodide.—Cuprous and cupric hydrates dissolve in the same salt at ordinary temperatures, and are precipitated on heating (Field, Chem. Soc. Qu. J. xvi. 28; Jahresb. 1863, p. 179).—According to Diehl (Jahresb. 1860, p. 78), the ferrocyanides of zinc, manganese, cobalt, nickel, cadmium, and tin are insoluble in aqueous hyposulphite of sodium, whereas those of potassium, copper, lead and silver, and the ferricyanides of silver and mercury, are dissolved by it. The white precipitate formed by ferrocyanide of potassium in ferrous salts is not dissolved by it; the Prussian-blues are converted into a white compound.—The alkaline cyanides and ferrocyanides are converted, by fusion with the hyposulphites of potassium and sodium, into sulphocyanates. (Fröhde, p. 514.)

Solutions of hyposulphites give, with *mercuric, plumbic* and *argentic salts*, white precipitates of metallic hyposulphites, which speedily become yellow, brown, and black, especially if heated, owing to the resolution of the hyposulphite into metallic sulphide and sulphuric acid:

$$Ag^2SO^3.H^2O \quad = \quad Ag^2S \ + \ H^2SO^4.$$

With *stannous chloride* they give off a brown, and with *mercurous nitrate, nickel-salts,* and *cobalt-salts,* a black precipitate of metallic sulphide.—With *ferrous salts* they give no precipitate, even at the boiling heat, under the ordinary atmospheric pressure; but by prolonged heating to 130°—140° in sealed tubes, the iron is completely precipitated as sulphide.—*Zinc* is but partially precipitated even at 120°, and *manganese* not at all, unless iron is also present, in which case a manganiferous sulphide of iron is thrown down under increased pressure (Wolcott Gibbs, Sill. Am. J. xxxvii. 346; Jahresb. 1864, p. 183).—When a soluble hyposulphite is boiled with an *aluminium-salt,* alumina and sulphur are precipitated, sulphurous oxide is evolved, and the acid of the aluminium-salt remains in solution combined with the base of the hyposulphite (Chancel, i. 185); *e.g.*:

$$3Na^2S^2O^3 \ + \ Al^2(SO^4)^3 \quad = \quad Al^2O^3 \ + \ S^3 \ + \ 3SO^2 \ + \ 3Na^2SO^4.$$

According to Gibbs, the precipitation is accelerated by heating under increased pressure, and the precipitated alumina is then insoluble in dilute sulphuric acid, and nearly insoluble in cold concentrated hydrochloric acid.

Hyposulphites heated with *hydrochloric acid,* give off sulphurous oxide and deposit sulphur, which in this case is yellow, not white, as it usually is when precipitated from solution. When treated with *iodine,* they form a metallic iodide and a tetrathionate, thus:

$$2Ba''S^2O^3 \ + \ I^2 \quad = \quad Ba''I^2 \ + \ Ba''S^4O^6.$$

These two reactions distinguish hyposulphurous from sulphurous acid. The reaction with iodine is sometimes used for the volumetric estimation of that substance (Brown, Chem. Soc. Qu. J. x. 71).—Hyposulphites treated with *hypochlorite of sodium,* or with chlorine in presence of water, are completely converted into sulphates even at ordinary temperatures; *e.g.*:

$$Na^2S^2O^3 \ + \ Cl^8 \ + \ 5H^2O \quad = \quad 8HCl \ + \ 2NaHSO^4.$$

Hyposulphites are oxidised by *permanganate of potassium,* and converted into sulphates and hyposulphates: in an alkaline solution, 1 at. hyposulphite of sodium takes up exactly 4 at. oxygen, and is converted into sulphate: $Na^2S^2O^3.H^2O + O^4 = 2NaHSO^4$ (Péan-de-St-Gilles, Ann. Ch. Phys. [3], lv. 374; Jahresb. 1858, p. 583). Neutral chromates are not decomposed by sodic hyposulphite even at the boiling heat; but *acid chromates* are reduced to neutral chromates, especially on heating, with separation of CrO^2. (E. Kopp, Jahresb. 1864, p. 233.)

Hyposulphites treated with *zinc* and *hydrochloric acid,* yield free sulphur and a large quantity of sulphydric acid. This reaction is extremely delicate, serving, according to E. J. Reynolds (Chem. News, viii. 283) for the detection of $\frac{1}{500.000}$th part of sodic hyposulphite in a solution, if a piece of paper moistened with acetate of lead be exposed to the evolved sulphydric acid.

All hyposulphites are decomposed by heat, those of the alkali-metals into a polysulphide and a sulphate; *e.g.*:

$$4Na^2S^2O^3 \quad = \quad 3Na^2SO^4 \ + \ Na^2S^5.$$

Those which contain water of crystallisation (*e.g.*, the potassium-, sodium-, and barium-salts) do not give it up till they are heated nearly to the point (about 220°) at which decomposition begins. (Pape, Jahresb. 1864, p. 57.)

To detect hyposulphurous acid in presence of sulphydric acid or a soluble sulphide, the solution is made neutral and precipitated by a zinc-salt, the sulphide of zinc filtered off, and the filtrate tested for hyposulphurous acid.

Soluble hyposulphites, especially the sodium-salt, are much used for fixing photographic pictures, which they effect by dissolving out the chloride of silver which has not been acted upon by light. The sodium-salt is also largely employed as an antichlore, for removing the last traces of chlorine from bleached fabrics. On the use of soluble hyposulphites as mordants in calico-printing, see E. Kopp (Dingl. pol. J. cl. 383).

Hyposulphite of Ammonium, $3(NH^4)^2S^2O^3.H^2O$ (Rammelsberg), is obtained by decomposing the calcium-salt with carbonate of ammonium, and separates, by evaporation, in very deliquescent needles or rhombic plates.

Hyposulphite of Barium, $Ba''S^2O^3.H^2O$ or $Ba''H^2S^2O^4$, is obtained, by mixing the solution of the sodium-salt with acetate of barium, as a white precipitate, the separation of which may be completed by addition of alcohol. It retains its water of crystallisation with great tenacity (H. Rose, Pogg. Ann. xxi. 437); gives it off at 215°, and decomposes at 220°—225° (Pape). The anhydrous salt, when heated to redness, gives off sulphur, and leaves a residue of sulphide, sulphite, and sulphate of barium (Rammelsberg, Pogg. Ann. lvi. 300):

$$6Ba''S^2O^3 = Ba''S + 2Ba''SO^3 + 3Ba''SO^4 + S^4.$$

Hyposulphite of Cadmium, obtained by mixing the solutions of cadmic sulphate and baric hyposulphite, is extremely soluble in water and in alcohol, and when concentrated by evaporation decomposes before solidifying.

Hyposulphite of Calcium, $Ca''S^2O^3.6H^2O$, or $Ca''H^2S^2O^4.5H^2O$.—This salt is usually prepared by boiling sulphur with milk of lime, and passing sulphurous acid gas into the solution of calcic sulphide thereby produced, till it becomes colourless and neutral:

$$2Ca''S + 3SO^2 = S + 2Ca''S^2O^3.$$

On evaporating the solution, at a temperature below 60°, the hyposulphite of calcium crystallises out (Herschel). This process is used on the large scale.

The sulphide of calcium contained in soda-waste or gas-lime may be converted into hyposulphite and sulphite by atmospheric oxidation. Messrs. Townshend and Walker employ for this purpose the soda-waste obtained in the lixiviation of crude soda (i. 793; v. 325), which contains a considerable quantity of insoluble calcic sulphide. The oxidation is effected by exposing the waste, in a state of dampness, to the air for some days, occasionally turning it over and sprinkling it with water, or with solution of calcic sulphide. When fully oxidised and lixiviated with water, it yields a solution of calcic hyposulphite and sulphite, the former salt predominating. If the product is lixiviated before the oxidation is complete, a yellow solution is formed, containing sulphide of calcium as well as sulphite and hyposulphite. The complete oxidation may then be effected by causing the yellow solution to percolate slowly through a tower filled with lumps of coke, and having openings at the lower part to admit the air. The sulphite and hyposulphite of calcium thus produced may be obtained in the solid form by evaporation, or merely brought down to the state of concentrated solution, and in either case used as an antichlore. Or the solution may be mixed with sulphate of sodium, whereby a solution of sodic sulphite and hyposulphite is obtained, together with a precipitate of calcic sulphate containing small quantities of sulphite and hyposulphite. This precipitate, dried at a temperature not exceeding 100° C., constitutes the product called "precipitated antichlore." It has been found very valuable in the manufacture of paper, as the hydrated calcic sulphate gives weight and body, while the sulphite and hyposulphite destroy any chlorine present in the paper-pulp (see Richardson and Watts's *Chemical Technology*, vol. i. pt. iii. p. 39).—A somewhat similar process has been patented by Jullion (*ibid.* p. 42), who however subjects the calcic sulphide contained in soda-waste or gas-lime only to partial oxidation, whereby he obtains a yellow solution called "sulphuretted hyposulphite of lime," consisting chiefly of calcic sulphide and hyposulphite. This solution may be decomposed by a strong acid, whereby sulphur is precipitated, and a mixture of sulphurous and sulphydric acid gases is given off, which may be utilised in various ways; or the solution may be treated with sulphurous acid gas, whereby sulphur is precipitated, and the whole of the calcic sulphide converted into hyposulphite.

Hyposulphite of calcium may also be prepared by decomposing chloride of calcium with hyposulphite of sodium, in hot concentrated solution. The liquid, as it cools, deposits a large quantity of sodic chloride; and if it be then concentrated at a temperature below 50°, and allowed to cool to 30°, after all the sodic chloride has separated out, it yields crystals of pure calcic hyposulphite. (Kessler.)

Hyposulphite of calcium crystallises in large, eight-sided, triclinic prisms, exhibiting the combination $\infty P'_{,} . \infty_{,}P' . \infty\breve{P}\infty . \infty\bar{P}\infty . oP$ (Kopp's *Krystallographie*, 2te Auflage, p. 239). It is easily soluble in water, and is decomposed, on heating the solution to 60°, into sulphate of calcium and free sulphur.

Hyposulphite of Cobalt, $Co''S^2O^3.6H^2O$ or $Co''H^2S^2O^4.5H^2O$.—Obtained, as a dark-red crystalline mass, by mixing the solutions of cobalt-sulphate and strontium-hyposulphite, and evaporating. (Rammelsberg.)

Hyposulphites of Copper.—Neither cupric nor cuprous hyposulphite is known in the separate state; but some double salts of cuprous hyposulphite with alkaline hyposulphites have been obtained by mixing the solutions of the latter with cupric salts. Their solutions are colourless, have a sweet taste, yield with alkalis a precipitate of cuprous oxide, and are decomposed by heating with acids.—A *potassium-salt*, $Cu^2K^2S^4O^6.2H^2O$, separates on mixing the solutions of potassic hyposulphite and cupric sulphate or acetate, as a yellow precipitate, which soon turns black, from formation of sulphide of copper, and is completely decomposed by water into sulphide of copper, sulphurous acid, and sulphuric acid. The solution of this double salt in hyposulphite of potassium deposits, on addition of alcohol, an oily liquid, which solidifies to a white salt having the composition $Cu^2K^6S^8O^{12}.3H^2O$ (Rammelsberg).—A *sodium-salt*, containing $Cu^6Na^4S^{10}O^{15}.5H^2O$ (Lenz), is obtained, like the first-mentioned potassium-salt, as a yellow crystalline precipitate, which it is best to wash with water containing acetic acid. From its solution in hyposulphite of sodium, alcohol throws down a white salt, $Cu^2Na^6S^8O^{12}.2H^2O$.—According to Schütte (Compt. rend. xlii. 1257), a salt having the composition $(Cu^2; Cu'')Na^2S^4O^6.NH^3$, is obtained, in small violet needles, by adding a concentrated solution of sodic hyposulphite to an ammoniacal solution of a cupric salt. The crystals are permanent in the air, give off ammonia at 100°, and are decomposed at a stronger heat, also by cold water.—H. Peltzer (Ann. Ch. Pharm. cxxvi. 351; cxxviii. 187; Jahresb. 1863, p. 277) describes a salt having the composition $Cu^2Cu''Na^4S^8O^{12}.2NH^3$, as separating in dark-blue needles or prisms, from a solution of cupric sulphate and sodic hyposulphite in ammonia, or as a violet powder on mixing equal volumes of the solutions of cupric sulphate and sodic hyposulphite both saturated with ammonia. It is decomposed but not dissolved by hot water, dissolves in ammonia and in sodic hyposulphite, and, when heated with potash-ley, yields a precipitate of cupric and cuprous oxides. Acetic acid dissolves the salt with yellowish-green colour, and alcohol throws down from the solution, first a white, then a canary-yellow, tolerably permanent salt, not containing ammonia. Hyposulphite of sodium produces in the acetic solution, after a while, a heavy white precipitate of a cuprous salt containing tetrathionic acid. A strong solution of silver-nitrate forms, in the same liquid, first a grey precipitate, which soon redissolves; then a precipitate which dissolves with blue colour in ammonia, quickly decomposes with formation of silver-sulphide, and gives the reactions of cupric oxide, silver, and hyposulphurous acid.

Hyposulphites of Gold.—*Sodio-aurous hyposulphite*, $AuNa^3S^4O^6.2H^2O$, is produced by mixing the solutions of auric chloride and sodic hyposulphite, and adding alcohol. Its aqueous solution yields, with chloride of barium, a gelatinous precipitate of *bario-aurous hyposulphite*, $Au^2\overset{''}{Ba}{}^3S^8O^{12}$; and this salt, decomposed by sulphuric acid, yields uncrystallisable hydrated *aurous hyposulphite*. A *sodio-auric hyposulphite* appears also to be formed by dropping a neutral solution of auric chloride into a solution of sodic hyposulphite (Fordos and Gélis). See Gold (ii. 931).

Hyposulphites of Iron.—The *ferric salt* is not known.—*Ferrous hyposulphite*, $2Fe''S^2O^3.5H^2O$, is produced, together with the sulphite, by dissolving iron in aqueous sulphurous acid. On evaporating the solution, or mixing it with alcohol, the sulphite separates out; and the mother-liquor, when further evaporated, yields crystals of ferrous hyposulphite, which are more stable than those of the sulphite, and may be kept unaltered if excluded from the air. Rammelsberg obtained the salt in small green crystals, mixed with a basic ferric salt, by mixing the solution of ferrous sulphate with hyposulphite of barium or strontium. On attempting to concentrate the salt further in contact with the air, a small quantity of ferric salt is first formed, which then acts upon the hyposulphite, converting it into ferrous tetrathionate, and the latter is resolved by further evaporation into ferrous sulphate, sulphurous acid, and sulphur. (Fordos and Gélis.)

Hyposulphite of Lead, $Pb''S^2O^3$, is a white precipitate, very sparingly soluble in water, but dissolving in alkaline hyposulphites, with formation of double salts. It may be dried at 100° without decomposition; but at a stronger heat, it blackens and gives off sulphurous oxide, and leaves a residue of sulphide and sulphate of lead. When heated in the air, it glows like tinder.

Ammonio-plumbic hyposulphite, $Pb''(NH^4)^4S^6O^9.5H^2O$, separates by spontaneous evaporation from its solution, obtained as above, in rhombic prisms shortened into tables. It dissolves in water without immediate decomposition, but the solution becomes cloudy after a while, from separation of plumbic hyposulphite; when heated, it yields sulphide of lead.—*Bario-plumbic hyposulphite* is a sparingly soluble salt, obtained by precipitating the solution of one of the alkaline double salts with acetate of barium.—*Calcio-plumbic hyposulphite*, $Pb''Ca^2S^6O^9.4H^2O$, is obtained in like manner as a crystallo-granular precipitate.—*Potassio-plumbic hyposulphite*, $Pb''K^4S^6O^9.2H^2O$, is prepared by agitating the recently precipitated lead-salt with a dilute and warm (but not boiling) solution of potassic hyposulphite. On cooling, the entire liquid solidifies to a thick magma of small crystals, which must be purified by expressing the mother-liquor, as they are decomposed by solution in water, the simple lead-salt then separating in crystalline spangles. The double salt dissolves easily in hyposulphite of potassium, and the lead is but slowly precipitated from the solution by sulphuric acid, sulphur being precipitated at the same time; the solution is not precipitated by soluble sulphates.—*Sodio-plumbic hyposulphite* is prepared in a similar manner. The strontio-plumbic salt is not crystalline, but separates from solution as a syrupy mass.

Hyposulphite of Magnesium, $Mg''S^2O^3.6H^2O$ or $Mg''H^2S^2O^4.5H^2O$, is prepared by boiling a solution of magnesic sulphite with sulphur, and evaporating over oil of vitriol. It forms small triclinic crystals, permanent in the air, and easily soluble. When heated, it melts, gives off water, sulphur, and sulphurous acid, and leaves when ignited a mixture of magnesic sulphate and sulphite with pure magnesia. Jullion prepares it by boiling pulverised soda-waste or gas-lime with carbonate of magnesium, whereby carbonate of calcium and insoluble sulphide of magnesium are produced, rendering the latter soluble by boiling it with sulphur or an alkaline polysulphide, and converting the soluble sulphide of magnesium into hyposulphite by treating the solution with sulphurous acid.—*Ammonio-magnesic hyposulphite*, $Mg''(NH^4)^2S^4O^6.6H^2O$, is obtained by decomposing ammonio-magnesic sulphite with hyposulphite of strontium. The concentrated solution becomes turbid when heated, and when cooled below the freezing-point of water, deposits very deliquescent crystals (Kessler).—*Potassio-magnesic hyposulphite*, $Mg''K^2S^4O^6.6H^2O$, is deposited from a hot solution of equivalent quantities of potassic and magnesic hyposulphites, in very soluble deliquescent crystals, which may be obtained of considerable size by immersing previously-formed crystals in the concentrated solution.

Hyposulphite of Manganese is known only in solution, and is produced by decomposing the barium- or strontium-salt with manganous sulphate; also (according to Rammelsberg) by dissolving recently precipitated sulphide of manganese in aqueous sulphurous acid. It is decomposed by evaporation into sulphur and manganous sulphur.

Hyposulphites of Mercury.—*Potassio-mercuric hyposulphite*, $Hg^3K^{10}S^{16}O^{24}$, is produced by dissolving mercuric oxide in hyposulphite of potassium. The liquid becomes warm, and on cooling deposits the double salt in colourless, sparingly soluble prisms. Acids decompose it, separating sulphur and sulphide of mercury. Iodide of potassium does not precipitate mercuric iodide from the solution.—*Ammonio-mercuric hyposulphite*, which is very easily decomposible, is separated from its solution by alcohol in colourless prisms.—The *sodio-mercuric salt* is not crystallisable.

Hyposulphite of Nickel, $Ni''S^2O^3.6H^2O = Ni''H^2S^2O^4.5H^2O$, prepared like the cobalt-salt, separates, by evaporation over oil of vitriol, in green triclinic crystals, which when heated give off water, sulphur, and sulphurous acid, leaving sulphide of nickel.—*Ammoniacal Hyposulphite of Nickel*, $Ni''S^2O^3.4NH^3.6H^2O$, is obtained, as a blue crystalline powder, when the blue ammoniacal solution of the preceding salt is mixed with alcohol. It decomposes quickly when exposed to the air.

Hyposulphites of Platinum.—Neither platinous nor platinic sulphite is known in the separate state.—*Sodio-platinous hyposulphite*, $Pt''Na^6S^8O^{12}.10H^2O$, is produced by dissolving ammonio-platinous chloride in a strong solution of sodic hyposulphite; and may be separated, by addition of absolute alcohol, as a dense, yellow, oily liquid, which gradually solidifies to a yellow crystalline mass. When purified by two more precipitations with alcohol, it forms a yellow noncrystalline mass, very soluble in water. Its solution is decomposed by hydrochloric acid, slowly in the cold, quickly when heated, with deposition of platinous sulphide and evolution of sulphurous oxide. It is not decomposed by caustic soda, or by sulphuretted hydrogen. (Schottländer, Ann. Ch. Pharm. cxl. 200; Bull. Soc. Chim. 1867, i. 403.)

Hyposulphite of Potassium, $K^2S^2O^3$.—This salt, which crystallises with various proportions of water, is prepared by boiling a concentrated solution of potassic sulphites with excess of sulphur, or by adding a hot solution of potassic dichromate by small portions to a hot solution of potassic pentasulphide, waiting after each addition till the separated chromic oxide has acquired a pure green colour (Döpping; Kessler). If the solution obtained by either of these methods be evaporated to 30°, the salt crystallises in very thin four-sided prisms, containing $3K^2S^2O^3.H^2O$. These crystals are very soluble in water, and deliquescent, but insoluble in alcohol. They give off their water at 200°, and the anhydrous salt decomposes, at a higher temperature, into a mixture of 1 at. potassic pentasulphide and 3 at. potassic sulphate. (Rammelsberg.)

The mother-liquor decanted from these prisms yields, if briskly stirred or shaken when cold, a quantity of small granular crystals; and if these be redissolved in the solution from which they have separated, with addition of a little water, the liquid on cooling deposits large colourless crystals, having a rhombic octahedron for their primary form. They contain 13·62 per cent. water, and, according to Kessler, consist of $3K^2S^2O^3.5H^2O$, or $3KHSO^2.H^2O$; according to Döpping, of $2K^2S^2O^3.3H^2O$ or $4KHSO^2.H^2O$. These crystals do not deliquesce in moderately damp air, but effloresce immediately over oil of vitriol, or when heated above 40°. This salt dissolves very easily in water, and with great depression of temperature; the solution is neutral, and remains unaltered even in contact with the air. Sometimes these octahedral crystals separate directly from solution either before or after the prismatic crystals, and they are always formed when an octahedral crystal is immersed in a solution of the salt evaporated at 30°.

Döpping mentions also a prismatic salt containing 8½ per cent. of water, and having the composition $K^2S^2O^3.H^2O$ or $KHSO^2$; this, however, Kessler was not able to obtain.

Plessy's salt, $K^2S^2O^3.2H^2O = 2KHSO^2.H^2O$, is regarded by Kessler as identical with the octahedral salt.

The compound $K^2S^2O^3.Hg''Cy$ was once obtained by Kessler, on mixing the solutions of equivalent quantities of potassic hyposulphite and mercuric cyanide, adding alcohol after a crystalline precipitate (probably consisting of potassio-mercuric hyposulphite and potassio-mercuric cyanide) had separated, and evaporating the mother-liquor in a vacuum. It crystallises in large four-sided prisms, which give off 2 per cent. water over oil of vitriol.

Hyposulphite of Silver.—This salt, on account of its extreme instability, is scarcely known in the separate state; but it forms two series of double salts, $R^4Ag^2S^6O^9$ and $RAgS^2O^3$ (R denoting an alkali-metal), prepared by dissolving silver-oxide in an alkaline hyposulphite, or by adding chloride or nitrate of silver to the solution of the alkaline hyposulphite. The salts of the first series dissolve easily in water, and are precipitated therefrom by alcohol; but those of the second series are insoluble or sparingly soluble in water, and separate, in crystalline or pulverulent form, when the salts of the first series are treated with an additional quantity of silver-salt.

These insoluble double salts dissolve easily in ammonia, and the ammoniacal solutions, as well as the aqueous solutions of the double salts of the first series, have an intensely sweet taste. The solutions may be used for silvering; the silver cannot be detected in any of them by hydrochloric acid. All these double salts decompose easily when heated, yielding sulphide and sulphate of silver: hence, in preparing them, the temperature must be kept as low as possible. They are likewise decomposed by alkalis, and by an excess of the alkaline hyposulphite.

Sodio-argentic hyposulphite, $Ag^2Na^4S^6O^9.2H^2O$, is produced by dropping a solution of sodic hyposulphite, with constant stirring, into a solution of silver-nitrate, till a permanent precipitate is formed, and separates in shining laminæ on adding alcohol to the liquid. If, instead of adding alcohol, the addition of the silver-salt be continued, the salt, $AgNaS^2O^3.H^2O$, separates in flocks, which soon become crystalline. (Herschel; Lenz.)

The ammonio-, potassio-, calcio-, strontio-, and plumbo-argentic hyposulphites may be prepared by similar processes. (Herschel.)

Hyposulphite of Sodium, $Na^2S^2O^3.5H^2O$, or $NaHSO^2.2H^2O$.—This salt, which is extensively used as an antichlore, and for fixing photographic pictures, is prepared:—1. By boiling sulphur with soda-ley, and passing sulphurous gas into the solution till it is completely decolorised (p. 630).—2. By igniting sulphate of sodium with charcoal, at a temperature not high enough to fuse the mass, moistening the pulverulent carbonaceous mass with water, and subjecting it to the action of sulphurous acid gas. (Anthon, Pharm. Centr. 1846, p. 414.)

3. By roasting a mixture of sulphur and sodic carbonate in a sulphur-furnace, and adding the product to a boiling solution of sulphur in caustic soda-ley, till the liquid becomes colourless. The clarified solution is then evaporated in iron pans, and the sulphate of sodium which separates is continually taken out. The concentrated liquid deposits hyposulphite of sodium in large pure crystals, and the mother-liquor, mixed with caustic soda, is used for dissolving fresh portions of sulphur. (Jahresb. 1862, p. 664.)

4. By decomposing the hyposulphite of calcium obtained from soda-waste or

gas-lime (p. 632) with carbonate of sodium, and evaporating the filtered solution to the crystallising point. (Richardson and Watts's *Chemical Technology*, vol. i. pt. iv. p. 185.)

Hyposulphite of sodium forms large, well-defined, monoclinic crystals, usually exhibiting the combination $\infty P . [\infty P2] . [\infty P\infty] . oP . [P\infty]$, also with $+ P$ and other faces subordinate. Axes $a : b : c = 2{\cdot}8507 : 1 : 0{\cdot}7825$. Angle $b : c = 76° 2'$; $\infty P : \infty P$ (orthod.) $= 37° 36'$; $[\infty P2] : [\infty P2]$ (orthod.) $= 68° 30'$; $[P\infty] : [P\infty]$ (clinod.) $= 150° 10'$. The crystals have a specific gravity of 1·672 (Buignet), dissolve easily in water, but are insoluble in alcohol. Respecting the specific gravity of its solutions, see Schiff (Jahresb. 1859, p. 41). The aqueous solution cannot be preserved unaltered even in closed vessels, but deposits sulphur, and is partly converted into sulphate of sodium; in contact with the air, it is gradually but completely oxidised to sulphate. The dry salt when heated gives off sulphur, and leaves a mixture of sulphide and sulphate of sodium. The crystals melt in their water of crystallisation at 56°; and if the fusion be performed in a small glass flask, the temperature raised to the boiling-point, the flask then immediately closed, and left to cool quickly on a surface which conducts heat slowly, the salt will remain liquid even at ordinary temperatures; but on immersing the bulb of a thermometer, or dropping a crystal into it, the whole will instantly solidify to a crystalline mass, with a rise of temperature which may amount to 25°. (Böttger.)

A saturated solution of sodic hyposulphite dissolves gypsum with moderate facility at ordinary temperatures, more quickly when gently heated, forming a sodio-calcic hyposulphite, which is precipitated by alcohol, together with excess of sodic hyposulphite, as a heavy oily liquid, which solidifies in needle-shaped crystals. This reaction affords the means of separating sulphate of calcium from sulphate of barium, which is not dissolved by hyposulphite of sodium (Diehl, J. pr. Chem. lxxix. 430; Jahresb. 1860, p. 78). For the reactions with other metallic salts, see p. 631.

Hyposulphite of Strontium, $Sr''S^2O^3.6H^2O$, is prepared like the barium-salt. Alcohol precipitates it from its solution in needles having a silky lustre; but even without the aid of alcohol, it separates in very large crystals. It retains 1 at. water at 180°, and, according to Kessler, the monohydrated salt is likewise obtained in small crystals, by evaporating the solution at or above 50°.

Hyposulphite of Thallium and Sodium, $Tl^4Na^6S^{10}O^{15}.10H^2O$ or $2Tl^2S^2O^3.3Na^2S^2O^3.10H^2O$, is formed by dissolving chloride of thallium in boiling aqueous hyposulphite of sodium, and crystallises in long, silky, interlaced needles,—or from a small quantity of water in small granules (containing an unknown amount of water). At a red heat, it is resolved into sulphide of sodium, sulphate of sodium, and sulphide of thallium. (G. Werther, J. pr. Chem. xci. 385.)

Hyposulphite of Zinc, $Zn''S^2O^3$, is produced by decomposing the barium-salt with sulphate of zinc; also, though with difficulty, by passing sulphurous acid gas into water in which sulphide of zinc is suspended (Rammelsberg); also, together with sulphite of zinc, by dissolving zinc in aqueous sulphurous acid (Mitscherlich). The sulphite crystallises out, and may be completely removed by alcohol; or (according to Berzelius), it may be wholly converted into hyposulphite by digesting the solution with sulphur.

Hyposulphite of zinc cannot be obtained in the crystalline form, but (according to Köne) it is precipitated by anhydrous ether from its aqueous solution, as an oily liquid, which dries up in a vacuum to a gummy deliquescent mass. The concentrated solution is gradually decomposed by exposure to the air, sulphide of zinc being separated, while trithionate of zinc remains in solution: $2Zn''S^2O^3 = Zn''S + Zn''S^3O^6$ (Fordos and Gélis, Compt. rend. xvi. 1070). The solution is also decomposed by heat into sulphuric acid, sulphurous acid, sulphide of zinc, and sulphate of zinc.

Hyposulphite of Zinc-ammonium, $(N^2H^6Zn)''S^2O^3$, is produced by heating hyposulphite of zinc with ammonia, and separates from the solution in slender crystals. (Rammelsberg.)

Dithionic Compounds.

DITHIONIC OR HYPOSULPHURIC ACID, $H^2S^2O^6$. (Welter and Gay-Lussac, Ann. Ch. Phys. [2], x. 312.—Heeren, Pogg. Ann. vii. 55.—Rammelsberg, *ibid.* lviii. 295.)—This acid, discovered by Welter in 1819, is produced as a manganous salt by the action of aqueous sulphurous acid on manganic peroxide:

$$MnO^2 + 2H^2SO^3 = Mn''S^2O^6 + 2H^2O.$$

To prepare the acid, sulphurous oxide gas is passed through water in which finely-divided manganic peroxide is suspended, as long as it continues to be absorbed.

Dithionate and sulphate of manganese are then formed, the dithionate being the principal product, provided the temperature be kept down; at higher temperatures, on the contrary, scarcely anything but sulphate is produced. On adding hydrate of barium to the impure solution of manganous dithionate, hydrate of manganese and sulphate of barium are precipitated, while dithionate of barium remains in solution; and by carefully precipitating the barium with an exactly sufficient quantity of sulphuric acid, a solution of dithionic acid is obtained, which may be concentrated in a vacuum over oil of vitriol, till it attains a specific gravity of 1·347 (Gay-Lussac; Heeren). Gélis (Ann. Ch. Phys. [3], lxv. 222) passes sulphurous oxide through water in which ferric hydrate is suspended, whereby a solution of ferric sulphite, $\mathrm{Fe^2(SO^3)^3}$, is produced; and this solution, when kept in a closed vessel, acquires after some time a light-green colour, and then contains a mixture of ferrous sulphite and dithionate:

$$\overset{\prime\prime\prime}{\mathrm{Fe}}{}^{2}\mathrm{(SO^3)^3} \;=\; \mathrm{Fe''SO^3} + \mathrm{Fe''S^2O^6}.$$

From this solution, the dithionic acid may be separated, by means of hydrate of barium, &c., in the manner above described.

Dithionic acid, when concentrated as highly as possible, is an inodorous, strongly acid, hydrated liquid, of specific gravity 1·347; on attempting to concentrate it further, it is resolved into sulphuric acid and sulphurous oxide: $\mathrm{H^2S^2O^6 = H^2SO^4 + SO^2}$. The dilute acid decomposes in the same manner at higher temperatures. In contact with the air, dithionic acid is gradually oxidised to sulphuric acid; the same change is produced by heating it with nitric acid, chlorine, or manganic peroxide.

Dithionates or Hyposulphates, $\mathrm{M^2S^2O^6}$.—These salts, investigated chiefly by Heeren, are all soluble in water, and are easily prepared by decomposing the barium-salt with the corresponding sulphates. The dithionates of the alkali-metals may also be obtained by dissolving the carbonates in sulphurous acid, boiling the neutral solution with finely pulverised manganic peroxide, and leaving the filtrate to crystallise (C. v. Hauer, J. pr. Chem. lxxx. 229). They are likewise produced, together with hyposulphites, when selenium is dissolved in an alkaline sulphite. (Rathke and Zschiesche, p. 630.)

The dithionates are permanent at ordinary temperatures, both in the solid state and in solution; but when heated, in some cases even at 100°, they give off sulphurous oxide, and leave a residue of neutral sulphate. The solid dithionates are decomposed by strong *sulphuric acid*, at ordinary temperatures, with brisk evolution of sulphurous oxide; the solutions, mixed with *sulphuric* or *hydrochloric acid*, are decomposed at the boiling heat, yielding sulphurous and sulphuric acids, *without separation of sulphur*: this reaction is characteristic of the dithionates. A solution of *potassic manganate* mixed with sulphuric acid is decolorised when boiled with a dithionate. Solid dithionates are decomposed by *phosphoric oxychloride* only when heated. The dry sodium-salt, distilled with *phosphoric pentachloride*, yields a distillate consisting of phosphoric oxychloride and sulphurous chloride, $\mathrm{SOCl^2}$. (Kraut, Ann. Ch. Pharm. cxviii. 95.)

Dithionate of Aluminium separates from its solution by slow evaporation in small crystals, mixed however with a considerable quantity of sulphate. (Heeren.)

Dithionate of Ammonium, $\mathrm{(NH^4)^2S^2O^6.H^2O}$, forms indistinct capillary crystals, very soluble in water, insoluble in alcohol.

Dithionate of Barium, $\mathrm{Ba''S^2O^6}$, prepared as above described, crystallises from the hot saturated solution on cooling, in crystals containing $\mathrm{Ba''S^2O^6.2H^2O}$, which, according to Sénarmont (Jahresb. 1857, p. 142), are trimetric, exhibiting the combination: $\infty\bar{P}\infty \,.\, \infty\breve{P}\infty \,.\, P \,.\, oP \,.\, \frac{1}{2}\bar{P}\infty \,.\, \frac{1}{3}\breve{P}\infty$, and having the axes $a : b : c = 0{\cdot}7199 : 1 : 0{\cdot}6920$; angle $P : \infty\breve{P}\infty = 128° 20'$; $P : oP = 130° 10'$. Rammelsberg also found them to be trimetric with nearly the same ratio of the axes. But, according to the measurements of v. Lang (Wien. Akad. Ber. [2], xlv. 27; Jahresb. 1862, p. 126), made upon well-developed specimens, these dihydrated crystals are monoclinic, exhibiting the combination $oP \,.\, [\infty P\infty] \,.\, +2P\infty \,.\, [P\infty] \,.\, +2P \,.\, [\frac{4}{3}P2] \,.\, [\infty P2] \,.\, +P \,.\, +[P\frac{9}{7}] \,.\, -[P\frac{9}{7}]$. Axes $a : b : c = 1 : 0{\cdot}9343 : 1{\cdot}4030$. Angle $b : c = 110° 37'$; $oP : +P\infty = 108° 22'$; $oP : +P = 103° 45'$; $+P : [P\infty] = 132° 12'$; $[\frac{4}{3}P2] : +2P\infty = 116° 14'$; $[P\frac{9}{7}] : [P\infty] = 118° 41'$; $[P\frac{9}{7}] : +P = 143° 22'$.—A *tetrahydrate*, $\mathrm{Ba''S^2O^6.4H^2O}$, is obtained, by spontaneous evaporation, in distinct, shining, monoclinic crystals, which effloresce quickly on exposure to the air. (Hoeren; Marignac). Dithionate of barium serves, as above mentioned, for the preparation of the other dithionates.

Dithionate of Barium and Magnesium, $\mathrm{Ba''Mg''S^4O^{12}.4H^2O}$, is obtained (according to Schiff, Ann. Ch. Pharm. cv. 239), by precipitating half the barium from baric dithionate with sulphuric acid, saturating the filtrate with magnesia, and evaporating; the double salt then separates on cooling in crystalline geodes, which give off their water completely at 90°.

Dithionate of Barium and Sodium, $\mathrm{Ba''Na^2S^4O^{12}.6H^2O}$, is produced (according to

Schiff), by decomposing the barium-salt with a calculated quantity of sodic sulphate. Kraut (Ann. Ch. Pharm. cxviii. 95), by mixing equivalent quantities of baric and sodic dithionates, obtained large transparent crystals, with curved edges and convex faces, containing $Ba''Na^2S^4O^{12}.4H^2O$, which were permanent in the air, and not resolved into the component salts by recrystallisation; he regards the salt obtained by Schiff as merely a mixture.

Dithionate of Cadmium is obtained, as a crystalline deliquescent mass, by evaporating a solution of the carbonate in dithionic acid (Heeren). It dissolves in ammonia, and the solution on cooling yields a crystalline powder, consisting of the salt $Cd''S^2O^6.4NH^3$ mixed with hydrate of cadmium. (Rammelsberg.)

Dithionate of Calcium, $Ca''S^2O^6.4H^2O$, prepared like the barium-salt, crystallises by spontaneous evaporation in tabular crystals, belonging to the hexagonal system and exhibiting the combination oP : P (*fig.* 239, ii. 139). Length of principal axis = 1·485. Angle P : P (terminal) = 128° 49′; P : P (lateral) = 119° 30′. According to Nörrenberg, they are optically negative. They are permanent in the air, and insoluble in alcohol. (Heeren.)

The *Dithionates of Cerium, Lanthanum*, and *Didymium*, obtained by double decomposition, are crystallisable.

Dithionate of Chromium, $\overset{'''}{Cr^2}S^6O^{18}$, is obtained by dissolving chromic hydrate in aqueous dithionic acid.

Dithionate of Cobalt, $Co''S^2O^6.6H^2O$, separates on evaporation in rose-coloured crystals (Heeren). By treating the solution with ammonia and evaporating, Rammelsberg obtained the salt $Co^2O^3.2S^2O^5.10NH^3$, in small rectangular prisms, which after a while turned brown, and lost their lustre.

Dithionates of Copper.—The normal cupric salt, $Cu''S^2O^6.4H^2O$, forms small, rhombic, efflorescent prisms.—A *basic salt*, $Cu''S^2O^6.3Cu''O.4H^2O$, is obtained, as a blue-green precipitate, on mixing the solution of the normal salt with a small quantity of ammonia (Heeren).—An *ammoniacal cupric dithionate*, $Cu''S^2O^6.4NH^3$, is obtained in thin, tabular, violet-blue prisms with oblique end-faces, by supersaturating the solution of the normal cupric salt with ammonia. (Heeren.)

Dithionates of Iron.—A *basic ferric dithionate* is produced (according to Heeren), by treating recently precipitated ferric hydrate with the aqueous acid, which, however, dissolves but little of it, the greater part being converted into an insoluble, brown, basic salt.—The *ferrous salt*, $Fe''S^2O^6.5H^2O$, obtained by double decomposition, crystallises on evaporation in oblique rhombic prisms, having the colour of ferrous sulphate.

Dithionate of Lead, $Pb''S^2O^6.4H^2O$, prepared by dissolving carbonate of lead in aqueous dithionic acid, forms large crystals belonging to the hexagonal system, isomorphous with the calcium- and strontium-salts, but exhibiting also the face ¼P, occurring hemihedrally with P. The crystals are permanent in the air, optically uniaxial and positive (Nörrenberg). The solution of this salt mixed with a quantity of ammonia, not sufficient for its complete decomposition, yields slender needles of a *diplumbic salt*, $Pb''S^2O^6.Pb''O$; with an excess of ammonia, a still more basic salt is produced. (Heeren.)

Dithionate of Lithium, $Li^2S^2O^6.2H^2O$, forms indistinct crystals, easily soluble in water, insoluble in alcohol. (Rammelsberg.)

Dithionate of Magnesium, $Mg''S^2O^6.6H^2O$, forms six-sided tables, permanent in the air, and very soluble in water.

Dithionate of Manganese, $Mn''S^2O^6.6H^2O$, prepared as already described (p. 636), crystallises, by spontaneous evaporation, in rose-coloured, mostly indistinct, deliquescent crystals (Marignac). According to Kraut (Jahresb. 1861, p. 118), it forms crystals containing 3 at. water. According to Guthe, these crystals are trimetric, exhibiting the combination $P \,.\, \infty\breve{P}\infty \,.\, \infty\bar{P}2$. Angles P . P in the terminal edges = 90° 32′ and 139° 36′; whence $\infty P : \infty P$ (macr.) = 31° 6′; $\infty\breve{P}2 : \infty\breve{P}2$ (macr.) = 91° 13′.

Dithionates of Mercury.—The mercurous salt, $Hg^2S^2O^6$, separates in colourless indistinct crystals, on evaporating a solution of recently precipitated mercurous oxide in the aqueous acid. It dissolves with difficulty in cold water, and is decomposed by hot water. When heated, it is resolved into mercury, sulphurous oxide, and sulphate of mercury (Rammelsberg).—A *basic mercuric dithionate* appears to be formed by digesting aqueous dithionic acid with excess of mercuric oxide.

Dithionate of Nickel, $Ni''S^2O^6.6H^2O$, separates by spontaneous evaporation in large, thin, green prisms. Its solution mixed with ammonia deposits the ammoniacal salt, $Ni''S^2O^6.6NH^3$, as a blue powder, which crystallises from solution in warm aqueous ammonia, in tabular prisms of a fine violet-blue colour; it is decomposed by water.

Dithionate of Potassium, $K^2S^2O^6$, prepared by decomposing the baric or manganous salt with an exactly equivalent quantity of potassic carbonate (or the baric salt with potassic sulphate), separates on evaporation, in crystals which are permanent in the air, decrepitate when heated, and are resolved at higher temperatures into sulphurous oxide and sulphate of potassium. It dissolves in 16 pts. of cold and 1½ pts. boiling water, but is insoluble in alcohol. (Heeren.)

Dithionate of Rubidium, $Rb^2S^2O^6$, crystallises isomorphously with the potassium-salt, in hard glassy crystals, belonging to the hexagonal system, and exhibiting the combination $\infty P \,.\, \infty P2 \,.\, oP \,.\, P \,.\, 2P2$. Length of principal axis = 0·6307. Angle P : P (terminal) = 145° 46′; P : P (lateral) = 72° 8′. (Piccard, J. pr. Chem. lxxxvi. 449.)

Dithionate of Silver, $Ag^2S^2O^6.2H^2O$.—Prepared by dissolving carbonate of silver in the aqueous acid, and crystallises in right rhombic prisms, permanent in the air (Heeren). By evaporating a solution of the salt mixed with sulphurous acid, at a temperature not exceeding 5°, Kraut obtained it in large crystals containing 6 or 7 at. water. Its solution in warm aqueous ammonia yields small shining crystals of the salt $Ag^2S^2O^6.4NH^3.H^2O$. (Rammelsberg.)

Dithionate of Sodium, $Na^2S^2O^6.2H^2O$, prepared like the potassium-salt, crystallises by spontaneous evaporation, in large, transparent, right rhombic prisms, permanent in the air, having a bitter taste, easily soluble in water, insoluble in alcohol (Heeren). It is optically biaxial and positive, and exhibits considerable dispersion, the angle of the axes being, in the air, for red light, 126° 25′, for violet, 134° 40′.

Dithionate of Sodium and Silver, $AgNaS^2O^6.2H^2O$, is obtained by spontaneous evaporation of a solution containing equivalent proportions of sodic and argentic dithionates, and recrystallisation, in large crystals, apparently isomorphous with its component salts, and exhibiting very distinct cleavage. They effloresce over oil of vitriol, but not in the open air. (Kraut.)

Dithionate of Strontium, $Sr''S^2O^6.H^2O$, prepared like the barium-salt, forms hexagonal crystals, isomorphous with the calcium- and lead-salts, and indistinctly cleavable parallel to oP. The crystals are permanent in the air, easily soluble in water, exhibit negative double refraction, and strong dispersion.

Dithionate of Thallium, $Tl^2S^2O^6$, is very soluble in water, and separates in vitreous tabular crystals, apparently isomorphous with the potassium-salt. (G. Werther, J. pr. Chem. xci. 385.)

The *Dithionates of Yttrium, Erbium*, and *Terbium* are crystallisable.

Dithionate of Zinc, $Zn''S^2O^6.6H^2O$.—This salt is very soluble in water, and its solution rarely yields distinct crystals (Heeren). Its solution in warm, concentrated, aqueous ammonia deposits, on cooling, small prisms of the salt $Zn''S^2O^6.4NH^3$. (Rammelsberg.)

Trithionic Compounds.

TRITHIONIC ACID, $H^2S^3O^6$. *Sulphuretted Hyposulphuric Acid.* (Langlois, Ann. Ch. Phys. [2], lxxix. 77.—Pelouze, *ibid.* lxxix. 85.—Kessler, Pogg. Ann. lxxiv. 250.)—This acid, discovered by Langlois in 1842, is obtained as a potassium-salt:—1. By gently heating an aqueous solution of acid potassic sulphite with sulphur:

$$\underset{\text{Acid sulphite.}}{6KHSO^3} + S^2 = \underset{\text{Trithionate.}}{2K^2S^3O^6} + \underset{\text{Hyposulphite.}}{K^2S^2O^3} + 3H^2O.$$

A saturated solution of the acid sulphite is digested with sulphur for some days at a moderate heat, till the yellow colour at first produced has disappeared. Sulphurous oxide is then evolved, and trithionate of potassium is left in solution, mixed with hyposulphite and sulphate (the latter resulting from the decomposition of the trithionate by heat). The warm filtered solution yields crystals of the trithionate, mixed with sulphur and a small quantity of sulphate: they may be purified by dissolving them in the smallest possible quantity of lukewarm water, and leaving the filtered solution to crystallise by cooling. (Langlois.)

2. By the action of sulphurous acid on hyposulphite of potassium:

$$2K^2S^2O^3 + 3SO^2 = 2K^2S^3O^6 + S.$$

A very concentrated solution of the hyposulphite is prepared by adding it to a mixture of 8 pts. water and 1 pt. alcohol, till the alcohol separates out; and through this solution warmed to 25°—30°, and kept in a state of concentration by frequent addition of the solid salt, sulphurous acid gas is passed, till the liquid turns yellow and smells of sulphurous acid. The liquid then deposits a considerable quantity of crystals of potassic trithionate, after which it becomes colourless, no longer smells of sulphurous acid; and if again saturated with hyposulphite, and treated with sulphurous acid, will yield a fresh quantity of the trithionate. To purify this salt, it is dissolved in water of 60° or 70°; and the solution, freed from sulphur by filtration, is mixed with eight times its volume of alcohol of 84 per cent., then gently warmed, and left to crystallise by cooling (Plessy, Ann. Ch. Phys. [3], xx. 162).—According to Rathke (Jahresb. 1864, p. 164), a mixed solution of hyposulphate and acid sulphite of potassium, yields very pure crystals of the trithionate. Rathke has also observed that the solution which yields these crystals is not precipitated, or but very slightly, by mercuric cyanide at the boiling heat, whereas this salt forms an immediate precipitate in a solution of the crystals themselves, even when very dilute; further, that the original solution, if not too concentrated, does not deposit sulphur on boiling, whereas the solution of the crystals themselves deposits it immediately. Hence Rathke concludes that the trithionate is not contained in the original solution, but is formed only at the moment of crystallisation: this appears also to be the case in the preparation of the salt by Langlois's method.—According to Langlois, a solution of sulphide of potassium may be used in the preceding mode of preparation, instead of the hyposulphite.

3. Chancel and Diacon (Compt. rend. lvi. 720) prepare trithionate of potassium by converting 2 pts. of potassic hydrate into acid sulphite, and 1 pt. into monosulphide; then pouring the former solution, with agitation, into the latter; saturating the mixture with sulphurous acid, evaporating quickly in thin layers, and dissolving the separated salt in water of 60° mixed with a little alcohol. The filtered solution, on cooling, deposits the trithionate in prismatic crystals. Its formation is represented by the equation:

$$4KHSO^3 + K^2S + 4SO^2 = 3K^2S^3O^6 + 2H^2O.$$

Trithionic acid separated from the concentrated solution of its potassium-salt by precipitating the potassium with an equivalent quantity of tartaric, perchloric, or silicofluoric acid, is a limpid inodorous liquid, having a sour and somewhat harsh and bitter taste. It is permanent in the dilute state; but on attempting to concentrate it in a vacuum over oil of vitriol, it begins to decompose, even at 0°, sulphurous oxide being evolved, sulphur deposited, and sulphurous acid remaining in solution: at 80° the decomposition takes place more quickly. By *nitric*, *chloric*, or *iodic acid*, it is immediately converted into sulphuric acid, with separation of sulphur. When boiled with *potash*, it is converted, according to Kessler, into hyposulphite and sulphate of potassium, as shown by the equation:

$$H^2S^3O^6 + 4KHO = K^2S^2O^3 + K^2SO^4 + 3H^2O.$$

According to Fordos and Gélis, the products of the decomposition are hyposulphite and sulphite.

The trithionates $M^2S^3O^6$ and $M''S^3O^6$, are but little known; they appear, however, to be all soluble in water, and are characterised by extreme instability. When heated to redness, or boiled with water, either alone or with addition of the acid, they are converted into sulphates, with evolution of sulphurous oxide and deposition of sulphur. Nitric acid and chlorine-water also quickly convert them into sulphates.

A solution of *silver-nitrate* forms, in a solution of potassic trithionate, a white precipitate, which gradually turns black.—*Mercurous nitrate* immediately forms a black precipitate, which after a while becomes perfectly white, and does not afterwards change colour on boiling. With a small quantity of mercurous nitrate, however, a permanently black precipitate is formed.—*Mercuric chloride* in small quantity produces a black; in excess, a white precipitate.—*Mercuric cyanide* forms no precipitate at first, but after some time a yellow precipitate, which turns black gradually in the cold, immediately on boiling.—*Cupric sulphate* boiled with potassic trithionate produces an immediate separation of sulphide of copper.

Trithionate of Ammonium is produced, together with sulphate, by saturating dry ammonia-gas with dry sulphurous oxide, and dissolving the product in water.

Trithionate of Barium, $Ba''S^3O^6.2H^2O$, is produced (according to Kessler) by saturating the acid with carbonate of barium, and mixing the solution with a large excess of absolute alcohol. The salt then separates in shining laminæ. Its solution decomposes very easily, depositing sulphate of barium.

Trithionate of Potassium, $K^2S^3O^6$, prepared as above described, crystallises in four-sided prisms bevelled with two faces. It has a slightly saline and bitter taste, and is insoluble in alcohol. The aqueous solution is neutral, and is decomposed by heat into sulphur, sulphurous oxide, and sulphate. The dry salt decomposes in like manner at 125°. According to Chancel and Diacon, it is converted by monosulphide of potassium into hyposulphite, without separation of sulphur:

$$K^2S^3O^6 + K^2S = 2K^2S^2O^3.$$

Trithionate of Zinc is produced, with separation of sulphide of zinc, by gradual decomposition of a concentrated solution of the hyposulphite. (Fordos and Gélis.)

Tetrathionic Compounds.

TETRATHIONIC ACID, $H^2S^4O^6$. *Acid hyposulfurique bisulfuré.* (Fordos and Gélis [1843], Ann. Ch. Pharm. xliv. 247.—Kessler, Pogg. Ann. lxxiv. 253.—Chancel and Diacon, Compt. rend. lvi. 510; Jahresb. 1863, p. 150.)—The salts of this acid are produced by the action of iodine on hyposulphites, thus:

$$2Ba''S^2O^3 + I^2 = Ba''I^2 + Ba''S^4O^6.$$

The barium-salt is prepared by adding iodine, in small successive portions, to hyposulphite of barium suspended in a very small quantity of water; after complete saturation, the crystalline pulp is digested with strong alcohol, which dissolves the iodide of barium and excess of iodine, and leaves the tetrathionate in the form of a white powder, which may be purified by dissolving it in the smallest possible quantity of water, and leaving the solution to evaporate. (Fordos.)

A salt of tetrathionic acid is also produced by carefully adding sulphuric acid to a mixture of hyposulphite and peroxide of lead or barium, according to the equation:

$$2PbS^2O^3 + PbO^2 + 2H^2SO^4 = PbS^4O^6 + 2PbSO^4 + 2H^2O;$$

further, by the action of peroxide of lead on pentathionic acid (Chancel and Diacon):

$$4H^2S^5O^6 + 5PbO^2 = 5PbS^4O^6 + 4H^2O.$$

Tetrathionic acid may be prepared by decomposing the barium- or lead-salt with the exact quantity of sulphuric acid required. According to Kessler, the lead-salt is better adapted for the purpose than the barium-salt, because the acid, in presence of strong bases, is apt to decompose, especially at the moment of liberation, into trithionic acid and free sulphur. The lead-salt must be decomposed by sulphuric, not by sulphydric acid, as in the latter case it would be converted partly, or perhaps entirely, into pentathionic acid by the action of the sulphide of lead produced in the reaction.

Tetrathionic acid is a colourless, inodorous, very acid liquid, of about the same degree of stability as dithionic acid. In dilute solution it may be boiled without decomposition, but in the concentrated state it is decomposed by heat into sulphuric acid, sulphurous acid, and sulphur. It is not decomposed by hydrochloric or dilute sulphuric acid in the cold, but a moderately dilute solution, heated with *hydrochloric acid*, gives off sulphuretted hydrogen. When heated with *nitric acid*, it evolves off red fumes, and deposits sulphur.—*Chlorine* converts it into sulphuric acid.

The tetrathionates $M^2S^4O^6$ and $M''S^4O^6$ are all easily soluble in water, but insoluble in alcohol, and are precipitated from their aqueous solutions by alcohol. They are produced either by saturating the acid with bases, or by double decomposition from the lead-salt. The solutions cannot, however, for the most part be evaporated without decomposition, the tetrathionates of the stronger bases being thereby converted into salts of acids containing a smaller proportion of sulphur, and those containing easily reducible bases being resolved into sulphide and sulphate.

Tetrathionic acid and its salts form, with *cupric sulphate*, a brown precipitate after long boiling; with *mercurous nitrate* a yellow precipitate, which slowly blackens on boiling; with *mercuric chloride*, by degrees, a yellowish precipitate, consisting of a compound of chloride and sulphide of mercury mixed with free sulphur; with *mercuric cyanide*, by degrees, a yellow precipitate, which blackens slowly in the cold, immediately on boiling; with *nitrate of silver*, a yellow precipitate, which soon turns black. When tetrathionic acid is supersaturated in the cold with ammonia, no alteration is produced in it by the addition of *ammoniacal solution of silver-nitrate*, or *mercuric cyanide*, or *sulphydric acid* (Kessler). This last reaction distinguishes tetrathionic from pentathionic acid. It is further distinguished from pentathionic acid by not being decomposed by peroxide of lead; and from all the other polythionic acids by the reaction of its potassium-salt with monosulphide of potassium, whereby it is converted into hyposulphite of potassium, with separation of sulphur: $K^2S^4O^6 + K^2S = 2K^2S^2O^3 + S$. (Chancel and Diacon.)

Tetrathionate of Barium, $Ba''S^4O^6.2H^2O$, may be prepared as above described. According to Kessler, it is obtained in large tabular crystals, by mixing the aqueous acid with an equivalent quantity of acetate of barium, and adding absolute alcohol.

Tetrathionate of Cadmium, obtained by double decomposition, separates, on evaporation in a vacuum, as a very deliquescent mass. (Kessler.)

Tetrathionates of Copper.—The *cupric salt* has not been obtained in the solid form. Its solution, when concentrated in a vacuum, deposits a large quantity of brown shining scales, whilst sulphuric acid and cupric sulphate remain in solution.—The *cuprous salt*, $Cu^2S^4O^6$, is produced by the action of hyposulphite of barium on sulphide of copper. It decomposes easily, even at ordinary temperatures, and still more when heated, into cupric sulphide and sulphuric anhydride: $Cu^2S^4O^6 = 2Cu''S + 2SO^3$. (Chancel and Diacon.)

Tetrathionate of Iron (ferrous), $Fe''S^4O^6$, is produced by the action of a ferric salt on ferrous hyposulphite: it is resolved on evaporation into ferrous sulphate, sulphurous acid, and sulphur. (Fordos and Gélis.)

Tetrathionate of Lead, $Pb''S^4O^6.2H^2O$, cannot be crystallised by evaporation, but separates in shining needles, on adding alcohol to the mixed concentrated solutions of plumbic acetate and tetrathionic acid. (Kessler.)

Tetrathionate of Nickel is obtained, as a deliquescent mass, by evaporating its solution in a vacuum.

Tetrathionate of Potassium, $K^2S^4O^6$, is prepared by the gradual addition of iodine to a concentrated solution of potassic hyposulphite, till the reddish-brown colour becomes permanent. The tetrathionate separates completely, and is dissolved in hot water; the solution is then filtered from free sulphur, and mixed with alcohol till the precipitate at first formed slowly redissolves in the liquid. On cooling, the salt separates in large crystals. When tetrathionic acid is added to a concentrated solution of potassic acetate, the salt separates in a pulverulent form, in which state it is more stable than when in large crystals. (Kessler.)

Tetrathionate of Sodium is prepared like the potassium-salt, but requires large quantities of alcohol to precipitate it from its aqueous solution. It melts in its water of crystallisation, when gently heated, with separation of sulphur and evolution of sulphurous oxide. (Kessler.)

Tetrathionate of Strontium, $Sr''S^4O^6.6H^2O$, may be prepared like the barium-salt, but is not so completely precipitated by alcohol. It separates by spontaneous evaporation in thin prisms, but is at the same time decomposed, for the most part, into sulphate of strontium, sulphurous acid, and sulphur. (Kessler.)

Pentathionic Compounds.

PENTATHIONIC ACID, $H^2S^5O^6$. (Wackenroder [1845], Ann. Ch. Pharm. lx. 189.—Lenoir, *ibid.* lxii. 253.—Fordos and Gélis, Ann. Ch. Phys. [3], xxii. 66.—Kessler, Pogg. Ann. lxxiv. 257.—Ludwig, Arch. Pharm. [2], lxxxv. 9.—Chancel and Diacon, Compt. rend. lvi. 710.)—This acid is produced by the mutual action of sulphurous and sulphydric acids:

$$5H^2SO^3 + 5H^2S = H^2S^5O^6 + 9H^2O + S^5.$$

To prepare it, Wackenroder passes sulphydric acid gas in excess through a saturated aqueous solution of sulphurous acid, filters, and digests the milky filtrate with slips of clean metallic copper, till it becomes clear—filters again—removes the dissolved copper by sulphydric acid, and drives off the excess of the latter by a gentle heat. The solution thus obtained is colourless, and destitute of odour; it may be concentrated, without decomposition, till it attains the specific gravity of 1·37.—Kessler passes sulphurous and sulphydric acid gases alternately through water, till the precipitated sulphur forms a thick magma at the bottom of the vessel; digests the filtered liquid with freshly precipitated carbonate of barium, to remove sulphuric acid; filters, and concentrates the filtrate over a water-bath, till it attains a density of 1·25—1·3. The acid liquid thus obtained may be further concentrated, in a vacuum, to the density of 1·6 at 22°.

According to Risler-Bonnet (Pogg. Ann. cxvi. 470; Jahresb. 1861, p. 60), pentathionic acid is also produced by the reaction of zinc on sulphurous acid; the zinc first dissolves in the acid, with evolution of hydrogen, which at the moment of liberation decomposes part of the sulphurous acid, yielding water and sulphydric acid; and the latter reacts on the sulphurous acid, so as to form pentathionic acid:

$$10H^2SO^3 + 5H^2S = 3H^2S^5O^6 + 12H^2O.$$

The solution exhibits the reactions of pentathionic acid as long as it retains free sulphurous acid, but the pentathionic acid is subsequently resolved into sulphuric acid, hyposulphurous acid, and free sulphur.

Pentathionic acid is colourless and inodorous, and has a strongly acid taste, inclining to bitter. It may be preserved unchanged at the temperature of the air; but on attempting to concentrate it, by heating beyond the density of 1·37, it is decomposed, sulphydric acid and afterwards sulphurous acid being evolved, while sulphuric acid and sulphur remain behind. It is not decomposed by sulphydric acid, or by dilute hydrochloric or sulphuric acid; the latter, however, when concentrated, decomposes it. By nitric acid, hypochlorous acid, or chlorine, it is oxidised, and converted into sulphuric acid. Metallic copper and iron decompose it at the boiling heat, the former with evolution of sulphurous acid and formation of sulphide of copper; the latter with evolution, first of sulphydric acid, then of sulphurous acid, a portion of the latter also remaining in the liquid (Wackenroder). A moderately concentrated solution of pentathionic acid gives off a faint sulphurous smell when boiled, but does not evolve sulphurous acid gas except when highly concentrated; on boiling it with hydrochloric acid, the odour of sulphydric acid is perceptible. On boiling the acid with solution of caustic potash, hyposulphite, sulphate, and sulphide of potassium are formed. (Kessler.)

The reactions of pentathionic acid with *cupric sulphate, mercurous nitrate, mercuric chloride, mercuric cyanide,* and *nitrate of silver,* are the same as those of tetrathionic acid. With *ammoniacal nitrate of silver,* however, it reacts differently.

When a solution of pentathionic acid is rapidly mixed with excess of ammonia, the addition of an ammoniacal solution of silver-nitrate quickly produces a brown colour, which gradually becomes darker, while sulphide of silver separates from the liquid (Kessler). According to Risler-Bonnet, it produces an immediate black precipitate. An ammoniacal solution of *mercuric chloride* added to the same liquid gradually produces a black precipitate of sulphide of mercury; and on the addition of sulphydric acid, a separation of sulphur takes place (Kessler). A recently prepared solution of pentathionic acid mixed with potash, decolorises a solution of indigo. (Risler-Bonnet.)

The pentathionates have not been much examined. They are very unstable, so much so, that it is difficult to obtain them in the solid state. In fact, the fifth atom of sulphur in the acid appears to be retained by only a feeble affinity; and in presence of a strong base, especially if the solution be concentrated, this last atom of sulphur is separated, and the pentathionic acid is reduced to tetrathionic acid, the salts of which have greater stability. Sometimes two atoms of sulphur are given up, and trithionic acid is produced. Kessler found that on mixing a solution of pentathionic acid of specific gravity 1·32, with alcohol of 96 per cent., washing the precipitate with alcohol, and dissolving it in warm water, a considerable quantity of sulphur remained undissolved; and the solution mixed with alcohol yielded crystals, having the form and composition of potassic tetrathionate.

The pentathionates of barium and lead are soluble in water, but cannot be obtained in the solid state by evaporation, even in a vacuum, decomposition taking place as soon as the solutions attain a certain degree of concentration. Lenoir, however, obtained the barium-salt, $Ba''S^5O^6.H^2O$, in definite crystals, by mixing the freshly prepared aqueous solution with strong alcohol. The salt then separated abundantly in transparent silky prisms, which changed within the liquid to larger and well-defined crystals.

Pentathionate of Potassium, $K^2S^5O^6$, crystallises (according to Rammelsberg, Jahresb. 1857, p. 136) in monoclinic prisms, exhibiting the combination $\infty P . [\infty P3] . \infty P\infty . +P . -P . +P3 . -P3$. Axes $a : b : c = 1 : 0·9285 : 1·2639$. Angle $b : c = 78° 45'$; $\infty P : \infty P$ (clinod.) $= 95° 24'$; $+P : +P$ (clinod.) $= 101° 38'$; $-P : -P$ (clinod.) $= 112° 12'$.

SULPHUR-ACIDS, or **SULPHANHYDRIDES.** Names sometimes applied to the sulphides of the more electronegative metals (arsenic, antimony, &c.), which, in combination with the electropositive sulphides, form sulphur-salts.

SULPHUR-BASES. The sulphides of the more electropositive metals, potassium, barium, copper, lead, &c.

SULPHURET. Syn. with Sulphide (p. 482).

SULPHURIC ACID and **ANHYDRIDE.** See Sulphur, Oxides and Oxygen-acids of (p. 569).

SULPHURIC CHLORIDE (p. 576).

SULPHURIC ETHERS (p. 620).

SULPHUROUS ACID and **ANHYDRIDE.** See Sulphur, Oxides and Oxygen-acids of (p. 540).

SULPHUROUS CHLORIDE (p. 542).

SULPHUROUS ETHERS (p. 551).

SULPHUR-SALTS. Compounds analogous to oxygen-salts, composed of sulphur-acids or sulphanhydrides and sulphur-bases: *e.g., sulpharsenate of potassium,* K^3AsS^4, or $3K^2S.AsS^5$, &c.

SULPHURYL, SO^2. The radicle of sulphuric acid and its derivatives.

SULZBERITE. Syn. with strontianite, or native carbonate of strontium. (See CARBONATES, i. 797.)

SUMACH. The powder of the dried leaves of various shrubs and trees of the genus *Rhus* (order *Terebinthaceæ*), especially of *Rh. coriaria* and *Rh. cotinus*. It contains colouring-matter and tannin, and is used in dyeing and calico-printing, as a substitute for nut-galls, in the production of grey colours, and in Turkey-red dyeing; also for tanning the finer kinds of leather. According to Chevreul, it contains a yellow colouring-matter, which separates from a concentrated decoction on cooling, in small crystalline grains. It forms a yellow precipitate with solution of alum, and may, therefore, be used for communicating a yellow dye to stuffs mordanted with alum. The decoction of sumach reacts strongly acid with litmus, gives a yellowish-white precipitate with stannous chloride, pale-yellow with acetate of lead, yellowish-brown with cupric acetate, and a blue flocculent precipitate with ferric chloride.

SUMBULAMIC ACID. A peculiar acid, contained (according to Reinsch) together with angelic acid, in sumbul-root.

SUMBUL-BALSAM. See SUMBUL-ROOT.

SUMBULIC ACID. The name given by Reinsch to an acid contained in sumbul-root, which he at first regarded as distinct from angelic acid, because its alcoholic solution is coloured blue by sulphuric acid; but, according to later experiments by Rieckher and Reinsch (Jahrb. pr. Pharm. xvi. 12), it does not exhibit this coloration when quite pure and free from sumbulamic acid, and must therefore be regarded as identical with angelic acid, with which it agrees in all other respects.

SUMBULINE. The name given by Murawieff to an alkaloïd supposed to exist in sumbul-root.

SUMBUL-OIL. A mixture of volatile oils obtained by the distillation of sumbul-balsam.

SUMBULOLIC ACID. Syn. with SUMBULIC or ANGELIC ACID.

SUMBUL-ROOT. *Musk-root.* The root of an umbelliferous plant, said to be indigenous in Persia. It usually occurs in commerce, in rather large cakes having a strong musk-like odour, and a faintly sweetish musklike taste, with aromatic burning aftertaste, like angelica and imperatoria root. Reinsch found in 100 pts. of sumbul-root 13 pts. water, 12·9 balsam, 28·4 starch and salts, 8 gum, 4 colouring-matter soluble in alcohol, 7 bitter substance, and 5 ash-constituents (containing a large quantity of potassic carbonate), besides mucilage, woody fibre, resin, wax, and traces of volatile oil not smelling of musk.

According to Reinsch, the balsam extracted from the root by ether has the colour and consistence of copaiba-balsam, a burning taste, and only a faint musk-like odour in the dry state, but gives out a strong odour of musk when in contact with water. Strong sulphuric acid dissolves it with fine blue colour. By dry distillation, the balsam gives off—first, a yellowish oil tasting like peppermint; afterwards a grass-green oil having the odour of cajeput, while the residue acquires an indigo-blue colour. On continuing the distillation, a blue oil passes over, which dissolves with blue colour in alcohol; paper on which the solution is dropt, acquires a musklike odour after a few days. The oil is coloured green by cold potash-ley; hot potash-ley dissolves it. The balsam dissolves in potash-ley, and, on adding water, a resinous mass separates, containing the potassium-salt of sumbulamic acid, which may be separated from it by dilute sulphuric acid. This acid is resinous at first, but is converted into a crystalline mass by long contact with water; it is said to form an ether. Further investigation is required to determine how far this acid differs from sumbulic or angelic acid.

Sommer (Arch. Pharm. cxxxviii. 1) has also investigated sumbul-root, but with somewhat different results. The extract obtained from the root by treatment with ether, gave, by distillation with water, a very small quantity of a pale-yellow, neutral, volatile oil, which in the concentrated state smelt more like angelica-root, but in the dilute state more like musk. This oil is mobile and lighter than water, but resinises quickly in contact with the air, becoming viscid, darker-coloured, and acid. It dissolves in nitric acid with violet colour, soon changing to yellow; by sulphuric acid it is turned brown, and carbonised. The balsam prepared with ether or alcohol yields by dry distillation (according to Sommer) one-third of its weight of a greenish mobile oil, smelling like creasote; afterwards white fumes are evolved, which thicken to a blue oil (about one-third of the resin); finally, tarry products pass over, and a carbonaceous residue is left. The blue oil sometimes contains needle-shaped crystals, which likewise condense in the neck of the retort.

The blue oil is a mixture of several bodies; it begins to boil at 150°, a pale-yellow oil then passing over; at 200°—280°, a light-blue, and at 285°—325° a dark-blue oil passes over, at which latter temperature partial decomposition takes place. The blue oil has a peculiar, not very agreeable odour, is lighter than water, slightly soluble therein, easily soluble in alcohol and ether. Heated with nitric acid, it yields oxalic acid. When distilled with potash, it gives off a neutral pale-blue oil, smelling like bergamot pears; and the residue, treated with sulphuric acid, gives off the odour of valerianic acid. The crystals obtained, together with the blue oil, consist of umbelliferone (*q. v.*). (Sommer.)

Sumbul-root is said to cause trembling and weakness of the limbs, confusion of the head, acceleration of the pulse, increased heat, and greater activity of the stomach. (Handw. d. Chem. viii. 440.)

SUNDVIKITE. A mineral from Kimito in Finland, allied to, and perhaps identical with, anorthite. (*Rammelsberg's Mineralchemie*, p. 593.)

SUNSTONE. Oligoclase from Tvedestrand in Norway (iv. 198).

SUPER. A prefix synonymous with PER (iv. 374).

SUPERPHOSPHATE. Acid phosphate of calcium, prepared on the large scale for manure, by treating bones, coprolites, &c. with sulphuric acid.

SURINAMINE. An alkaloïd, occurring, according to Hüttenschmidt (Mag. Pharm. vii. 287), in the bark of *Geoffroya inermis*.

SURTURBRAND. Fibrous lignite, so called in Iceland, where it occurs in large quantities.

SUSANNITE, or **SUZANNITE.** A sulphato-carbonate of lead having the same composition as leadhillite (27·5 per cent. $PbSO^4$ and 72·5 $PbCO^3$), but crystallising in rhombohedral forms, derived from a primitive rhombohedron in which the length of the principal axis is 1·1062 and R : R = 94°; it exhibits the faces −2R, ∞R, oR, and cleaves easily parallel to oR. Hardness = 2·5. Specific gravity = 6·55. Lustre resinous to adamantine. Colour white, green, yellow, and brownish-black. Streak uncoloured. It occurs in attached crystals at Leadhills in Scotland, and at Moldawa in the Bannat. (Dana, ii. 373.)

SVANBERGITE. A mineral discovered by Ijelström (Jahresb. 1854, p. 681), together with lazulite, on the Horrsjöberg in Wermland, Sweden, in cube-like rhombohedrons, resembling those of beudantite, and cleaving parallel to the terminal face. Hardness = 5·0. Specific gravity = 3·30. Colour pale red, or yellow. Transparent to translucent. Before the blowpipe it becomes decolorised, and melts only in thin splinters. The pulverised mineral dissolves partially in strong acids, and the residue becomes incandescent when heated. Contains 17·32 per cent. SO^3, 17·8 P^2O^5, 37·84 Al^2O^3, 1·40 FeO, 6·0 lime, 12·84 Na^2O, and 6·80 water, with a trace of chlorine; whence the formula is, perhaps, $2(2Al'''HO^2.Na^2SO^4) + (2Al'''HO^2.Ca''P^2O^6)$, or, according to Rammelsberg (*Mineralchemie*, p. 361), $(\frac{2}{3}Na^2O.\frac{1}{3}CaO)^3.P^2O^5 + (3Al^2O^3.2SO^4) + 3H^2O$.

SWAGA. The Thibetian name for borax.

SWAMP-ORE. Bog iron-ore.

SWIETENIA. A genus of trees belonging to the meliaceous order. The bark of *Swietenia senegalensis*, or *Cail-cedra*, is used in Senegal as a febrifuge. The bark of *Sw. febrifuga*, indigenous in India, is the *Cortex Soyamidæ*, which, according to Duneau (Trommsdorff's Journal, iii. 257), contains a bitter principle, tannin, volatile oil, and resin. According to Overbeck (Arch. Pharm. [2] lxviii. 271), the bark contains an amorphous bitter principle, but no base.

SYCOCERYLIC ACID. See the next article.

SYCOCERYLIC ALCOHOL. $C^{18}H^{30}O = \left.\begin{matrix}C^{18}H^{29}\\H\end{matrix}\right\}O$. (De la Rue and Müller, Phil. Trans. 1860, p. 43; Chem. Soc. Qu. J. v. 62.)—This compound, homologous with benzylic alcohol (C^7H^8O) and cymylic alcohol ($C^{10}H^{14}O$), is produced by treating sycocerylic acetate (*infra*) with sodium-alcohol, and purified by precipitation with water and crystallisation from ordinary alcohol. It forms very thin crystals, resembling caffeine, usually aggregated in masses like wavellite; melts at 90° to a liquid heavier than water, and solidifies in the crystalline state on cooling; after being strongly heated, it solidifies to a transparent glass, which becomes crystalline in contact with alcohol; distils partly undecomposed.—It is insoluble in *water*, aqueous *ammonia*, and *alkalis*

It dissolves readily in *ethylic alcohol*: a hot saturated solution forms a semisolid mass of crystals on cooling; a solution in very dilute alcohol deposits, on cooling, a jelly, which afterwards becomes crystalline. Dissolves in *ether*, *benzene*, *chloroform*, and *light mineral oil*.

Decompositions.—1. Sycocerylic alcohol is but slowly attacked by boiling with dilute *nitric acid*: the dark-yellow resin formed after six hours, when washed and dried, and afterwards dissolved in warm alcohol, yields white and yellow crystals, easily soluble in aqueous ammonia and potash, and precipitable by alcoholic neutral acetate of lead; probably a mixture of sycocerylic acid, $C^{18}H^{28}O^{2}$, and nitrosycocerylic acid.—2. Moderately dilute aqueous *chromic acid*, boiled with sycocerylic alcohol for eight hours, produces no sycocerylic acid: on one occasion, neutral thin prisms, probably of sycocerylic aldehyde, $C^{18}H^{28}O$, were produced.—3. The alcohol dissolves easily in *oil of vitriol*, forming a brown solution, from which water throws down a viscid resin; no conjugated compound of sulphuric acid remains in solution.—4. Sycocerylic alcohol is readily attacked by *chlorine* and *bromine*, and forms yellow crystals with *iodine*.—5. A solution of sycocerylic alcohol in benzene evolves hydrochloric acid gas when treated with *pentachloride of phosphorus* at 60°. If, after the evolution of gas has ceased, the remaining chloride of phosphorus be removed, and the benzene solution washed with water and aqueous alkali and evaporated, there remains an amorphous, greenish, viscid residue, easily soluble in ether and chloroform, but difficultly soluble in alcohol. On one occasion crystals were also obtained.—6. *Potassium* evolves hydrogen from melted sycocerylic alcohol, and becomes covered with a white crust, which, when heated till it melts, blackens and takes fire.—7. Sycocerylic alcohol, treated with fused *caustic potash*, evolves hydrogen without forming sycocerylic acid. —8. With *chloride of acetyl* it forms acetate of sycoceryl, and with *chloride of benzoyl* benzoate of sycoceryl.

SYCOCERYLIC ALDEHYDE. See the last article.

SYCOCERYLIC ETHERS. (De la Rue and Müller, *loc. cit.*) ***Sycocerylic Acetate***, $C^{20}H^{32}O^{2} = C^{2}H^{3}(C^{18}H^{29})O^{2}$.—This ether is contained, together with sycoretin, in the resin of *Ficus rubiginosa* from New South Wales (ii. 646). To obtain it, the sycoretin is dissolved out of the resin by cold alcohol, and the residue is boiled with alcohol. The solution, on cooling, deposits crystals of sycocerylic acetate, mixed, towards the end of the crystallisation, with a small quantity of a flocculent substance; and by leaving the solution to cool to 40°, then straining off the liquid, recrystallising the solid residue from boiling alcohol, and treating the product at 30° with a quantity of ether not sufficient to dissolve it, the sycocerylic acetate is obtained pure, while a neutral crystalline substance remains undissolved. Sycocerylic acetate is also produced by treating sycocerylic alcohol with chloride of acetyl.

Sycocerylic acetate crystallises from alcohol, in thin laminæ resembling cholesterin, and from ether in flat six-sided tables. It melts at 118°—120°, and solidifies below 80° to a mass which is transparent at first, but afterwards becomes opaque and crystalline. It distils unchanged; but when it is too strongly heated, the distillate smells rancid, and like acetic acid. It is brittle; strongly electric when rubbed; neutral. It dissolves very easily in hot *alcohol*, and in *acetic acid*, *acetone*, *chloroform*, *ether*, *benzene*, and *oil of turpentine*. It is not precipitated by alcoholic *neutral acetate of lead*, or by aloholic *acetate of copper*.

Hot dilute *nitric acid* converts sycocerylic acetate into a resin. The easily prepared solution in fuming nitric acid is precipitated by water in amorphous yellow flocks. It dissolves easily and without coloration in *oil of vitriol*; the solution becomes brown on standing, and gives off traces of sulphurous and acetic acids; water precipitates from the solution a hard substance, fusible below 100°, difficultly soluble in alcohol, and easily soluble in chloroform and benzene. It forms resinous compounds with *chlorine*, *bromine*, and *iodine*; the last two, when added gradually to a warm alcoholic solution of the acetate, form crystals of a colourless bromine- or iodine-compound, which are deposited on cooling. It is not affected by boiling solution of *caustic potash*, but is decomposed by the fused hydrate, with liberation of hydrogen.—*Sodium-alcohol* decomposes it even at 90°, forming acetic acid and sycocerylic alcohol.

Sycocerylic Benzoate, $C^{25}H^{34}O^{2} = C^{7}H^{5}(C^{18}H^{29})O^{2}$.—Prepared by dissolving sycocerylic alcohol in chloride of benzoyl (no gas being evolved in the cold), and heating the solution as long as hydrochloric acid gas is given off. The crystalline mass formed on cooling is thrown into a warm aqueous solution of acid potassic carbonate, with which it is warmed for several hours. The resin thereby separated, after washing with warm water and boiling alcohol, is dissolved in boiling ether, from which it is obtained in crystals. Boiling absolute *alcohol* dissolves only a trace of the crystalline substance, and deposits it again, on cooling, in small crystals recognisable under the microscope. It dissolves with difficulty in cold *ether*, and in all proportions in *chloro-*

form and *benzene*, crystallising in prisms on evaporation. *Sodium-alcohol* decomposes it only on long boiling, with formation of sycocerylic alcohol and sodic benzoate.

SYCORETIN. The resin of *Ficus rubiginosa* is resolved, by treatment with alcohol, into about 73 per cent. of sycoretin soluble in cold alcohol, 14 per cent. of sycocerylic acetate soluble in hot alcohol, and 13 per cent. of residue, consisting of caoutchouc, sand, and fragments of bark.

On mixing the neutral pale-brown solution in cold alcohol with water, the sycoretin is precipitated, and may be rendered colourless by repeated solution and precipitation. A saturated alcoholic solution deposits, in the cold, a small quantity of a crystalline substance, sycoretin in a purer state remaining in solution. The latter may be separated, by fractional precipitation with water, into two portions, the first of which contains 74·65 per cent. C and 10·11 H; the second, 77·89 per cent. C and 9·94 H.

Sycoretin is amorphous, white, neutral, very brittle, and highly electric. It melts in boiling water to a thick liquid, which floats on the surface. Melts below 100°. Sycoretin is insoluble in *water*, dilute *acids*, *ammonia*, and aqueous *alkalis*. It is not precipitated from its alcoholic solution by *neutral acetate of lead*, or *acetate of copper*.—Dissolves easily in *alcohol*, *ether*, *chloroform*, and *oil of turpentine*. (De la Rue and Müller, *loc. cit.*)

Sycoretin undergoes decomposition at a few degrees above its melting-point, frothing up, and giving off water with a wax-like odour. When further heated, it melts quietly, and yields a distillate containing acetic acid and tar, charcoal being left behind.—It is attacked by *nitric acid*, and dissolved on boiling therewith; water precipitates from the yellow solution a slightly acid nitro-compound, which dissolves with dark colour in aqueous alkalis, and forms an explosive compound with potash. In this reaction a little oxalic acid is formed, but no picric acid.—Sycoretin dissolves in *oil of vitriol* with fine green colour, without forming sugar: water throws down from the solution a brown precipitate, less soluble than sycoretin.—*Caustic potash* acts on sycoretin in the same way as oil of vitriol.

SYENITE. A rock allied to granite, and consisting essentially of a crystallo-granular mixture of orthoclase and hornblende, the former being often more or less replaced by oligoclase. Quartz and mica also occur in syenite, giving it more or less of a granitic character, while, on the other hand, the occurrence of hornblende in granite renders it more or less syenitic; in fact, the two rocks pass into one another by insensible gradations. In like manner the occurrence of rather large crystals or masses of orthoclase in syenite gives rise to transitions between that rock and porphyry; and in other cases, the alternation of layers of hornblende with felspar produces syenitic slate, or (if mica is also present) syenitic gneiss. Titanitic syenite and zircon-syenite are syenites in which titanite and zircon occur imbedded.

SYEPOORITE. Native protosulphide of cobalt, $Co''S$, occurring at Syepoor, in North-western India, in steel-grey crystalline grains or masses, of specific gravity 5·45 (i. 1050).

SYHEDRITE. A silicate, occurring in the trap of Thore-gate, in the Syhedree Mountains, Bombay, in irregularly laminated masses, having a fine-green colour, vitreous lustre, hardness = 3·5, and specific gravity = 2·321. It gives by analysis 56·92 per cent. SiO^2, 15·06 Al^2O^3, 2·71 FeO, 6·45 CaO, 2·4 MgO, and 16·40 water, and therefore approaches in composition to stilbite (p. 433); but it differs from that mineral in colour, and in being less easily decomposed by acids. (Shepard and Tyler, Sill. Am. J. [2] xl. 110; Jahresb. 1865, p. 891.)

SYLVAN. Native tellurium.

SYLVANITE. *Graphic Tellurium. Graphic Gold. Yellow Tellurium. Müllerite. Aurotellurite. Schrifterz. Schrifttellur. Tellure natif auro-argentifère. Aurum graphicum.*—A telluride of gold and silver, sometimes also containing lead and antimony, occurring in narrow veins in the porphyry mountains of Offenbanya and Nagyag, in Transylvania. It contains a large proportion of gold, and is a valuable ore. It forms trimetric crystals, mostly small and needle-shaped, and grouped in such a manner that the combinations are difficult to make out. The crystals frequently also cross one another at angles of 60° and 120°, probably in consequence of twin-formation; and by a repetition of this grouping on the surfaces of rocks, triangular and rhombic figures are produced, like oriental writing characters: hence the name, *graphic tellurium*. The primary form of the crystals is a rhombic prism having the angle $\infty P : \infty P = 110° 48'$; $oP : P\infty = 119° 26\frac{1}{2}'$; and therefore $a : b : c : = 1 : 1·4496 : 1·7721$. The prism ∞P is combined with $\infty\breve{P}2$, $\infty\breve{P}\infty$, $\infty\bar{P}\infty$, oP, forming elongated prismatic crystals, the ends of which are modified by several pyramids and domes. Cleavage very distinct parallel to $\infty\bar{P}\infty$, less distinct parallel to $\infty\breve{P}\infty$. The mineral occurs also imbedded in laminæ and masses.

Hardness = 1·5 to 2. Specific gravity = 7·99 to 8·33. Lustre metallic. Streak and colour pure steel-grey to silver-white, sometimes nearly brass-yellow. Fracture uneven. Very sectile. Before the blowpipe, it melts easily, tinging the flame greenish-blue, covering the charcoal with a white oxide, and finally leaving a ductile metallic globule. It dissolves easily in nitric acid.

The following analyses are by Petz (Pogg. Ann. lvii, 472):—*a.* Thin needle-shaped crystals: specific gravity = 8·28.—*b.* Indistinct crystals: specific gravity = 8·28.—*c.* Long white crystals: specific gravity = 8·27.—*d.* Thick white crystals: specific gravity = 7·99.—*e.* Short yellowish crystals: specific gravity = 8·33.—*f, g.* Light yellow masses:

	Offenbanya.		Nagyag.				
	a	*b.*	*c*	*d.*	*e.*	*f.*	*g.*
Tellurium	59·97	58·81	55·39	48·40	51·52	44·54	49·96
Antimony	0·58	0·66	2·50	8·42	5·75	8·54	3·82
Gold	26·97	26·47	24·89	28·98	27·10	25·31	29·62
Silver	11·47	11·31	14·68	10·69	7·47	10·40	2·78
Lead	0·25	2·75	2·54	3·51	8·16	11·21	13·82
Copper	0·76						
	100·00	100·00	100·00	100·00	100·00	100·00	100·00

These analyses are most easily reduced to a formula on the hypothesis that the tellurium and antimony on the one hand, and the gold, silver, and lead on the other, replace one another isomorphously. On this supposition the whole of the analyses may be included under the general formula $(Au^2; Ag^2; Pb'')(Te; Sb)^3$. The composition of the mineral from Offenbanya is very nearly expressed by the simpler formula, $Au^2Ag^2Te^6$, or $Au^2Te^3.Ag^2Te^3$. This variety is sometimes specially distinguished as graphic tellurium; and that which contains lead and antimony in addition, as white tellurium.

SYLVIC ACID, $C^{20}H^{30}O^2$. (Unverdorben, Pogg. Ann. vii. 311; viii. 40, 407; xi. 28, 230, 393; xiv. 116; xvii. 186.—Trommsdorff, Ann. Ch. Pharm. xiii. 169. —H. Rose, Pogg. Ann. xxxiii. 42; liii. 374.—Laurent, Ann. Ch. Phys. [2], lxv. 324; lxviii. 395; lxxii. 459; [3], xxii. 459.—Sievert, Zeitschr. f. die ges. Naturwissenschaften, xiv. 311; Jahresb. 1859, p. 508.—Maly, Wien. Akad. Ber. xliv. 121; Jahresb. 1861. p. 389.)—This acid was discovered and investigated by Unverdorben, but confounded by him and all later investigators (except Maly), with abietic acid, the acid existing ready-formed in pine-resin. Owing to this confusion, it is not always clear which statements refer to abietic and which to sylvic acid. Unverdorben, however, seems to have examined principally an acid prepared with sulphuric acid—therefore sylvic acid. Laurent's statements apply better to sylvic acid, though his method of preparation must have yielded abietic acid.

Two acids found by Baup (Ann. Ch. Phys. [2] xxxi. 108) in French colophony, *Acide pinique* and *Acide abiétique*, as well as Lecanu and Bussy's *crystallised acid from turpentine* (J. Pharm. xiii. 62), appear also to belong to this head.

Formation and Preparation.—1. *From Abietic Acid.* An alcoholic solution of abietic acid is precipitated by dilute sulphuric acid, and the hardened crystalline precipitate is washed with alcohol, and afterwards crystallised from that liquid (Maly).—Sylvic acid is obtained also, together with sylvinolic acid, by passing hydrochloric acid gas into a solution of abietic acid in alcohol. (Maly.)

2. *From White Pitch, Colophony, &c.*—White pitch is allowed to stand, covered with an equal quantity of alcohol, till it is completely saturated with the liquid, and until the turpentine-like deposit formed at first has become crystalline. It is then collected on a cloth, triturated with a little alcohol, washed with that liquid on the filter, and afterwards dissolved in a small quantity of hot absolute alcohol containing sulphuric acid: the solution, on cooling, solidifies to a crystalline mass. Purification is effected by pressing the crystals, and repeatedly subjecting a hot alcoholic solution to fractional precipitation with hot water, whereby the less pure portions are thrown down first. The alcoholic solution mixed with a quantity of hot water barely sufficient to produce turbidity, yields large crystals on cooling. (Trommsdorff.)

Laurent boils pine-resin with water to free it from turpentine; extracts the pinic acid by means of cold alcohol, and dissolves the residue in boiling alcohol. On cooling, the solution yields crystals, which are freed from adhering oil by washing with cold alcohol, and recrystallisation from boiling alcohol. Unverdorben, and likewise Trommsdorff and Sievert, employ similar methods. The product thus obtained is abietic acid. (Maly.)

Long standing of the alcoholic solution reduces the yield of the crystals. (Sievert.)

Properties.—Sylvic acid forms colourless, transparent, tabular, rhomboïdal prisms, with four-sided summits (Unverdorben); indistinctly crystalline masses, also triangular laminæ (Rose; Laurent). According to Sievert, the crystals are combinations derived from a rhombic prism of 96° and 84°, having the acute lateral edges much truncated, and terminated by sphenoïdal faces, developed to such an extent as completely to obliterate two faces of the prism. They are vitreous, brittle, and triturable to a white powder.

Sylvic acid does not lose weight at 100°, or in a vacuum, and melts without loss of weight (Unverdorben) at 152·5°, but becomes quite fluid at higher temperatures (Trommsdorff). In a warm tube the crystallised acid, as well as that which has been previously fused, melts at 162°; but when heated in a retort, it cakes together (partially at 118°, and completely at 150°), and melts to a thin clear liquid, which turns thick at 120°, viscid at 110°; and solidifies to a glassy mass, afterwards melting partially at 135°, and completely at 155° (Sievert). Sylvic acid sublimes partially at 170°, in a thin crust, which, when dissolved in alcohol, yields crystals of the unchanged acid; the residue turns dark-red at 240°, but does not boil even at 290° (Sievert). It distils without much decomposition, yielding a trace of water, and a colophony-like distillate, an alcoholic solution of which deposits crystals of unchanged sylvic acid, whilst the residue contains a trace of charcoal (Laurent). Inodorous and tasteless; reddens litmus. Rotates a ray of polarised light to the left, more powerfully than pimaric acid. Specific gravity = 1·1011 at 18°. (Sievert.)

Sylvic acid is soluble in *acetic acid.* It dissolves very slightly in cold alcohol of 65 per cent., and in about 3 pts. of the boiling liquid, from which it crystallises on cooling, about $\frac{1}{25}$th only remaining in solution; in about 3 pts. of cold and 1 pt. of boiling absolute alcohol or ether, and is thrown down from the former solution by an equal quantity of water, as a semitransparent oil, which hardens to a crystalline solid on addition of more water, or on exposure to the air (Unverdorben). Sylvic acid is soluble in 10 pts. of cold and in $\frac{4}{5}$ths of boiling alcohol of 92 per cent.; more freely, therefore, than pimaric acid (Sievert). It dissolves in *acetic ether, rock-oil,* and *oil of turpentine,* without crystallising therefrom. (Unverdorben.)

Decompositions.—1. Sylvic acid submitted to *dry distillation* (*supra*) yields water and empyreumatic oil, then a little gas, followed first by a thinner and afterwards by a thicker oil, containing sylvic and pinic acids and a large quantity of a neutral resin and oils.—2. *Nitric acid* slowly decomposes sylvic acid, and dissolves it only on prolonged boiling; water throws down from the solution yellow flocks, soluble in ammonia, caustic potash, and alcohol.—3. *Oil of vitriol* rapidly dissolves sylvic acid, forming a yellowish-brown solution, from which water precipitates unchanged sylvic acid and a large quantity of pinic acid. (Unverdorben.)

Sylvates.—Sylvic acid combines with *bases,* with elimination of water (Unverdorben; Laurent)—(contrary to Rose's statement). It expels the acid from carbonates, and when melted also from succinates and benzoates, and from chloride of calcium; but salts of sylvic acid dissolved in water are decomposed by boric and acetic, and by stronger acids, with precipitation of sylvic acid. The salts are obtained:—α. By dissolving the acid in the aqueous base.—β. By precipitating an acetate dissolved in alcohol by means of alcoholic sylvic acid, dissolving the precipitate in ether, and reprecipitating by alcohol, which retains in solution the excess of sylvic acid.—γ. By double decomposition. Some of the sylvates are crystallisable; a few of them are soluble in water and alcohol, and all of them in ether. (Unverdorben.)

Sylvate of Ammonium is a viscid mass, more soluble in alcohol or ether than in water; decomposed by heat.—The *barium-salt* is precipitated from aqueous solution in crystalline flocks, soluble in 3,000 pts. of water, in 6 pts. of cold and a smaller quantity of boiling absolute alcohol, from which it is deposited in microscopic crystalline flocks on cooling (Unverdorben).—The *normal calcium-salt,* $C^{40}H^{58}Ca''O^4$, is obtained by precipitating the potassium-salt with chloride of calcium, and a salt containing a smaller proportion of calcium is formed by precipitating alcoholic sylvic acid with an alcoholic solution of calcic acetate. (Sievert.)

The *cupric salt,* $C^{40}H^{58}Cu''O^4$, is obtained, in pale-blue flocks, on mixing the alcoholic solutions of sylvic acid and cupric acetate. By dissolving this precipitate in aqueous ammonia, and leaving the solution to cool, or diluting it with water, the same salt is thrown down as a dark-blue mass, triturable to a pale-blue powder when dry. (Sievert.)

The *ferrous* and *ferric salts* dissolve slightly in cold alcohol, easily in ether.

Lead-salt.—The precipitate thrown down by alcoholic sylvic acid from alcoholic plumbic acetate, is a white, amorphous, easily fusible powder, containing, on the average, 26·94 per cent. oxide of lead, agreeing nearly with the formula $C^{40}H^{58}Pb''O^4$, which requires 26·17 PbO (Rose). Sylvic acid heated to 168° with oxide of lead, loses

3·02 per cent. water; calculation from the same formula requires 2·97 per cent. (Sievert.)

The *magnesium-salt* dissolves in all proportions of alcohol of 65 per cent., and in absolute alcohol; from the latter solution, a double volume of water throws down a colourless semifluid salt, which dries up in the air to a transparent resin, and dissolves in ether and in mineral naphtha.—The *manganese-* and *zinc-salts* are soluble in absolute alcohol.

Sylvates of Potassium.—a. The *normal salt*, $C^{20}H^{29}KO^2$, is formed by boiling sylvic acid with 6 pts. of alcohol and with carbonate of potassium, and is deposited from the filtrate on cooling in delicate white needles, which may also be obtained by mixing the salt γ with alcoholic sylvic acid (Unverdorben; Sievert). It melts to a resin when heated; dissolves very slightly in water, slowly in 20 pts. of alcohol, more freely in hot alcohol; abundantly in warm ether and oil of turpentine, and to a less extent in olive-oil (Unverdorben).—*β.* An *acid salt*, $C^{20}H^{29}KO^2.3C^{20}H^{30}O^2$, is produced by boiling alcoholic potash neutralised with sylvic acid, and solidifies, on cooling, to a crystalline mass, which may be purified by recrystallising and pressing. The same salt is precipitated from alcoholic sylvic acid by an alcoholic solution of potassic acetate. It forms fine silky tufts of delicate needles; decomposes when boiled with water, three-fourths of the acid being precipitated, whilst the normal salt remains in solution (Sievert).—γ. A sparingly soluble *basic salt* appears to be formed by dissolving sylvic acid precipitated by water in caustic potash, and adding more sylvic acid (Rose). Carbonate of potassium added to an ethereal solution of sylvic acid throws down a colourless amorphous salt. (Unverdorben.)

The *silver-salt*, $C^{20}H^{29}AgO^2$, crystallises from alcohol in shining granules on spontaneous evaporation. When boiled with potash and oil of turpentine, it behaves like pinate of silver. Dissolves in 15 pts. of cold, and in a smaller quantity of boiling alcohol, and instantaneously in ether, which takes it up from water when suspended therein. (Unverdorben.)

The *sodium-salt* is obtained in crystals, by boiling alcoholic sylvic acid with excess of sodic carbonate, and cooling the filtrate. (Unverdorben.)

OXYSYLVIC ACID (?)—When an alcoholic solution of sylvic acid is left for some time exposed to the air, or allowed to evaporate slowly, a viscid uncrystallisable substance remains, which melts over the water-bath, losing a little water, and forms, on cooling, a white brittle mass like colophony. This, according to Hesse (Ann. Ch. Pharm. xxix. 141) and H. Rose, is an oxysylvic acid; Hesse found it to contain $C^{20}H^{30}O^4$. Rose however, in one experiment, found that the residue had the same composition as sylvic acid.

SYLVINE, or **SYLVITE.** Chloride of potassium, occurring in cubic crystals about the fumaroles of Vesuvius.

SYLVINOLIC ACID, $C^{25}H^{36}O^4$. (Maly, Wien. Akad. Ber. [2], xliv. 121; Jaresb. 1861, p. 389.)—An acid produced, together with sylvic acid, by saturating an alcoholic solution of abietic acid with hydrochloric acid gas; the sylvic acid then crystallises out, while the sylvinolic acid remains in solution, and is precipitated therefrom by water, as a white flocculent powder, easily soluble in alcohol and in ether. On evaporating either of these solutions, the acid remains as an amorphous pitchy mass, which melts with decomposition at 130°. Sylvinolic acid is dibasic.

The *potassium-* and *sodium-salts* are uncrystallisable, soluble in water and in alcohol. —The *calcium-salt*, $C^{25}H^{34}Ca''O^4$, is a flocculent precipitate.—The *silver-salt*, $C^{25}H^{34}Ag^2O^4$, is a pulverulent precipitate nearly insoluble in ammonia.

SYMBOLS, CHEMICAL. See FORMULÆ (ii. 695), and NOTATION (iv. 136).

SYMMORPHOSIS. A name applied by Liebig (Ann. Ch. Pharm. xxx. 255), to the kind of chemical metamorphosis which consists in the union of several simpler molecules into a molecule of greater complexity: *e.g.*, the conversion of 2 at. potassic cyanide and 1 at. ferrous cyanide into 1 at. potassic ferrocyanide, of 3 at. cyanic acid into 1 at. cyanuric acid, &c.

SYMPATHETIC INK. See INK (iii. 272).

SYMPHYTUM. A genus of plants, belonging to the order *Boraginaceæ*. *S. asperrimum* contains, in 100 pts. of the fresh herb, 88 pts. water, 6 pts. matter soluble in water, 3·2 soluble in dilute potash, 2·6 woody fibre, and 2·3 ash free from carbonic acid. The ash contains, in 100 pts.: 31·3 K^2O, 10·9 Na^2O, 20·5 CaO, 1·2 MgO, 0·4 Al^2O^3, 17·2 SiO^2, 3·9 SO^3, 11·4 P^2O^5 and 3·1 Cl.

The root of comfrey (*S. officinale*) contains a large quantity of vegetable mucilage ($C^6H^{10}O^5$, according to Schmidt), and a small quantity of asparagine.

SYMPLESITE. A mineral supposed to be a ferrous arsenate, found at Lobenstein in Voigtland, in minute, monoclinic, prismatic crystals resembling cobalt-bloom, cleavable parallel to the large lateral face. It has a greenish-blue colour and vitreous lustre, pearly on the cleavage-face; hardness = 2·5 nearly; specific gravity = 2·957; subtransparent to subtranslucent. Heated in a glass tube, it turns brown, and loses 25 per cent. water. On charcoal it emits an alliaceous odour, turns black without melting, and is afterwards magnetic. (Breithaupt, J. pr. Chem. x. 501.)

SYNANTHERIN. See Sinistrin (p. 311).

SYNAPTASE. Syn. with Emulsin (ii. 486).

SYNDESMIDES. Laurent's name for the so-called conjugated compounds.

SYNOVIA. A clear, yellowish, very viscid, alkaline fluid, found in the joints of animals, where it serves the purpose of lubrication. It contains—water 94·85, albumin and extractives 3·51, fat 0·8, salts 1·00. (Frerichs.)

SYNTHESIS, CHEMICAL. The formation of compounds by the union of their elements or proximate constituents. On the synthesis of organic compounds, see Organic Chemistry (iv. 216); also Berthelot (*Chimie organique fondée sur la synthèse*, 2 tomes, Paris, 1860; and Chem. Soc. Qu. J. xvii. 37).

SYNTONIN (συντείνω). *Muscle-fibrin.*—This name was given by Liebig to a substance which can readily be prepared from muscular or contractile tissues of all kinds. Muscle freed from blood, finely minced, and thoroughly washed in the cold until the wash-water no longer gives signs of the presence of albumin, is treated with tenfold its volume of diluted (·1 per cent.) hydrochloric acid, and left to stand for 24 hours. The acid solution, after being strained and filtered, is carefully neutralised with sodic carbonate, and the resulting precipitate filtered off and washed. The operation should be carried on at a low temperature, and pushed forward as speedily as possible, in order to avoid decomposition.

Syntonin thus prepared appears on the filter as a white, opaque, gelatinous mass, readily separating into flakes and pellicles. Composition: C 54·06, H 7·28, N 16·05, O 21·50, S 1·11. It is readily soluble in very dilute hydrochloric acid, in feebly alkaline liquids (such as a solution of sodic carbonate), in baryta-water, and in lime-water. It is quite insoluble in solutions of sodic chloride, &c., at all degrees of concentration.

The hydrochloric acid (·1 per cent.) solution is not coagulated by heat, but the addition in the cold of chloride of sodium, calcium, or ammonium, or of sulphate of sodium or magnesium, produces in dilute solutions a milky turbidity, in concentrated solutions a gelatinous precipitate, which on being boiled separates into flakes. The sodic carbonate (1 per cent.) solution is not coagulated by heat, but is rendered turbid in the cold by sodic chloride, or by a mixture of magnesian sulphate and chloride of ammonium; the turbidity increases when the mixture is boiled, and the froth formed contains opaque flakes. The lime-water solution is not coagulated by heat, but froths freely; and the froth contains flakes, which may be separated on standing. Only a fraction, however, of the syntonin is thus, so to speak, coagulated. In the lime-water solution the chlorides of sodium, ammonium, and magnesium produce in the cold little or no turbidity, on boiling a more or less copious deposit; sulphate of magnesium produces in the cold a slight turbidity, on boiling a flaky deposit; sulphate of sodium produces not even a turbidity, either in the cold or on boiling. A lime-water solution, which has been boiled and allowed to stand, still exhibits these reactions (Kühne, *Protoplasma*). From the alkaline solutions, syntonin may be thrown down by a stream of carbonic anhydride. Although neither the alkaline nor the acid solutions are coagulated by heat, syntonin, when suspended in water and heated for a few minutes to 85°, is altered, and enters into an insoluble form. With strong acetic acid, syntonin forms a turbid gelatinous mass. A solution of syntonin in dilute hydrochloric acid exhibits a specific lævorotatory power of 72° for yellow light.

Although syntonin is most readily obtained from muscle, it may be prepared in many other ways. If fibrin or coagulated albumin be treated with fuming hydrochloric acid, the solution, filtered and diluted with twice its bulk of water, gives a copious deposit, which, when separated and dissolved in water, forms a solution identical in its reactions with an acid solution of syntonin. If a solution of potassic albuminate be precipitated with acetic acid, the washed deposit dissolves in hydrochloric acid of 1 per cent., and the solution is undistinguishable from an acid solution of syntonin. The uncoagulated albumin of hen's eggs, treated with a sufficient quantity of ·1 per cent. hydrochloric acid, forms a solution which, after 24 hours' standing, becomes uncoagulable by heat, and gives all the reactions of syntonin. In fact, all the forms of albumin treated with dilute hydrochloric acid, give rise, in a greater or less extent, to syntonin; and the parapeptone of Meissner, the initial stage of peptonification, cannot, by any of its reactions, be distinguished from syntonin. Lastly, the alkaline solutions of syntonin seem in no way to differ from the solutions of ordinary potassic albuminate.

Syntonin, therefore, is no special muscle-product, though it is more easily and speedily formed out of myosin than out of any other proteid substance. M. F.

SYRIA. A red dye-stuff, occurring in commerce as a dark-red, tasteless, and inodorous powder, which imparts a red colour to water and alcohol, and burns with the odour of horn when heated. According to Vizey (J. Pharm. xxvi. 167), it consists of the incompletely exhausted residue of *Coccus Ilicis*, therefore for the most part of chitin, mixed with coccus-red.

SYRINGA VULGARIS. *Common Lilac.*—The leaves of this plant contain, according to Dumenil (Trommsd. N. J. xi. 117), uncrystallisable sugar.—Ludwig (Arch. Pharm. [2] xci. 289) found mannite in them, also in the young branches. Bernays and Kromayer (*infra*) found in the leaves, branches, and bark, a glucoside called *syringin*.—Meillet (Ann. Ch. Pharm. xl. 319) obtained from the leaves and green seed-capsules, a crystallisable substance, which he designates as *lilacin*; it resembles syringin in all its properties, excepting in having a bitter taste, and being insoluble in water. According to Mulder (J. pr. Chem. xxxii. 172), the waxy substance contained in the leaves has the composition of ordinary wax. The odoriferous principle of the flowers may be obtained (according to Favret, J. Chim. méd. xiv. 212), by extraction with ether, as a viscid oil, composed of a waxy body and a mobile oil.

SYRINGENIN. $C^{13}H^{22}O^5.H^2O$.—A substance obtained, together with fermentable sugar, by warming syringin with dilute sulphuric or hydrochloric acid. It is deposited in viscid cohering flocks, and forms, after washing with water, a light rose-coloured amorphous mass, which becomes anhydrous at 100°, melts at 170°—180°, is insoluble in water and in ether, dissolves with cherry-red colour in alcohol, and separates from this solution, on evaporation, as a light cinnamon-coloured powder, composed of transparent globules. It reacts with acids like syringin. (Kromayer.)

SYRINGIN. $C^{19}H^{28}O^{10}.H^2O$. (Bernays, J. pr. Chem. xxv. 121.—Kromayer, Arch. Pharm. [2] cviii. 7; cix. 18, 216; cxiii. 19; Jahresb. 1862, p. 484; 1863, p. 592.)—This compound, discovered by Bernays in 1841, and more completely investigated by Kromayer, occurs in the bark of the lilac, more abundantly in March than in April, not in the leaves or in the half-ripe fruit, and only in traces in the leaf-buds. It disappears as the season advances, its place being apparently supplied by syringopicrin (Kromayer). Ligustrin from privet-bark (iii. 694) is (according to Kromayer) identical with syringin. Meillet's lilacin (*supra*) is probably also the same substance.

To prepare syringin, the bark is exhausted with boiling water; the extract precipitated with basic acetate of lead; the filtrate treated with sulphydric acid; and after removal of the sulphide of lead, evaporated to a thin syrup, which solidifies in the course of a day to a crystalline pulp. This mass is purified by stirring it up with cold water, then pressing, and recrystallising it from boiling water, with aid of animal charcoal. The syringin dissolved in the wash-waters is obtained by evaporating the liquid, and agitating the residue with alcohol, which takes up the syringin. (Bernays; Kromayer.)

Syringin crystallises from alcohol in long, colourless, transparent needles, containing 4·5 per cent. (1 at.) water, which they give off at 115°, leaving anhydrous syringin, $C^{19}H^{28}O^{10}$, which melts at 212° to a colourless liquid, and solidifies on cooling to an amorphous, transparent, hard, friable, tasteless, neutral mass (Kromayer). Ligustrin from privet melts at 185°—190°. (Kromayer.)

Syringin dissolves sparingly in cold, easily in hot *water*; it is soluble also in *alcohol*, but not in ether; it does not precipitate metallic salts.

Decompositions.—1. Syringin, when *heated*, decomposes below its melting-point, giving off an odour of caramel, and burning away.—2. The aqueous or alcoholic solution of syringin acquires a fine dark-blue colour when mixed with an equal volume of *oil of vitriol*; with a larger quantity of oil of vitriol, the colour changes to a beautiful violet, and the liquid on standing deposits blue, and on addition of water, grey-blue flocks, which dissolve with cherry-red colour in alcohol and in ammonia.—3. When cautiously heated with fuming hydrochloric acid, it dissolves without coloration, but on boiling, the solution assumes a light violet-red colour, and deposits blue flocks.—4. An aqueous solution of syringin through which *chlorine-gas* is passed acquires a red-brown colour, but after a while becomes quite colourless. At the same time an acid is formed, having a bitter irritating taste, and assuming a dark-blue colour when mixed with ferric chloride.—5. Syringin dissolves quickly in strong *nitric acid*, forming a deep blood-red solution.

6. When aqueous syringin is heated with dilute *hydrochloric acid*, the solution becomes milky, and deposits adhering lumps of syringenin, whilst fermentable sugar remains dissolved:

$$C^{19}H^{28}O^{10} + H^2O = C^{13}H^{18}O^5 + C^6H^{12}O^6.$$

100 pts. crystallised syringin yielded 61·77 pts. air-dry syringenin and, on the average, 41 pts. sugar (calc. 62·67 pts. hydrate of syringenin and 41·47 sugar: Kromayer).

Syringin does not reduce either *cuprate of potassium* or *nitrate of silver*, and is not altered by *alkalis*. (Kromayer.)

SYRINGOPICRIN. This substance remains in the alcoholic mother-liquor from which syringin has crystallised, and may be extracted therefrom by animal charcoal. By treating the charcoal with hot alcohol (after washing it with warm water), a solution is obtained, which yields by evaporation (after being again treated with charcoal) a yellowish bitter substance, which is soluble in water and in alcohol, but not in ether; is precipitated by tannic acid, but not by basic acetate of lead; and does not reduce an alkaline cupric solution till it has been boiled with dilute sulphuric acid. (Kromayer, *loc. cit.*)

SYRUP. A concentrated solution of sugar. In the sugar-manufacture, the term is applied especially to the mother-liquor remaining after the cane-sugar has crystallised out. In pharmaceutical language, it is applied to solutions of sugar, either in pure water, in the decoction or infusion of any medicinal substance, in vinous infusions or in pressed and fermented fruit-juices.

SZAJBELYITE. A hydrated borate of magnesium, occurring imbedded, in rounded grains and microscopic needles, in the fine-grained limestone of the metalliferous deposits of Rezbanya in Hungary, and remaining behind when the limestone is dissolved in dilute acids. Specific gravity of the needles = 2·7, of the grains = 3·0. It gives off water when heated, but reabsorbs it after cooling. Before the blowpipe, it splits and swells up on the edges with strong incandescence, then melts to a tumefied and finally horny brownish-grey mass; colours the flame red to yellow-red. In phosphorus-salt it dissolves slowly to a clear glass, yellowish while hot, colourless after cooling; in borax, after prolonged effervescence, to a clear bead having a faint reddish-grey colour, but remaining colourless after exposure to the reducing flame. (K. F. Peters, Wien. Akad. Ber. xliv. [2] 143; xlvii. [2] 347; Jahresb. 1862, p. 1029.)

The following analyses by A. Stromeyer (Jahresb. 1863, p. 836), show that the composition of the needles is $5MgO.2B^2O^3.\frac{4}{3}H^2O$, and that of the grains, $5MgO.2B^2O^3.\frac{8}{3}H^2O$:

		B^2O.	MgO.	Fe^2O^3.	H^2O.	Cl.	Quartz.	Charcoal and MnO.		
Needles	.	36·66	52·49	1·66	6·99	0·49	0·20	trace	=	98·49
Grains	.	34·60	49·44	3·20	12·37	0·20	. .	. .	=	99·81

SZESKO. The Hungarian name of native sodic carbonate.

T

TABASHEER. Hydrated silica, occurring in stony concretions in the joints of the bamboo. It resembles hydrophane, and when thrown upon water does not sink till completely saturated therewith. It is the least refractive of all known solids, its index of refraction, for the yellow ray, being 1·115. Rost van Tonningen (Jahresb. 1860, p. 531) found in tabasheer from Java, 86·39 per cent. silica soluble in potash, 0·42 ferric oxide, 0·24 lime, 4·81 potash, 0·51 organic matter, and 7·63 water.

TABERGITE. A chloritic mineral from Taberg in Wermland, Sweden; closely resembling clinochlore in external aspect and in reactions; and containing, according to Svanberg (Berz. Jahresb. xx. 235), 35·76 per cent. silica, 13·03 alumina, 30·00 magnesia, 6·34 ferrous oxide, 1·64 manganous oxide, 2·07 potash, 11·76 water, and 0·67 fluorine. According to Descloizeaux (Ann. Min. xi. 280), it is optically biaxial, like clinochlore, and differs in composition from that mineral only in consequence of admixtures.

TABULAR SPAR. *Wollastonite.* Native silicate of calcium, $Ca''SiO^3$. (See Silicates, p. 252.)

TACAMAHAC. *Gummi Takamahak.*—A resin formerly used for fumigation and for plasters. There are two varieties of it:—*a.* West Indian tacamahac, from *Elaphrium tomentosum*, Jacq. (*Fagara octandra*, L.) and *E. excelsum*, Kth., trees belonging to the order *Burseraceæ*, and indigenous in Mexico, the West Indies, and South America. The resin exudes from the bark, and hardens on exposure to the air. It forms reddish or brownish lumps, having a bitter aromatic taste, imperfectly soluble in alcohol and alkalis, perfectly soluble in ether and in oils, both fat and volatile.—*β.* The East Indian variety, from *Calophyllum inophyllum*, L. (according to Lindley from *C. Calaba*, L.), an East Indian tree belonging to the order *Clusiaceæ*, is very rare. It is a greenish-yellow or orange-coloured, soft, resinous mass, which gradually hardens, has an agreeable lavender-like odour, and aromatic somewhat bitter taste; melts easily, and dissolves completely in alcohol.

TACHYAPHALTITE. A mineral discovered by Weibye (Pogg. Ann. lxxxviii. 160), at Krageröe in Norway, where it occurs imbedded in granite veins in the gneiss. According to Berlin, it contains 34·58 per cent. silica, 38·96 zirconia, 12·32 thorina(?) 3·72 ferric oxide, 1·85 alumina, and 8·49 water. It forms dimetric crystals, like those of zircon, being combinations of the prisms ∞P and $\infty P \infty$ with two octahedrons—one of 110° (terminal edge), the other of 50°. Cleavage not very distinct. Fracture conchoïdal. Hardness = 5·52. Specific gravity = 3·6. Lustre submetallic to vitreous. Colour dark reddish-brown. Streak dirty-yellow. Subtranslucent. Heated in a tube, it gives off water with slight fluorine reaction. Before the blowpipe it becomes dirty-white, but does not melt. In borax it dissolves with difficulty; with soda, on platinum, it forms a dirty yellowish-brown slag.

TACHYDRITE. $Ca''Mg''^2Cl^6.12H^2O$ or $Ca''Cl^2.2Mg''Cl^2.12H^2O$.—This mineral occurs in the saline deposits of Stassfurt, in roundish, yellow, transparent to translucent lumps, which are imbedded in compact anhydrite, and contain small crystals of the latter enclosed within themselves. It cleaves distinctly in two directions. Deliquesces quickly when exposed to the air.

TACHYLYTE. *Conchoïdal Augite.*—A silicate occurring in basalt on the Säsebühl near Daansfeld in Hanover, and containing (according to Schnedermann) 55·74 per cent. silica, 12·40 alumina, 13·06 ferroso-ferric oxide, 7·28 lime, 5·92 magnesia, 3·88 soda, 0·60 potash, 0·19 manganous oxide, and 2·73 water. It is amorphous, with conchoïdal, even or uneven fracture; black and opaque, with waxy lustre and dark-grey streak; brittle and somewhat magnetic; hardness = 6·5; specific gravity = 2·565–2·593. Before the blowpipe it melts very easily, and with intumescence, to a blistered, brownish-green, magnetic glass, and gives with borax the reaction of iron.

Hyalomelane, a mineral occurring in the porous basalt of the Vogelsgebirge in Hesse, is usually regarded as identical with tachylyte, but according to Hausmann (*Handb. d. Mineral.* ii. 546), it is a distinct species. According to an analysis by C. G. Gmelin (Pogg. Ann. xlix. 234), it contains:

SiO^2.	TiO^2.	Al^2O^3.	FeO.	CaO.	MgO.	Na^2O.	K^2O.	MnO.	Water and ammonia.		
50·22	1·41	17·84	10·26	8·25	3·37	5·18	3·86	0·40	0·50	=	101·29

Nearly allied to it is a mineral from the Wetterau, likewise analysed by Gmelin (Leonhard's N. Jahrb. f. Mineral., 1840, p. 549), which has a specific gravity of 2·705, does not gelatinise with acids, and is not decomposed even by boiling with strong sulphuric acid; also a scoriaceous augite, described by D. L. G. Karsten, and analysed by Klaproth (*Beiträge*, iv. 190), from a limestone deposit at Guiliane in Sicily. (Handw. d. Chem., viii. 467.)

TÆNIIN, or *Koussin.*—A resinous substance, supposed to constitute the active principle of kousso-flowers (the flowers of *Brayera anthelmintica*). It is extracted by digesting the flowers with strong alcohol containing a little potash, and is obtained by evaporation as a resinous mass, or as a white powder having a bitter nauseous taste. It melts at about 100°, is nearly insoluble in water, soluble in 1300 pts. spirit of 45 per cent. at 17°, and in 12 pts. alcohol of 90 per cent.; it dissolves in ether in nearly all proportions, and with tolerable facility in alkalis, whence it is precipitated by acids. (Pavesi, Buchn. N. Repert. viii. 325.—Bedall, *ibid.* 546.)

TAGILITE. A basic cupric phosphate, $\overline{Cu}{}^3P^2O^8.Cu''H^2O^2$, from Nischne-Tagilsk (iv. 561).

TAGUA-NUT. The fruit of *Phytelephas macrocarpa*, worked as "vegetable ivory."

TA-HONG. [illegible] —containing ferric oxide, used in China as a red enamel [illegible]

TAIGU WOOD. A wood from Paraguay, resembling guaiacum-wood in appearance and specific gravity. It has a greenish-brown colour when fresh; becomes covered, on exposure to the air, with a greenish-yellow crystalline powder; and exhibits under the microscope yellow oblique prisms, together with shining, colourless, thin, six-sided tables: the latter are not altered by alkalis; the former, which consist of taiguic acid, are reddened thereby. Strong boiling alcohol extracts from it 13·7 per cent. of a mixture of taiguic acid with resinous and waxy substances. The wood, after drying in hydrogen-gas, yields, when boiled with water, 5·7 per cent. of a gum-resin smelling like benzoin, after which alcohol again extracts from it 2·5 per cent. of resinous substance.

TAIGUIC ACID. (Arnaudon, Cimento, vii. 37; Jahresb. 1858, p. 264.)—This acid, which occurs in the cold alcoholic extract of taigu wood (*supra*), is freed from admixed resins by repeated treatment with alcohol, and from waxy matters by ether: the solution is then evaporated, and the residue dried: 100 pts. of the wood yield 2 pts. of the acid.

Taiguic acid crystallises in oblique prisms having a fine yellow colour: it is tasteless and inodorous; but when rubbed, emits an unpleasant odour, and becomes electric: it melts at 135°, and sublimes at 180°. It is but very slightly soluble in water, even at the boiling heat (about 0·001); but when heated with water to 140° in a sealed tube, it dissolves in larger quantity, and crystallises on cooling. Acetone, ethers, benzene, and strong alcohol dissolve it freely. It contains 70·9 per cent. carbon, 5·9 hydrogen, and 23·2 oxygen, agreeing with the empirical formula C^4H^4O.

Taiguic acid unites with bases, forming crystallisable salts, from which it is separated unaltered by the stronger acids. With the alkalis it forms easily soluble salts having a deep red colour, the production of which is quite independent of atmospheric oxygen; hence taiguic acid forms a very delicate test for the presence of alkalis. The neutral solutions of the alkaline taiguates form, with neutral acetate of lead, an amorphous scarlet precipitate, which, in contact with water, gradually becomes crystalline and reddish-yellow; it is slightly soluble in water, more soluble in alcohol, and is obtained in pointed crystals by evaporation of the alcoholic solution.—Nitrate of silver forms, in neutral solutions of the alkaline taiguates, a cinnabar-coloured precipitate, which is decomposed by exposure to light, is nearly insoluble in water and in ether, moderately soluble in alcohol, freely in ammonia.

TAKOURAVE. Syn. with NEPHRITE (iv. 31).

TALC. $4Mg''O.5SiO^2.\frac{4}{3}H^2O$.—This mineral occurs both crystallised and massive; the massive variety is called steatite,* and was formerly regarded as a distinct species; but it has the same composition as crystalline talc.

Talc usually forms lamellar crystals, which cleave perfectly in one direction, but are too incompletely developed to admit of an exact determination of their crystalline system; they are, however, optically biaxial, and, besides the principal cleavage, exhibit also traces of cleavage in two directions obliquely inclined to one another. The crystals are of various sizes, forming plates, laminæ, and scales, and are sometimes elongated in one direction. They also occur aggregated, in crystallo-laminar, radio-laminar, or scaly groups, which in larger masses often exhibit a true slaty structure (talcose slate). The lamellæ are very flexible but not elastic, and unctuous to the touch. Talc is very soft, its hardness being, in fact, adopted as the unit of the scale. Specific gravity = 2·6 to 2·8. It is colourless, white, grey, greenish-white and greenish-grey, apple-green, leek-green, and yellowish-white to yellowish-grey, transparent (in thin lamellæ) to merely translucent on the edges, and has a waxy lustre, nacreous on the perfect cleavage-faces. When heated before the blowpipe, it glows brightly, usually exfoliates and burns hard (to a hardness of 6), but does not fuse; with phosphorus-salt it yields a skeleton of silica, and when moistened with cobalt-solution, and ignited, it becomes pale-red. It is insoluble in acids both before and after ignition.

Compact steatite (*Speckstein* of the Germans), which occurs massive, imbedded in kidney-shaped and nodular lumps, also as pseudomorphs after quartz and dolomite, has an uneven to splintery fracture, a greasy feel, and does not adhere to the tongue. Its specific gravity and hardness are, for the most part, the same as those of talc: the hardness, however, is sometimes rather greater (= 1·5). It is white, grey, yellow, red, green, dull, opaque to translucent on the edges. When heated in a glass tube, it gives off a little water; before the blowpipe it does not melt, but burns to a degree of hardness sufficient to scratch glass; when ignited with cobalt-solution, it becomes pale red. It is decomposed by boiling sulphuric acid, differing in that respect from crystalline talc.

Potstone, or *Lapis ollaris*, is a coarse dark-coloured steatite, more or less impure.

Pure talc, $4Mg''O.5SiO^2.\frac{4}{3}H^2O$, contains 62·14 per cent. silica, 32·92 magnesia, and 4·94 water. The numerous analyses of the mineral in its several varieties exhibit but slight deviation from this composition—viz., from about 62 to 64 per cent. silica, 28 to 33 magnesia, and 2·5 to 5 water, with from 0·5 to 7 per cent. ferrous oxide replacing part of the magnesia, and occasionally small quantities of alumina, lime, &c., which must be regarded as impurities. Some varieties appear to be anhydrous, or to contain but very little water; but this result is perhaps due to defective analysis, as the water is expelled only at a very strong red heat. (For the individual analyses, see Rammelsberg's *Mineralchemie*, p. 517.)

---

* Soapstone (also called steatite) is a mineral of different composition—viz., silicate of magnesium and aluminium (p. 324).

Talc is a very widely diffused mineral, some of its varieties (especially common talc, potstone, and steatite) forming extensive beds in regions of crystalline rocks. Apple-green talc occurs in Unst, one of the Shetland Isles; also on the Greiner Mountain in Salzburg, and in the Valais, &c. Potstone occurs in the Valais and the Grisons, and at Wald in Styria. Extensive beds of steatite occur in various parts of the New England States—also in New Jersey, Pennsylvania, &c.

Green talcose minerals occur at Fahlun in Sweden, and at Gastein in the Tyrol. A white, large-laminated, and radio-laminated talc from Pressnitz, in Bohemia, contains about 68 per cent. silica, 26 magnesia, 1·2 to 1·6 ferrous oxide, and 4·1 water. (Scheerer.)

Slabs of steatite are extensively employed as firestones in furnaces and stoves. It may be turned in a lathe, and formed into tubes by boring. When ground, it is used for diminishing friction. It is also employed in the manufacture of some kinds of porcelain. Venetian talc is used for removing oil-stains from woollen cloths, &c. (Dana, ii. 277.)

TALC, INDURATED. The harder varieties of steatite.

TALC, WHITE, from China; syn. with Agalmatolite (i. 60).

TALC-ALUM. A term sometimes applied to magnesio-aluminic sulphate (p. 583).

TALCAPATITE. A variety of apatite containing magnesia, occurring in six-sided crystals, grouped or single, in the chlorite-slate of the Schischimskan Mountains, near Slatoust in the Ural. According to Hermann (J. pr. Chem. xxxi. 101), it contains 37·50 per cent. lime, 7·74 magnesia, 39·02 phosphoric acid, 2·10 sulphuric acid, 0·91 chlorine, 2·23 fluorine (and loss), 1·00 oxide of iron, and 9·50 insoluble matter. The soluble portion may be represented approximately by the formula $3Ca^3P^2O^8.Mg^3P^2O^8$; but it is probably only an impure apatite, the magnesia being derived from the gangue.

TALC-CHLORITE. Syn. with Clinochlore.

TALC-IRON-ORE. *Magnesian Iron-ore. Talkeisenerz. Tesseranus magnesifer.*—This name is applied by Breithaupt (*Handb. d. Mineralogie*, iii. 778) to an iron-ore from the State of New York, consisting (according to Plattner) of ferrous oxide with much magnesia, a somewhat considerable quantity of titanic acid, and a small quantity of alumina, but no chromium. It forms cubo-octahedrons, fissured internally, but exhibiting only traces of cleavage parallel to the cubic and octahedral faces. It is opaque, iron-black with black streak, and nearly semimetallic lustre. Hardness = 6·0. Specific gravity = 4·0 to 4·5. Very slightly magnetic. Behaves before the blowpipe like titaniferous iron-ore.

TALC-IRONSTONE. *Talkeisenstein.*—Breithaupt's name for a magnetic iron-ore from Sparta in New Jersey, having the ferrous oxide partly replaced by magnesia. It is slightly magnetic, and has a density of 4·41 to 4·42. Allied to this is the magnesiferous magnetic iron-ore occurring in imperfect octahedrons in the slates of the Mourne Mountains in Ireland, and containing, according to Andrews (J. pr. Chem. lvii. 376), 71·41 per cent. Fe^2O^3, 21·59 Fe^2O, and 6·45 MgO.—Also Rammelsberg's magnoferrite from Vesuvius (iii. 784).

TALC-GARNET. *Talkgranat. Talkthongranat.* Magnesian garnet from Arendal in Norway (ii. 772).

TALCITE, or **TALXITE.** A mineral from Wicklow in Ireland, allied to nacrite (iv. 1).

TALCOÏD. This name was applied by Naumann to the white laminated talc from Pressnitz in Bohemia (*supra*).

TALCOSE SLATE. A dark slaty rock, having a somewhat greasy feel, and consisting largely of talc, intimately mixed with felspar and quartz.

TALLICOONAH-OIL. Syn. with Carapa-oil (i. 749).

TALLINGITE. An oxychloride of copper, allied to atacamite, from the Botallack mine in Cornwall. It forms greenish-blue, thin, somewhat crystalline crusts, composed of small spherules. Hardness = 3. Specific gravity = 3·5. It is insoluble in water, easily soluble in dilute acids and in ammonia, and turns green, with loss of water, at 100°. It contains 66·24 per cent. cupric oxide, 11·33 chlorine, and 24·16 water (= 101·73), besides traces of carbonic acid, arsenic, alumina, and sodic chloride: whence the formula, $Cu''Cl^2.4Cu''H^2O^2.4H^2O$ (Church, Chem. Soc. Qu. J. xviii. 77). For atacamite, Church calculates the formula $Cu''Cl^2.3Cu''H^2O^2.H^2O$. (Compare i. 429.)

Another cupric oxychloride from the same mine, called *botallackite*, occurring in thin pale mountain-green crusts, of specific gravity 3·6, was found to contain 66·25 per cent. $Cu''O$, 14·76 Cl, and 22·45 H^2O (= 103·22), whence the formula $Cu''Cl^2.3Cu''H^2O^2.3H^2O$. A blue cupric oxychloride, also from the same mine, appeared, from a preliminary analysis, to consist of $Cu''Cl^2.6Cu''H^2O^2.6H^2O$. (Church, *ibid.* 212.)

TALLOW. This name is applied to the harder and less fusible fats, occurring chiefly, though not exclusively, in the animal kingdom, the most common being beef and mutton tallow. The most solid of the vegetable fats are cacao-fat, from *Theobroma Cacao*; Chinese tallow, from the berries of *Stillingia sebifera*; myrica-tallow, from the berries of *Myrica cerifera* (which, however, is rather a wax); virola-tallow, from the shelled almonds of *Myristica sebifera*; and piney-tallow, from the fruit of *Valeria indica*. Cocoanut-fat is also frequently called a tallow, though it has rather the consistence of butter. (See the names of the several plants in this Dictionary; also *Gmelin's Handbook*, xvi. 385—400.)

Animal tallow consists chiefly of stearin, palmitin, and olein, the stearin predominating, but varying with the species of the animal (*e.g.*, mutton and deer tallow are mostly harder and less fusible than beef-tallow), and with the age, mode of feeding, &c. The tallow is separated from the cellular tissue in which it is enclosed (the entire mass constituting suet) by melting. This operation is performed at the lowest possible temperature, and is much facilitated by the addition of dilute sulphuric acid (1 pt. oil of vitriol and 20 pts. water to 100 pts. tallow). The melted tallow is white, if pure; a less pure tallow, which has a yellowish colour, may be bleached by exposure to light and air; more rarely, the bleaching is effected by the use of chemical reagents—*e.g.*, by heating 100 pts. of the tallow with 1 pt. sulphuric acid and ½ pt. red chromate of potash, or 200 pts. tallow with 1 pt. nitric acid and 1 pt. oil of vitriol.

Tallow, especially that of the ox and sheep, is largely used for the manufacture of soap and candles; in smaller quantity also in pharmacy.

TALMI GOLD, an alloy used for the manufacture of trinkets, contains, according to Sauerwein (Dingl. l. clxx. 154), 86·4 per cent. copper, 12·2 zinc, 1·1 tin, and 0·3 iron.

TA-LOU. The Chinese name for a glass flux, consisting chiefly of silicate of lead with a little copper, used as an enamel colour on porcelain. (Ebelmen and Salvétat, Ann. Ch. Phys. [3] xxxv. 344.)

TALTALITE. The name given by Domeyko (Jahresb. 1863, p. 815) to a black or brown-black crystalline mineral from a mine in the desert of Atacama, containing 44·5 per cent. CuO, 2·4 CaO, 0·8 MgO, 16·2 Al^2O^3, 11·3 Fe^2O^3, 20·8 SiO^2, 0·7 Cl, and 2·5 loss by ignition (= 99·2). According to Ulex (*ibid.* 1865, p. 888), it is a fine-grained mixture of atacamite, malachite, red hæmatite, and calcspar, intersected by crystals of tourmalin.

TAMARINDS. *Fructus Tamarindarum.*—The pulpy mass contained in the pods of *Tamarindus indica*, a leguminous tree growing in the East and West Indies, in Egypt, and in Arabia. It has a faint vinous odour and agreeably acid taste. Vauquelin (Ann. Chim. v. 92) found in East Indian tamarinds, sugar, gum, pectic acid, malic, citric and tartaric acids, acid tartrate of potassium, and cellulose. Scheele did not find citric acid. According to Gorup-Besanez (Buchn. Repert. lxviii. 260), tamarinds likewise contain acetic and formic acids.

TAMARITE. *Chalcophyllite. Copper-mica* (in part).—A basic cupric arsenate, occurring in rhombohedral crystals, also foliated, massive, and in druses. Principal axis of rhombohedron = 2·5536. Angle R : R (terminal) = 69° 48′; oR : R = 108° 4′. Observed combination, oR . R, also with +2R, $-\frac{1}{2}$R, and ∞R. Cleavage highly perfect parallel to oR, which plane is sometimes triangularly striated. Hardness = 2. Specific gravity = 2·4 to 2·66. Lustre pearly on the base, vitreous or subadamantine on the other faces. Colour emerald- or grass-green to verditer-green. Streak somewhat paler. Fracture scarcely observable. Sectile. When heated it decrepitates and exfoliates. Before the blowpipe it yields a scoriaceous mass enclosing a button of copper.

Analyses.—*a*, by Chenevix (Phil. Trans. 1801).—*b*. Specific gravity = 2·435 (Hermann, J. pr. Chem. xxxiii. 294).—*c*, *d*. Specific gravity = 2·659 (Damour, Ann. Ch. Phys. [3] xiii. 404):

	As^2O^5.	P^2O^5.	CuO.	FeO.	Al^2O^3.	H^2O.		
a.	21	. .	58	. .	. .	21	=	100
b.	17·51	. .	44·45	2·92	3·93	31·19	=	100
c.	19·35	1·29	52·92	. .	1·80	23·94	=	99·30
d.	21·27	1·56	52·30	. .	2·13	22·58	=	99·84

These widely different results cannot be reduced to a single formula:

a may be approximately represented by $8CuO.As^2O^5.13H^2O = Cu^3As^2O^8.5CuH^2O^2.8aq.$
c and *d* „ „ $8CuO.As^2O^5.15H^2O = Cu^3As^2O^8.5CuH^2O^2.10aq.$
b „ „ $8CuO.As^2O^5.23H^2O = Cu^3As^2O^8.5CuH^2O^2.18aq.$

The principal Cornish localities of this mineral are the copper mines of Tingtang, Huel Gorland, and Huel Unity, near Redruth. It occurs also crystallised in iron-ore at Sayda in Saxony, in minute crystals at Herrengrund in Hungary, and at Moldawa in the Bannat. It is sometimes found altered to chrysocolla.

TAMARIX. From the flowers of the French tamarisk (*Tamarix gallica*), a crystalline iridescent substance may be obtained, by exhaustion with alcohol and evaporation (Landerer). The leaves contain a large quantity of potassic sulphate. *T. laxa* grows chiefly on the Kirghis Steppe: 100 pts. of the young air-dried plant yield 33·7 per cent. ash, containing 12·5 per cent. sodic carbonate, 52·0 sodic chloride, 1·6 sodic sulphate, and 3·0 potassic sulphate, together with 38·8 pts. insoluble salts. (Göbel.)
Tamarix mannifera yields, in consequence of the puncture of an insect (*Coccus manniferus*), a saccharine substance, the so-called *Manna of Sinai*, which is a yellow syrup containing 55 per cent. cane-sugar, 25 inverted sugar, 20 dextrin, &c. (Berthelot, Compt. rend. liii. 583.)

TAMTAMS, or *Gong-gongs*.—Chinese musical instruments having the form of a kettle-drum, and sounded by beating them with a stick covered with leather. According to Klaproth, they are formed of an alloy of 78 pts. copper to 22 pts. tin. According to Genth (Mitth. d. Gewerbevereins, f. Hannover, 1859, p. 106), they consist of 80 per cent. copper and 20 per cent. tin. According to Julien (Compt. rend. xxiv. 1069), the Chinese alloy the copper for these instruments, and for cymbals, &c., with ½ pt. of tin.

TANACETIC ACID. An acid said by Peschier (J. Chim. méd. iv. 58), to exist in the flowers of the common tansy (*Tanacetum vulgare*). It is crystalline, soluble in water, forms crystallisable salts with potash and soda, and precipitates the solutions of calcium, barium, zinc, lead, silver, copper, and mercury.

TANACETIN. A bitter substance obtained from the leaves and flowers of tansy. It is prepared in the same manner as absinthin from wormwood (i. 2), and forms a yellowish-white, granular, inodorous mass, easily soluble in ether, sparingly in alcohol, still less in water. The solution has a bitter and rather sharp taste, and is precipitated by plumbic, ferric, and mercurous salts, not by tannic acid. (Fromberg, Geig. Magaz. viii. 35.—Leroy, J. Chim. méd. xxi. 357.)

TANACETUM VULGARE. *Tansy.*—The leaves of this plant contain volatile oil, a bitter extractive matter called tanacetin (*supra*), tannin, sugar, malic acid, and other substances. The flowers contain the same constituents, but are richer in volatile oil, and (according to Peschier) they also contain tanacetic acid. The seeds contain volatile oil, fat oil, and a bitter substance.

The volatile oil of tansy, obtained by distilling the leaves or flowers with water, has a specific gravity of 0·92 to 0·93, dissolves easily in alcohol of specific gravity 0·85, thickens on exposure to the air, dissolves in iodine, but is not sensibly acted upon by it. When distilled with chromate of potassium and sulphuric acid, it yields a volatile crystalline body, having the composition of ordinary camphor (Persoz, Compt. rend. viii. 433; Vohl, Pharm. Centralbl. 1853, p. 318). It is decomposed and dissolved by nitric and by sulphuric acid.

TANAH-AMPO. A plastic earth, occurring in Java, and used by the natives as food, after being dried over a charcoal-fire. (Mohnike, J. Chim. méd. iv. 58.)

TANGHINIA MADAGASCARIENSIS. A shrub indigenous in Madagascar, the kernels of which contain, besides fat oil and the ordinary plant-constituents, a crystallisable substance called tanghin-camphor or tanghinin. To prepare this substance, the almonds are freed from oil by pressure, then exhausted with ether, and the ethereal solution is left to evaporate. Tanghinin then remains behind, and may be obtained, by solution in alcohol and spontaneous evaporation, in colourless, transparent, shining scales, which effloresce on exposure to the air. It has a sharp bitter taste, and afterwards produces a feeling of constriction in the throat. It melts to a resin when gently heated, but is not volatile. It dissolves in acetic acid, without entering into combination, and is coloured yellow by other acids and by alkalis. The alcoholic solution forms white precipitates with lead-, mercury-, and silver-salts. Tanghinin is very poisonous, quickly producing fatal effects.

TANGIWAITE. A variety of nephrite from Tangiwai in New Zealand. (Jahresb. 1864, p. 351.)

TANKITE. A mineral from Norway resembling chiastolite: specific gravity = 2·936. (Breithaupt, Schw. J. 1829, p. 246.)

TANNASPIDIC ACID. $C^{26}H^{29}O^{11}$ (?). (Luck, Pharm. Centr. 1851, p. 667.)—An acid contained, together with pteritannic acid, in the root of the male fern (*Aspidium Filix mas*). The method of extracting these acids and separating them with ether has been already described (iv. 745). The impure tannaspidic acid left undissolved by the ether is purified by solution in alcohol, and evaporation in a retort filled with hydrogen.

Tannaspidic acid forms a black-brown, shining, amorphous mass, triturable to a red-brown powder. It is insoluble in water, ether, oil of turpentine, and fixed oils, easily soluble in strong alcohol, soluble also in warm acetic acid. The alcoholic solution evaporated by heat, in contact with the air, leaves a residue no longer soluble in alcohol. Strong sulphuric acid dissolves it, forming a dark-green liquid, which soon becomes brown-red on the surface. Nitric acid dissolves and decomposes it. With chlorine it forms substitution-products.

Tannaspidic acid dissolves easily in potash or ammonia, forming a dark-brown solution, which quickly absorbs oxygen, especially when warmed, acquiring a brown-red colour: acids added to the latter solution throw down a black powder. The alcoholic solution of tannaspidic acid is precipitated by chloride of barium, chloride of calcium, acetate of copper, nitrate of silver, and chloride of platinum,—also, after addition of ammonia, by zinc-, mercury-, and tin-salts. Ferric chloride colours the alcoholic solution green, and on addition of ammonia a green precipitate is formed. The solution of tannaspidic acid precipitates an alcoholic solution of isinglass, but not a solution of tartar-emetic.

By treating the alcoholic solution of the acid with neutral acetate of lead, a precipitate is formed, which dries up to a black shining mass, containing on the average 43·4 per cent. carbon, 3·6 hydrogen, 22·3 oxygen, and 30·60 plumbic oxide, agreeing approximately with the formula $C^{26}H^{26}Pb''O^{11}$, which requires 43·2 per cent. C, 3·6 H, 22·2 O, and 31·0 PbO.

Chlorotannaspidic Acids.—When dry chlorine-gas is passed over dry tannaspidic acid, a substitution-product is formed, containing 2 at. chlorine, and yielding on trituration a cinnamon-brown powder, having a fruity odour and sour astringent taste, soluble with brown colour in alcohol and aqueous alkalis, but insoluble in water, ether, oil of turpentine, and fixed oils. Tannaspidic acid suspended in water is converted by chlorine or by hypochlorous acid into a product containing 3 at. chlorine; and the air-dried acid, treated with moist chlorine-gas, yields a product containing 4 at. chlorine.

Ethyl-tannaspidic Acid.—The alcoholic solution of tannaspidic acid turns red when boiled with hydrochloric acid, and water added to the solution throws down a red substance.

TANNECORTEPINIC ACID. $C^{28}H^{28}O^{12}$? (Kawalier, Wien. Akad. Ber. xxix. 10.)—An acid resembling the tannic acids, occurring, about Easter-time, in the bark of Scotch fir-trees from 20 to 25 years old. To prepare it, the bark is exhausted with alcohol; the extract left on evaporation is treated with water; the clear aqueous solution is repeatedly precipitated with neutral lead-acetate, a lead-salt mixed with resin then remaining in solution; the clear solutions are precipitated with basic lead-acetate; the washed precipitate is suspended in water, and decomposed by sulphydric acid; and the liquid is concentrated in a stream of carbonic anhydride. Tannecortepinic acid is then deposited in crusts, which yield by trituration a reddish-brown powder having an astringent taste. It is soluble in water, and the solution, warmed with sulphuric or hydrochloric acid, yields a red precipitate having nearly the same composition as the acid, together with a very small quantity of sugar. The aqueous solution of the acid mixed with ferric chloride, acquires a greenish colour, changing to red-brown on standing, and afterwards deposits a blackish-green precipitate.

TANNENITE. A sulphide of copper and bismuth, $Cu^{2}S.Bi^{2}S^{3}$, occurring at Tannenbaum, in the Erzgebirge (ii. 77); also, according to Domeyko (Ann. Min. [6], v. 453), in the mines of Cerro Blanco, near Copiapo, in long tin-white needles, intersecting copper-pyrites. Analysis gave 22·4 per cent. sulphur, 52·7 bismuth, 20·6 copper, and 4·1 iron (= 99·8).

TANNIC ACID. TANNIN. These terms are applied to certain substances occurring in the bark and other parts of plants, and distinguished by the following characters. They are mostly amorphous, have a slight acid reaction, and a rough but not sour taste; colour ferric salts black-blue or green; precipitate albumin and gelatin from their solutions; and unite with animal membrane into a mass which resists putrefaction, namely leather, the skin then becoming tanned. All these substances were formerly supposed to be identical with gallotannic acid (ii. 762), or to differ from it only in consequence of the admixture of foreign matters; but more exact investigation has shown that most of them differ in some essential properties from gallotannic acid, which indeed exists only in Turkish and Chinese gall-nuts, and in ordinary oak-apples. Of the other varieties of tannin, the most distinctly characterised are *caffetannic acid* (i. 709), *catechutannic* or *cachoutannic acid* (i. 817), *morintannic acid* or tannin of fustic (iii. 1049), *quercitannic acid* or tannin of oak-bark (v. 6), and *quinotannic* or *cinchona-tannic acid* (v. 30).

The tannins may be divided into two groups—those which give black or blue, and those which give olive-green precipitates with ferric salts; and Stenhouse has shown that most of the tannins which give bluish-black precipitates with ferric salts are glucosides, being resolved by boiling with dilute acids into glucose and another substance, a property first pointed out by Strecker in the case of gallotannic acid, which yields glucose and gallic acid:

$$C^{27}H^{22}O^{17} + 4H^2O = C^6H^{12}O^6 + 3C^7H^6O^5;$$

whereas, among those which give green precipitates with ferric salts, only one (namely, the tannin of willow-bark) appears to be a glucoside.

Gallotannic acid submitted to dry distillation yields pyrogallic and metagallic acids, together with carbonic anhydride (ii. 765):

$$\underset{\text{Gallotannic acid.}}{C^{27}H^{22}O^{17}} = \underset{\text{Pyrogallic acid.}}{3C^6H^6O^3} + \underset{\text{Metagallic acid.}}{C^6H^4O^2} + 3CO^2;$$

whereas all those tannins which turn ferric salts green, yield, by dry distillation, oxyphenic acid or pyrocatechin, $C^6H^6O^2$, which differs from pyrogallic acid by containing 1 at. oxygen less (iv. 315).

All tannins are remarkable for the avidity with which they absorb oxygen, especially in presence of alkalis, being thereby converted into bodies of various colour—red, brown, black, and even green: *e.g.*, gallotannic acid into tannoxylic or tannomelanic acid; caffetannic acid into viridic acid; quinotannic acid into cinchona-red, &c.

Tannins occur especially in perennial plants, but are likewise found in annuals and biennials. They occur in the perennial roots of herbaceous plants, in the bark of most tree-stems, and in the young branches of shrubs and other woody plants. They are also found in the husks of fruits and seeds, and in unripe fruits, less frequently in the leaves, and least of all in the petals. According to Wahlenberg, they are never found in the interior of the seed, or in poisonous plants, or in such as contain caoutchouc or milky juice.

Iron-blueing tannins are found in gall-nuts and oak-apples; in the leaves, bark, &c. of the oak, poplar, birch, hazel-nut, and other trees; the leaves of *Arbutus Uva-ursi*, *Arbutus Unedo*, and *Lythrum Salicaria*; the stalks of *Ribes rubrum*; the bark of *Cornus mascula*, and many other plants and vegetable organs. Iron-greening tannins occur in catechu, cinchona-barks, pines, and fir; in the root of *Crameria triandra*, *Rheum rhaponticum*, *Potentilla tormentilla*; in the bark of *Salix triandra* and *S. undulata*, of *Alnus glutinosa*, *Pinus Larix*, *Rhizophora Mangle* (the common black mangrove), and of many other plants.

R. Wagner (Bull. Soc. Chim. 1866, ii. 461) divides tannins into pathological tannins, found only in diseased vegetable tissues, such as gall-nuts and oak-apples; and physiological tannins, which occur in bark and other parts of plants in their ordinary state. Both kinds of tannins precipitate gelatin from its solution, but only the physiological tannins are capable of forming with it a true leather not liable to putrefy.

All varieties of tannin are precipitated by organic alkaloïds. According to Wagner, 1 gramme of quercitannic acid requires for precipitation 0·3715 grm. of cinchonine; and assuming that the tannins of sumach and other astringent substances form, with a solution of sulphate of cinchonine, precipitates having the same composition, he obtains the following results respecting the strength of various substances used in tanning:—

Bark of young oaks contains . .	10·80 per cent tannin.
Ordinary oak-bark	6·25 „
Pine-bark	7·33 „
Beech-bark	2·00 „

Sumach (first quality) contains	16·50	per cent. tannin.
„ (second quality)	13·00	„
Valonia (first quality)	26·75	„
„ (second quality)	19·00	„
Bablah	14·50	„
Grape-seeds freed from oil	6·50	„
Hops (harvest of 1865)	4·25	„

Schulzeff (Bull. Soc. Chim. 1866, ii. 465) has observed that the precipitation of tannin by gelatin is greatly facilitated by the addition of sal-ammoniac, and he has applied the reaction to facilitate the volumetric estimation of tannin. For this purpose he saturates a graduated solution of tannin with sal-ammoniac, and determines the number of cubic centimetres of a solution of gelatin required to precipitate a given quantity of the former. He then exhausts the substance to be analysed with boiling water, and adds to the extract the titrated solution of gelatin. The deposition of the precipitate may be still further facilitated by introducing into the vessel a small quantity of pounded glass or sharp sand.

TANNIGENAMIC ACID. Syn. with Gallamic Acid (ii. 759).

TANNINGENIC ACID. Syn. with Catechin (i. 816).

TANNOMELANIC ACID. $C^6H^4O^3$.—This acid, discovered by Büchner (Ann. Ch. Pharm. liii. 373), who however assigned to it the formula $C^{14}H^5O^8$, is produced by adding gallotannic acid to boiling potash-ley of specific gravity 1·27, as long as effervescence is thereby produced. The liquid is kept in a state of ebullition, till a sample mixed with acetic acid remains clear on cooling, then supersaturated with acetic acid, and evaporated to dryness over the water-bath; and the residue is treated with strong alcohol, which dissolves acetate and gallate of potassium. The residue is dissolved in water, and the solution is mixed with acetic acid and acetate of lead, which throws down tannomelanate of lead, in the form of a black-brown powder containing (according to Gerhardt) $3C^{12}H^6Pb''O^6.2Pb''H^2O^2$. Tannomelanic acid may be supposed to be formed either from gallic or from tannoxylic acid (*infra*):

$$\underset{\text{Gallic acid.}}{C^7H^6O^5} + O = \underset{\text{Tannomelanic acid.}}{C^6H^4O^3} + CO^2 + H^2O.$$

$$\underset{\text{Tannoxylic acid.}}{C^7H^6O^6} = \underset{\text{Tannomelanic acid.}}{C^6H^4O^3} + CO^2 + H^2O.$$

TANNOPIC ACID. $C^{28}H^{30}O^{14}$? (Rochleder and Kawalier, Wien. Akad. Ber. xxix. 22.)—A kind of tannin occurring in the needles of the Scotch fir, gathered about Easter. The alcoholic extract of the needles, evaporated after addition of water, yielded a watery liquid together with resin. The liquid was mixed with neutral acetate of lead; the clear filtrate completely precipitated with that salt; the washed precipitate drenched with dilute acetic acid; and the filtrate precipitated with basic acetate of lead. The resulting precipitate, suspended in water and decomposed by sulphydric acid, yielded a solution of tannopic acid, which was precipitated therefrom by sulphuric acid. This acid, in warm solution, oxidises readily in contact with the air; whether it is thereby converted into oxypinitannic acid (iv. 319), and whether the same conversion takes place in the living plant, has not been determined. The acid is decomposed by sulphuric or hydrochloric acid, yielding a red easily decomposible product.

TANNOXYLIC ACID. *Rufitannic Acid.*—An acid produced by the oxidation of gallic acid under the influence of alkalis. It was discovered by Büchner (Ann. Ch. Pharm. liii. 369), who assigned to it the formula $C^{15}H^5O^{11}$ or $C^{15}H^{10}O^{11}$, or, in the free state, perhaps $C^{15}H^6O^{12}$ or $C^{15}H^{12}O^{12}$. According to Gerhardt, its composition and formation are better represented by the formula $C^7H^6O^6$. To prepare it, a moderately strong solution of potash is saturated in the cold with tannic acid; and the solution, which soon turns red, is left to stand for some days till it becomes dark-red and nearly opaque. It is then precipitated with acetate of lead, the resulting brick-red precipitate is treated with hot acetic acid to dissolve undecomposed tannate of lead, and the tannoxylate of lead ($8C^7H^4Pb''O^6.3Pb''H^2O^2$, according to Gerhardt), which remains as a red precipitate, is decomposed by heating with alcohol and sulphuric acid. A dark-red solution of tannoxylic acid is thereby obtained, which on evaporation leaves the acid as a brown-red amorphous substance. It may be supposed to be formed from gallic acid by simple addition of oxygen: $C^7H^6O^5 + O = C^7H^6O^6$. (Gerhardt.)

TANSY. See Tanacetum Vulgare (p. 658).

TANTALITE. Native ferrous tantalate. See Tantalates (p. 666).

TANTALUM. *Atomic weight*, 182. *Symbol*, Ta. (Ekeberg, Crell's Annalen. 1803, Bd. i.—Berzelius, Pogg. Ann. iv. 6.—Wöhler, *ibid.* xlviii. 91.—H. Rose, *ibid.* lxiii. 317; lxix. 115; lxx. 157; lxxiv. 85, 285; xc. 456; xcix. 65; Jahresb. 1856, p. 366; 1857, p. 176.—Hermann, J. pr. Chem. lxv. 81; lxx. 193; Jahresb. 1857, p. 175; 1858, p. 149; Bull. Soc. Chim. 1866, ii. 22.—Blomstrand, Jahresb. 1865, p. 195; Bull. Soc. Chim. 1866, ii. 27.—Marignac, *ibid.* pp. 111, 118.)

This metal was discovered in 1802, by Ekeberg, in two Swedish minerals, tantalite and yttrotantalite. A very similar metal, columbium, had been discovered in the preceding year by Hatchett (Crell's Annalen. 1802, i. 197, 257, 352), in columbite from Massachusetts; and Wollaston, in 1807 (Gilb. Ann. xxxvii. 98), on comparing the compounds of these metals, concluded that they were identical, an opinion which was for many years received as correct; but their separate identity has been completely established by the researches of H. Rose (commenced in 1846), who gave to the metal obtained from the American and Bavarian columbites the name *Niobium* (iv. 48), by which it is now universally known. More recently, Marignac has shown that nearly all tantalites and columbites contain both tantalum and niobium or columbium; some tantalates from Kimito in Finland being, however, free from niobium, and some of the Greenland columbites containing only the latter metal unmixed with tantalum. In all these minerals, tantalum exists as a tantalate of iron and manganese; yttrotantalite is essentially a tantalate of yttrium, containing also uranium, calcium, iron, and other metals. Tantalum is also contained in some varieties of wolfram.

Metallic tantalum is obtained by heating the fluotantalate of potassium or sodium with metallic sodium in a well-covered iron crucible, and washing out the soluble salts with water. The reduced metal thus obtained is not quite pure, being more or less contaminated with acid tantalate of sodium, the quantity of which may, however, be diminished by covering the mixture in the crucible with chloride of potassium.

Tantalum is a black powder, which (according to H. Rose) is a good conductor of electricity, and, after ignition in a stream of hydrogen, has a specific gravity of 10·78. When heated in the air, it burns with a bright light, and is converted, though with difficulty, into tantalic oxide. It is not attacked by sulphuric, hydrochloric, nitric, or even nitromuriatic acid. It dissolves slowly in warm aqueous hydrofluoric acid, with evolution of hydrogen, and very rapidly in a mixture of hydrofluoric and nitric acids.

Tantalum in its principal compounds is pentatomic, the formula of tantalic chloride being $TaCl^5$, that of tantalic fluoride TaF^5, and that of tantalic oxide (which, in combination with bases, forms the tantalates) TaO^5. There is also a tantalous oxide having the composition TaO^2, and a corresponding sulphide, TaS^2.

TANTALUM, BROMIDE OF, probably $TaBr^5$.—Prepared, like the chloride, by passing bromine-vapour through a tube filled with a mixture of tantalic oxide and porous charcoal. It is usually coloured yellow by excess of bromine, from which it cannot easily be freed.

TANTALUM, CHLORIDE OF, or **TANTALIC CHLORIDE,** $TaCl^5$.—Tantalum is not attacked by chlorine at ordinary temperatures, but, when gently heated in a stream of the gas, it is converted, with incandescence, into tantalic chloride, which distils off.

The chloride is prepared by passing chlorine-gas over a heated mixture of tantalic oxide and charcoal. Tantalic oxide is mixed with starch or sugar, and the mixture completely charred by ignition in a covered crucible. It is then introduced in small pieces into a glass tube, which is strongly heated by a charcoal-fire, while a stream of dry carbonic anhydride is passed through it. As soon as all the moisture is expelled, the tube is left to cool, the flow of carbonic anhydride being still kept up; the carbonic anhydride apparatus is then replaced by a chlorine apparatus, and the tube again heated, after the carbonic anhydride and atmospheric air have been completely expelled by the chlorine. Chloride of tantalum is then obtained in the form of a sublimate having a pure yellow colour. If, however, the tantalic oxide contains tungstic oxide, the colour of the sublimate is red; and if stannic or titanic oxide is present, yellow drops of liquid chloride are also produced. (H. Rose and R. Weber, Ann. Ch. Pharm. lxxxviii. 246.)

Tantalic chloride begins to volatilise at 144°, and melts to a yellow liquid at 221°. Its vapour-density, at temperatures between 350° and 440°, is equal to 12·42 (Deville and Troost, Bull. Soc. Chim. 1866, ii. 120); agreeing very nearly with the density calculated from the formula $TaCl^5$, namely 12·46 ($= \frac{182 + 5 \,.\, 35{\cdot}5}{2} \times 0{\cdot}0693$).

Tantalic chloride is decomposed by *water*, yielding hydrochloric and tantalic acids, but the decomposition is not complete even at the boiling heat; water containing a small quantity of ammonia decomposes it, even at ordinary temperatures.—*Potash* decomposes it, but not completely; *carbonate of potassium* does not affect it, even at the boiling heat.—*Hydrochloric acid* dissolves tantalic chloride at ordinary temperatures, forming a turbid liquid, which gelatinises after a while; the jelly yields to cold water only traces of tantalic acid. Boiling hydrochloric acid dissolves tantalic chloride incompletely, and the liquid does not gelatinise.—Strong *sulphuric acid* dissolves the chloride, at ordinary or slightly elevated temperatures, with evolution of hydrochloric acid, forming an opaline liquid, which becomes very turbid at the boiling heat, and solidifies to an opaline jelly on cooling.—*Ammonia-gas* converts tantalic chloride, at a red heat, into nitride of tantalum. (H. Rose.)

TANTALUM, DETECTION AND ESTIMATION OF. 1. *Blowpipe Reactions.*—Tantalic oxide, fused with *borax*, either in the outer or in the inner flame, forms a transparent glass, which however, if the quantity of tantalum is somewhat large, may be rendered opaque by interrupted blowing or flaming, but recovers its transparency by long exposure to the continued blast. A very large quantity of tantalic oxide renders the glass opaque.—With *microcosmic salt* it forms, in either flame, a clear colourless glass, which does not turn red on addition of a ferrous salt.—With *sodic carbonate* it produces effervescence, but does not fuse into a bead or undergo reduction.

2. *Reactions in Solution.*—The tantalates of the alkali-metals are soluble in water (p. 666).—*Hydrochloric acid*, added in excess to the solutions, first precipitates tantalic acid, and then redissolves it, forming a slightly opalescent liquid.—*Sulphuric acid* also precipitates the tantalic acid, but does not redissolve it when added in excess.—*Carbonic acid gas*, passed through the solution of an alkaline tantalate, precipitates the whole of the tantalic acid in the form of an acid salt.—*Chloride* or *sulphate of ammonium* also precipitates the tantalic acid from these solutions, in the form of hydrate mixed with small quantities of ammonia and the fixed alkali. The presence of carbonate of potassium or sodium prevents the formation of this precipitate at ordinary temperatures; but it then appears after boiling for some time. Sulphide of ammonium produces no precipitate.—*Chloride of barium* or *calcium* forms a precipitate of tantalate of barium or calcium, insoluble in water and in ammoniacal salts.—*Nitrate of silver* forms, in the solution of a neutral alkaline tantalate, a white precipitate, which is turned brown by a small quantity of ammonia, and dissolves in a larger quantity. A solution of *basic mercurous nitrate* forms a yellowish-white precipitate, which turns black when heated.—*Ferrocyanide of potassium*, added to a very slightly acidulated solution of an alkaline tantalate, forms a yellow precipitate; *ferricyanide of potassium* a white precipitate.—*Infusion of galls*, added to a solution of an alkaline tantalate acidulated with sulphuric or hydrochloric acid, forms a light-yellow precipitate, soluble in alkalis.—*Zinc*, immersed in the solution of an alkaline tantalate acidulated with hydrochloric acid, does not produce any blue colour; neither is that colour produced, or but very faintly, on addition of sulphuric acid. But if chloride of tantalum be dissolved in strong sulphuric acid, and then water and metallic zinc added, a fine blue colour is produced, which does not change to brown, but soon disappears. The blue colour is also produced on placing zinc in a solution of tantalic chloride in hydrochloric acid to which a small quantity of water has been added; too much water, however, prevents its formation.

These characters are sufficient to distinguish tantalum from all other metals. From niobium, which it most resembles, it is distinguished by the behaviour of tantalic oxide before the blowpipe, especially with microcosmic salt; (2), by the reactions of the soluble tantalates with hydrochloric acid, sal-ammoniac, ferrocyanide and ferricyanide of potassium, and infusion of galls.[*]—From titanium it is distinguished by the behaviour of the oxides before the blowpipe; by the perfect insolubility of tantalic oxide in strong sulphuric acid after ignition; and by the fact that when tantalic oxide is fused with acid sulphate of potassium, and the mass treated with cold water, the tantalic oxide remains undissolved in combination with sulphuric acid, whereas titanic oxide similarly treated yields a fused mass, which dissolves completely in a considerable quantity of cold water, provided the fusion has been sufficiently prolonged.—From silica, tantalic oxide is distinguished by its behaviour before the blowpipe, silica being insoluble in microcosmic salt, and fusing to a transparent bead when heated on charcoal with a small quantity of sodic carbonate. The behaviour of tantalic oxide with zinc, with tincture of galls, and with hydrofluoric acid, also distinguishes it from silica.

---

[*] See vol. iv. pp. 50, 51.—The niobous oxide and niobites there mentioned are the compounds now called niobic oxide and niobates, Marignac having shown that there is only one oxide of niobium, and that Rose's niobic acid was a mixture of niobic and tantalic acids (iv. 785).

3. *Estimation and Separation.*—Tantalum is estimated in the form of tantalic oxide, Ta^2O^5, containing 81·98 per cent. of the metal. Tantalic oxide or anhydride may be separated from the bases with which it occurs in nature—namely, lime, magnesia, yttria, zirconia, and the oxides of iron, manganese, and uranium—by fusion with *hydrate* or, better, with *acid sulphate of potassium*, in the manner to be presently described (p. 665). Some tantalates may be decomposed by *sulphuric acid*, the tantalic acid being separated in the insoluble state, and all the bases passing into solution. Tantalate of zirconium may be decomposed in this manner. On treating that compound with strong sulphuric acid, and digesting the cooled mass for some time with a large quantity of water, sulphate of zirconium dissolves, and tantalic oxide remains in combination with sulphuric acid, from which it may be purified by repeated boiling with water.

From the alkalis, tantalic acid may be completely separated by sulphuric acid, provided the compound is soluble in water. In the contrary case, it must first be fused with carbonate or hydrate of potassium. If, however, the quantity of alkali is to be likewise estimated, the compound must be rendered soluble by fusion with sulphate of ammonium. (H. Rose.)

From titanium, with which it sometimes occurs in nature, tantalum may be separated by fusing the mineral with acid sulphate of potassium, and treating the fused mass with a large quantity of water. Titanic acid then dissolves, especially if the water is slightly acidulated with hydrochloric acid, while tantalic sulphate remains undissolved. The titanic acid is precipitated from the solution by boiling: the separation is, however, not very complete. In some cases the decomposition may be effected by sulphuric acid.

The separation of tantalum from niobium is effected by means of *acid fluoride of potassium*, whereby the former metal is converted into fluotantalate of potassium, $2KF.TaF^5$, requiring 151 to 157 pts. of water acidulated with hydrofluoric acid to dissolve it at ordinary temperatures, and the latter into fluoxyniobate of potassium, $2KF.NbOF^3.H^2O$, soluble in 12·4 to 13 pts. of cold water. The mineral (a tantalite or columbite) having been decomposed by fusion with three times its weight of acid potassic sulphate, the collective weight of the niobic and tantalic oxides thereby separated is ascertained; they are then again fused with acid sulphate of potassium; the sulphate is dissolved out by water; the residue is treated with hydrofluoric acid; and a boiling solution of hydropotassic fluoride is gradually added. The liquid thus obtained yields, after a certain degree of concentration, a deposit of potassic fluotantalate, which must be washed with water on a weighed filter, till the wash-waters no longer yield an orange-coloured precipitate with infusion of galls.

4. *Atomic Weight of Tantalum.*—The older experiments on the constitution of the tantalum-compounds did not yield correct results, because the tantalum used was impure, containing niobium. Berzelius regarded tantalic oxide as Ta^2O^3; H. Rose regarded it as TaO^2, the chloride as $TaCl^4$, &c. But from the observations of Marignac on the isomorphism of the fluotantalates and fluoniobates, and from the vapour-density of the chloride (p. 662), it appears that tantalum is pentatomic, forming the compounds $TaCl^5$, TaF^5, Ta^2O^5, &c.

Marignac has determined the atomic weight of tantalum chiefly from the composition of the fluotantalates of potassium and ammonium, which are anhydrous and do not undergo any alteration at 100°. The potassium-salt was treated with pure concentrated sulphuric acid; the excess of that acid gradually driven off, the temperature being finally raised to 400°; and the residue was boiled with water, which dissolved the acid sulphate of potassium, and left tantalic sulphate in small granular crystals, which, when calcined at a strong heat, yielded pure tantalic oxide. The acid sulphate of potassium was reduced, by evaporation and calcination, to neutral sulphate, which was weighed. Four closely accordant analyses yielded, as a mean result, 56·6 pts. tantalic oxide to 45·4 pts. neutral sulphate of potassium, according to which the atomic weight of tantalic oxide, Ta^2O^5, = 414·6, and that of tantalum = 182·3.

By calculating merely from the weight of the neutral sulphate of potassium compared with the original weight of the fluotantalate, $2KF.TaF^5$, the atomic weight of that salt is found to be 392·8, whence Ta = 181·8, a number very near the preceding.

Fluotantalate of ammonium, by conversion into tantalic oxide, loses 36·75 per cent. of its weight, a loss corresponding to the replacement of $2NH^4 + 7F = 169$ by $\frac{5}{2}O = 40$, leaving a difference of 129; and the proportion, $36{\cdot}75 : 100 = 129 : x$, gives $x = 351$ for the atomic weight of fluotantalate of ammonium, whence Ta = 182. This is the number adopted by Marignac for the atomic weight of tantalum;[*] it agrees perfectly with the vapour-density of the chloride (p. 662).

---

[*] H. Rose (Ann. Ch. Pharm. c. 126) found in impure chloride of tantalum 49·25 per cent. tantalum and 50·75 chlorine, which, for the formula $TaCl^5$, gives Ta = 172.

TANTALUM, FLUORIDE OF. TaF^5.—Ignited tantalic oxide does not dissolve in aqueous hydrofluoric acid, but the hydrate dissolves, forming a clear solution, which, when evaporated, partly gives off the tantalum as fluoride, but likewise leaves a residue of oxyfluoride. (H. Rose.)

Fluotantalates, $2MF.TaF^5 = M^2TaF^7$.—The solution of tantalic fluoride mixed with alkaline fluorides forms soluble and crystallisable double salts, partially studied by Berzelius and H. Rose, more completely by Marignac. There do not appear to be any fluoxytantalates corresponding to the fluoxyniobates (iv. 786), unless the insoluble compounds which tend to form when the fluotantalates are dissolved in water, can be considered as such; but these compounds do not crystallise, and do not appear to possess a constant composition. (Marignac.)

Fluotantalate of Ammonium, $(NH^4)^2TaF^7$, is anhydrous, very soluble in water, and crystallises in thin plates with bevelled edges.

The *potassium-salt*, K^2TaF^7, crystallises in monoclinic prisms isomorphous with the fluoniobate. It is more soluble in hot than in cold water. By prolonged boiling with water, it changes into an insoluble salt, the composition of which is nearly that represented by the formula $Ta^2O^5.2K^2TaF^7$. The formation of this insoluble compound affords the means of detecting the smallest quantity of fluotantalate in a solution of fluoxyniobate of potassium. (Marignac.)

The *sodium-salt*, $Na^2TaF^7.H^2O$, forms monoclinic prisms, which give off their water of crystallisation at 100°.

The *cupric salt*, $Cu''Ta^2F^7.4H^2O = Cu''F^2.Ta^2F^5.4H^2O$, prepared by adding cupric oxide to a solution of tantalic oxide in hydrofluoric acid, forms beautiful blue, transparent, rhomboïdal prisms with four-sided summits. It is deliquescent, and very soluble in water.

The *zinc-salt*, $Zn''Ta^2F^7.7H^2O = ZnF^2.TaF^2.7H^2O$, prepared like the copper-salt, is too deliquescent to admit of complete purification, so that its formula must be regarded as only approximate. (Marignac.)

TANTALUM, NITRIDE OF. Obtained by the action of ammonia-gas on chloride of tantalum, at a heat gradually raised to redness; or less pure by heating tantalic oxide in ammonia-gas. It is a black microcrystalline powder, which acquires metallic lustre by burnishing, and conducts electricity; when fused with hydrate of potassium, it gives off ammonia-gas. It is not attacked by nitric acid, or by a mixture of that acid with hydrochloric or hydrofluoric acid. (H. Rose, Ann. Ch. Pharm. c. 146).

TANTALUM, OXIDES OF. Tantalum forms two oxides, a dioxide and a pentoxide, the latter uniting with bases, and forming the tantalates.

Dioxide of Tantalum, or **Tantalous Oxide,** TaO^2.—This oxide is produced by exposing tantalic oxide in a brasqued crucible to the strongest heat of a blast-furnace, a thin film on the outside being at the same time reduced to the state of metal. It is a dark-grey mass, which scratches glass, and acquires metallic lustre by burnishing (Berzelius). When heated to redness, in contact with the air, it takes up 4 per cent. of oxygen, and is converted into tantalic oxide. By calculation, TaO^2 requires 3·74 per cent. of oxygen to convert it into Ta^2O^5. (Marignac.)

Pentoxide of Tantalum, Tantalic Oxide or **Anhydride,** Ta^2O^5. In the hydrated state, **Tantalic Acid.**—This oxide is formed when tantalum burns in the air, also by the action of water on tantalic chloride, and may be separated as a hydrate from the tantalates by the action of acids. It is usually prepared from tantalite, which is a tantalate of iron and manganese, containing small quantities of stannic and tungstic acids, and a varying (sometimes considerable) quantity of niobic acid, by fusing the pulverised and levigated mineral with twice its weight of potassic hydrate; or, better, with excess of acid potassic sulphite (6 or 8 pts. according to Berzelius, 3 pts. according to Marignac), in a platinum crucible.

The mass, when cold, is pulverised and repeatedly boiled with fresh quantities of water, till no more sulphate of potassium, iron, or manganese is dissolved out of it; and the residue, consisting of tantalic acid mixed with ferric oxide, stannic acid, tungstic acid, and niobic acid, is then digested with sulphide of ammonium containing excess of sulphur, which removes the tin and tungsten as sulphides, and converts the iron into insoluble sulphide. The liquid is filtered, and the tantalic acid is washed with water containing sulphide of ammonium, then boiled with strong hydrochloric acid to remove the iron, and washed with boiling water. It may still, however, contain silicic and niobic acids. To remove the former, it is dissolved in aqueous hydrofluoric acid, the filtered solution mixed with sulphuric acid and evaporated to dryness, and the residue ignited as long as its weight continues to diminish (Berzelius; H. Rose). To remove the niobium, the tantalic acid is redissolved in aqueous hydrofluoric acid, and treated with acid fluoride of potassium in the manner already described (p. 664). The pure fluotantalate of potassium thus obtained is decomposed by heating with sulphuric acid; the sulphate of potassium dissolved out by boiling with water; and the remaining tantalic sulphate strongly ignited to expel the sulphuric acid (**Marignac**). By this process, Marignac has prepared considerable quantities of tantalic oxide from columbites containing that compound together with niobic oxide.

Anhydrous tantalic oxide, obtained by igniting the hydrate or sulphate, is a white powder, which remains white when heated, or acquires but a very faint tinge of yellow. Its specific gravity varies from 7·022 to 8·264, increasing with the temperature to which it has been exposed (**H. Rose**); according to **Marignac**, the specific gravity = 7·60 to 7·64. **Nordenskjöld** and **Chydenius** (Pogg. Ann. cx. 642; Jahresb. 1860, p. 145), by fusing it with microcosmic salt, and treating the fused mass with hydrochloric acid, obtained, together with the amorphous oxide, a small quantity of heavy needle-shaped crystals, which were rhombic combinations with the dominant faces, ∞P, $\bar{P}\infty$, and the angles $\infty P : \infty P = 100° 42'$; $\bar{P}\infty : \bar{P}\infty$ over the principal axis $= 90° 20'$. Tantalic oxide neither melts nor volatilises when heated, and is destitute of taste and smell. It is reduced to the metallic state in the circuit of a very powerful voltaic battery; partially also by very strong ignition in contact with *charcoal*. When heated in *ammonia-gas*, it yields nitride of tantalum; and by ignition in *cyanogen-gas*, it is partially converted into nitride and cyanide of tantalum (**H. Rose**). Ignited in vapour of *carbonic disulphide*, it yields disulphide of tantalum:

$$Ta^2O^5 + 5CS^2 = 2TaS^2 + 5CO + S^6.$$

Tantalic oxide is insoluble in all acids, and can only be rendered soluble by fusion with hydrate or carbonate of potassium.

Hydrated tantalic oxide, or *Tantalic acid*, obtained by precipitating an aqueous solution of potassic tantalate with hydrochloric acid, or by decomposing tantalic chloride with water containing a little ammonia, is a snow-white bulky powder, which reddens litmus-powder while moist, and dissolves in hydrochloric and hydrofluoric acids. When strongly heated, it gives off its water and becomes incandescent. The hydrate, obtained by fusing tantalite with acid sulphate of potassium as above described, is of a denser and more crystalline character, insoluble in all acids except hydrofluoric and strong sulphuric acids, and is precipitated from the sulphuric solution by water. When heated it becomes anhydrous, but does not emit light.

Tantalates, $\left.\begin{matrix}M^2O\\ \text{or } M''O\end{matrix}\right\}Ta^2O^5$ and $4M^2O.3Ta^2O^5$ * (according to **Marignac**).—The first of these formulæ includes the native tantalates; the second, certain easily crystallisable tantalates of the alkali-metals.

The tantalates of the *alkali-metals* are soluble in water, and are obtained by fusing tantalic oxide with caustic alkalis. Tantalic oxide fused with *hydrate of potassium* in a silver crucible, forms a transparent mass of potassic tantalate, which, after cooling, dissolves completely in water. With *hydrate of sodium*, it fuses into an opaque turbid mass, and ultimately deposits a sediment, which is not taken up by fusion with any excess of the alkali. Water poured upon the fused mass when cold, dissolves out the excess of soda, but not a trace of tantalic acid; and the residue, when treated with fresh water, dissolves and forms an opalescent solution of acid sodic tantalate, which salt is completely insoluble in a strong solution of caustic soda, and is therefore precipitated on mixing the liquid with the solution of soda previously obtained by treating the fused mass with water. When tantalic oxide is fused with *potassic or sodic carbonate*, the fused mass is not completely soluble in water.

The tantalates of the *earth-metals* and *heavy metals* are insoluble in water, and are formed by precipitation (p. 663).

Ferrous Tantalate, $FeO.Ta^2O^5$.—This salt occurs native as **tantalite** and **tapiolite**, rarely however quite pure, the iron being generally more or less replaced by manganese, and the tantalum by niobium, tin, and zirconium. Columbite or niobite is a mineral of analogous constitution, containing both tantalum and niobium, the latter however predominating: some of the Greenland columbites contain only niobium, without tantalum.

Tantalite is found at several localities in Finland, at Broddbo and Finbo near Fahlun in Sweden, and at Chanteloub near Limoges in France. It occurs in trimetric crystals having the axes $a : b : c = 0·6517 : 0·8170 : 1$, and usually bounded by the faces P and $\infty\breve{P}\frac{4}{3}$, with $\infty\breve{P}\infty$, $\infty\bar{P}\infty$, $\breve{P}\frac{3}{2}$, $\breve{P}\frac{1}{2}$, $\breve{P}\infty$, and $3\breve{P}\infty$ subordinate. Angle $P : P$ (terminal) $= 126° 1'$ and $112° 32'$; (lateral) $= 91° 44'$. Twins united by the face $\infty\breve{P}\infty$ are of frequent occurrence (**A. E. Nordenskjöld**, Pogg. Ann. ci.

---

* According to H. Rose, the formula of the normal tantalates is $M^2O.2TaO^2$, which, with the pentatomic value of tantalum, becomes $5M^2O.4Ta^2O^5$. Several acid tantalates are described by **Rose** and by **Hermann**, for which see *Handw. d. Chem.* viii. 507.

625; Jahresb. 1857, p. 682). The mineral likewise occurs massive, and imbedded, in angular fragments of irregular shape. Hardness = 6·0 to 6·5. Specific gravity = about 7·0 to 8·0. Opaque, with imperfect metallic lustre and iron-black colour, black-brown to cinnamon-brown when pulverised. Fracture mostly uneven.

Nordenskjöld distinguishes as **ixiolite**, a stanniferous and manganiferous variety of tantalite, occurring, together with the preceding (which he designates as **skogbölite**, or simply as tantalite), at Skogböle in Finland. It likewise forms trimetric prisms, but having the axes $a : b : c$ = 0·5508 : 1·2460 : 1, and exhibiting the dominant combination $oP . \infty\bar{P}\infty . \infty\breve{P}\infty$, with P, ∞P; $\breve{P}\infty$, $3\breve{P}\infty$, and $\frac{1}{3}\bar{P}\infty$ subordinate. Hardness = 6·0 to 6·5. Specific gravity = 7·0 to 7·1. Lustre faintly metallic. Colour black-grey to steel-grey, brown in powder. Fracture flat, conchoïdal, sometimes nearly uneven.

The more stanniferous varieties of tantalite are designated by Hausmann (*Lehrb. d. Mineral.* p. 960) as **Cassiterotantalite**, the less stanniferous as **Siderotantalite**; the former are also sometimes designated, according to their localities, as **Finbo** and **Broddbo tantalites**, the latter as **Kimito** and **Tammela tantalites**.

Tapiolite, occurring at Sukkula in Tammela, Finland, has the composition of tantalite, but crystallises in dimetric forms, having the same angles and ratio of axes as rutile; ferrous tantalate is therefore dimorphous (or trimorphous, if ixiolite is really a distinct crystallographic species). (Nordenskjöld, Pogg. Ann. cxxii. 604; Jahresb. 1864, p. 855.)

All tantalites (including tapiolite) are infusible and unalterable before the blowpipe. They dissolve easily in borax and microcosmic salt, giving the reactions of iron and manganese. The more stanniferous varieties, heated on charcoal with sodic carbonate, yield numerous spangles of tin. Tantalites are not attacked by acids.

The following analyses of tantalite are from Rammelsberg's *Mineralchemie*, pp. 390, 391; those of tapiolite are by Arppe (Jahresb. 1862, p. 753) and A. Nordenskjöld (Pogg. Ann. cxxii. 604; Jahresb. 1864, p. 856):—

Marignac found in a Swedish tantalite:

Ta^2O^5	Nb^2O^5	SnO^2	FeO	MnO	
65·60	10·88	8·10	8·95	6·61	= 100·14.

He has also determined the quantity of tantalic oxide in various columbites, and concludes that if a perfect separation of the tantalic and niobic oxides could be effected, the specific gravity of this mineral would be found to increase proportionally to the percentage of tantalic oxide present. The following are the numbers obtained:—

Tantalite	7·03	65·6

Tantalite and columbite may be represented by the general formula (FeO; MnO)(Ta^2O^5; Nb^2O^5). Pure tantalite, as that of Kimito, contains from 83 to 85·8 per cent. tantalic oxide, and pure columbite or niobite, from Greenland, contains 76 to 78 per cent. niobic oxide; the other varieties yield intermediate numbers. (**Marignac.**)

Tantalate of Yttrium, or *Yttrotantalite*, is found native at Ytterby, in Sweden, in red felspar, and at Broddbo and Finbo near Fahlun, imbedded in quartz and albite. It exhibits the following varieties:—*a.* The black variety exhibits indistinct traces of crystallisation, in four- or six-sided irregular prisms and plates. Hardness = 5·5. Specific gravity = 5·395 (**Berzelius**), 5·67 (**Rose**), and 6·40 after heating. Lustre submetallic. Streak grey. Opaque.—*β.* The yellow variety is non-crystalline, and occurs in laminæ in the fissures of felspar. Hardness = 5. Specific gravity = 5·882 (**Ekeberg**); 5·810 (**Potyka**). Lustre resinous on the surface, vitreous on the fracture. Colour yellowish-brown to greenish. Streak white. Opaque.—*γ.* The brown variety occurs with the yellow in thin plates, or rarely in grains, presenting no trace of crystallisation. Hardness = 4·5 to 5. Lustre vitreous inclining to resinous. Colour black, with a very light shade of brown; slightly yellow in thin plates by transmitted light. Streak white.

The several varieties of yttrotantalite give off, when heated, from 3·9 to 5·54 per cent. water, are infusible alone before the blowpipe, but decrepitate, and assume a lighter colour. The black variety froths and fuses with carbonate of sodium. They dissolve in borax, but are not acted upon by acids.

The following analyses are taken from Rammelsberg's *Mineralchemie*, pp. 399, 400:—*a.* Black: lost by ignition 5·74 per cent. water (**Berzelius**).—*b.* Brown-black: those specimens which retained their colour on ignition lost 2·72 per cent. water; those which became yellowish, lost 6·06 per cent. (**Berzelius**).—*c.* Yellow:

lost by ignition 4·85 per cent. water (Berzelius).—*d.* Black: specific gravity = 5·67: lost by ignition 3·9 to 4·6 to 5·54 per cent., turning yellowish-brown, and acquired a specific gravity of 6·4 (Peretz).—*e.* Specific gravity 5·458 (Chandler).—*f.* *Yellow*, turning yellowish-brown before the blowpipe; partially decomposible by sulphuric acid. Specific gravity = 5·810 (Potyka):

The later analyses (*d*, *e*, *f*) may be represented, approximately, by the formula $2YO.TaO^2$ (Ta = 137) or $5YO.Ta^2O^3$ (Ta = 182). As, however, the mineral contains tungsten in varying proportion, the brown varieties apparently containing more than the yellow, the composition cannot be regarded as definitely established, especially as the formula just given takes no account of the water.

TANTALUM, SULPHIDE OF, TaS^2?, is obtained by igniting tantalic oxide in vapour of carbonic disulphide (p. 666), or by exposing tantalic chloride to the action of sulphydric acid gas: the product is not perfectly definite in either case. The first process yields a product containing 28·5 per cent., the second 24·08 per cent. sulphur: the formula above given requires 26·01 per cent. Sulphide of tantalum is a black substance, which acquires a brass-yellow colour by trituration in an agate mortar. Heated in an atmosphere of chlorine-gas, it is converted into tantalic chloride and chloride of sulphur. (H. Rose.)

TAPANHOACANGA. *Iron Conglomerate.*—A peculiar conglomerate occurring near Villa Rica, Itabira, Congonhas da Campo, Marianna, and other places in the province of Minas Geraes, Brazil, superposed on ferruginous mica-slate, clay-slate, itacolumite, and talcose slate, and consisting for the most part of angular fragments of iron-glance, ferruginous mica-slate, magnetic iron-ore, and brown hæmatite, bound together by an argillaceous cement, consisting of yellow, brown, or red ochre. The proportion of cement varies, and the mass contains, besides the minerals above mentioned, fragments of itacolumite, clay-slate, quarzite, and other rocks. The conglomerate often contains imbedded laminæ of gold. (*Handw. d. Chem.* viii. 512.)

TAPIOCA. A kind of starch obtained from the roots of *Janipha Manihot* (p. 408).

TAPIOLITE. The quadratic variety of ferrous tantalate found at Sukkula in Finland (p. 667).

TAR. *Theer. Goudron.*—A brown-black, viscid, oily liquid, produced, together with gaseous and watery products, in the dry distillation of organic bodies and bituminous minerals (ii. 339). It has generally an unpleasant, and sometimes a highly fetid odour; and is a mixture of various substances, acid, neutral, and alkaline, varying in composition according to the nature of the original body and the temperature applied in the distillation. Tar obtained from vegetable substances has an acid reaction, but coal-tar and the tar of animal substances are alkaline.

The principal groups of compounds contained in tars are liquid and solid hydrocarbons, alcohols, ethers, acids, and bases, together with resins, and empyreumatic products of indeterminate composition. On subjecting the tar to repeated distillation, the more volatile and liquid hydrocarbons, together with the alcohols and ethers, pass over first, while the less volatile oils consist chiefly of acid and basic compounds, and the last portions which distil over contain the solid hydrocarbons. The residue left after about half the tar has distilled over—called pitch, and likewise asphalt, when obtained from coal-tar—also contains solid hydrocarbons, together with resinous compounds.

By fractional distillation, the more volatile constituents of the tar are separated into portions of constant boiling-point, or boiling at temperatures comprised within narrow limits. The oily portions are treated with dilute acids, or (as Hofmann recommends) with hydrochloric acid gas, to remove the basic constituents. The several alkalis are then separated one from the other by fractional distillation, or by fractional precipitation of their platinum-salts (see PICOLINE, iv. 637). The oils freed from these bases are heated with strong sulphuric acid, which decomposes a number of indeterminate ampyreumatic products, whereby the subsequent separation of the remaining constituents is much facilitated.—The acid products contained in the several distillates are removed by means of alkalis. Strong potash-ley forms, with creosote and phenol, crystallised compounds, by means of which these bodies can be separated from the rest (iv. 389). Potash-ley and milk of lime are also frequently used to free the neutral oils from resinous bodies.—The separation of the neutral oily hydrocarbons one from the other is effected partly by fractional distillation, partly by other methods. Mansfield, by subjecting the portion of light coal-tar oil boiling between 80° and 90°, to a cold of − 10°, separated benzene in the crystalline form from the other hydrocarbons contained in it (i. 542). The olefines C^nH^{2n} may often be conveniently separated from other hydrocarbons by combining them with bromine (iii. 187); and by treating the bromine-compounds with sodium, the olefines may be set free, and separated one from another by fractional distillation. The hydrocarbons of the benzene-series, C^nH^{2n-6}, may be separated from mixtures of hydrocarbons by converting them into nitro-compounds.

The chief liquid constituents of wood-tar are methylic acetate, acetone, hydrocarbons—namely toluene, xylene, and cumene—methol (a mixture of volatile oils boiling between 100° and 265°), eupione, creosote, and a number of indefinite oxidised compounds, including picamar and capnomor. Amongst the solid portions are resinous matters more or less resembling colophony; also paraffin, naphthalene ($C^{10}H^8$), anthracene ($C^{14}H^{10}$), chrysene ($C^{18}H^{12}$), retene ($C^{18}H^{18}$), pyroxanthin, pittacal, and cedriret.

The more volatile portion of coal-tar, called *light-oil* or *coal-naphtha*, consists mainly of benzene and its homologues, together with a number of bases, $C^nH^{2n-5}N$, commencing with pyridine, C^5H^5N; the naphtha from cannel and Boghead coal is chiefly composed of alcoholic hydrides, homologous with marsh-gas, together with olefines and homologues of benzene. The less volatile oil, or *dead-oil* of coal-tar, contains phenol and cresol; also aniline, picoline, chinoline, and other volatile bases, and a number of solid hydrocarbons, including naphthalene, anthracene, chrysene, &c.—The tars obtained from peat and lignite are intermediate in composition between wood-tar and coal-tar. Shale-tar contains the same hydrocarbons as Boghead naphtha; also phenol, and a large quantity of the bases, $C^nH^{2n-5}N$, homologous with pyridine. (See NAPHTHA, iv. 2.)

The preparation of tar from coal, peat, lignite, and bituminous shale, has acquired great importance of late years, for obtaining paraffin and paraffin-oils for illumination and lubrication (iv. 342). Coal-tar has also acquired great value as the source of aniline-colours, and of phenol, picric acid, &c. Heavy coal-oil or dead-oil is remarkable for its antiseptic qualities, and is commonly used, without further purification, for the preservation of timber for railway sleepers, &c. It is also consumed as a fuel in common lamps, but is chiefly used for burning into lampblack.

Wood-tar likewise possesses powerful antiseptic properties, due to the creosote which it contains: hence it is also much used for the preservation of wood, especially in shipbuilding. In Russia and Sweden it is prepared, by a rude kind of distillation, from the resinous wood of the pine. A conical cavity is formed in the side of a hillock, the apex of the cone being below, and terminating in an aperture which opens into a trough leading to a reservoir for the tar. The kiln is filled with wood and partially covered over with turf; the pile is lighted at the top, and the combustion is regulated by covering it more or less completely with turf. The wood is thus charred from above downward, and the tar flows out at the bottom, charged with a considerable quantity of resin, and mixed with acetic acid and oil of turpentine. On heating, an impure essence of turpentine is distilled, leaving a black resinous substance, which constitutes ordinary pitch. The tar thus prepared is known in commerce as *Stockholm tar*.

The process just described is evidently a very wasteful one, especially entailing the loss of the greater part of the more volatile products of the distillation—acetic acid, wood-spirit, &c. Accordingly, wood-tar is now more generally prepared, like the other kinds of tar, by distillation in cylinders. (For details, see *Handw. d. Chem.*, viii. 650.)

TARAXACIN. See the next article.

TARAXACUM OFFICINALE. *Leontodon Taraxacum. Dandelion.*—The herb and root of this plant are used, either singly or together, for the preparation of *Extract of Dandelion*. The herb contains the usual plant-constituents—albumin, gum, sugar, mucilage, &c. The root contains a milky juice, which, on exposure to the air, coagulates, deposits caoutchouc, and acquires a violet-brown colour. John found in it a bitter extractive matter, together with sugar, gum, traces of resin, free vegetable acid, and the ordinary salts. The substance here called gum is doubtless partly inulin (iii. 277), the presence of which in the aqueous extract of dandelion has been demonstrated by Frickinger (Buchn. Repert. xxiii. 45), Widemann (*ibid.* xliii. 281), Overbeck (Arch. Pharm. xxiii. 240), and others. T. and H. Smith (Pharm. J. Trans. viii. 480), by treating the extract of the root prepared with cold water and evaporated to a syrup, with alcohol, obtained a precipitate of albumin, pectin, &c.; and the liquid filtered therefrom deposited, on evaporation, crystals of mannite. They are, however, of opinion that the mannite does not pre-exist in the root, but is produced from cane-sugar, or from inulin, by fermentation, under the influence of the albumin. Perhaps its formation is connected with that of lactic acid, the calcium-salt of which constitutes the deposit often formed in *Mellago taraxaci*, especially after long standing.

The bitter substance of the root, the so-called taraxacin, and the resin, have been examined by Polex (Arch. Pharm. xix. 50). The mliky juice of the root is received in water and heated to the boiling-point, and the liquid is filtered from the coagulum of resin and albumin which forms on cooling. The filtrate, after concentration and further evaporation in free air, at a moderate heat, deposits taraxacin in warty crystals, which may be purified by recrystallisation from water or alcohol. They taste pleasantly bitter, and somewhat sharp; melt easily, giving off inflammable, non-ammoniacal vapours; and dissolve readily in ether, alcohol, and boiling water. Taraxacin also dissolves without alteration in concentrated acids, and is indifferent to most other reagents. (Polex.)

If the coagulum above mentioned be exhausted with boiling alcohol, and the filtrate left to evaporate, resin of taraxacum is deposited, in white cauliflower-like crusts. It melts easily, takes fire with difficulty, is dissolved by ether, not by caustic alkalis, is but slightly attacked by nitric acid, but is dissolved with yellow colour by warm sulphuric acid. The sharp-tasting alcoholic solution is not precipitated by basic acetate of lead (Polex). See also Kromayer (Arch. Pharm. cv. 6), who designates the dried milky juice of dandelion as leontodium.

TARNOWITZITE. Breithaupt's name for the plumbiferous arragonite of Tarnowitz in Upper Silesia, sometimes containing as much as 4 per cent. of plumbic carbonate. It forms prismatic or pointed crystals, and cylindrical aggregates of white or greenish colour. It has a specific gravity of 2·8 to 3·01, and if moistened with sulphuric acid, after ignition, turns first red and then black. According to Websky (Zeitschr. d. deutsch. geolog. Gesellsch. ix. 737), the crystals have the same form as those of arragonite.

TARTAR. A generic name for salts of tartaric acid, but applied especially to the acid tartrate of potassium, which in the crude state, as deposited from fermenting grape-juice, is called crude tartar or argol, and when purified by solution and recrystallisation, cream of tartar.

Crude tartar or argol is of a pale, pinkish, or dark-red colour, according as it is deposited from white or from red wines. It forms a hard crystalline crust, varying in thickness with the character of the grape, the degree of ripeness which it has been allowed to attain, and the peculiarities of the processes adopted in different vineyards. Besides acid tartrate of potassium, which is its essential constituent, it usually contains tartrate of calcium and various impurities. Scheurer-Kestner found in a sample from Tuscany, 73·67 per cent. tartaric acid, 22·13 potash, 0·62 glucose, 0·88 cellulose, 0·32 silica, 0·26 oxide of iron, 1·39 magnesia, and 0·73 colouring-matter. The same chemist gives the following statement of the results of numerous analyses of tartars from various localities :—

Locality.	Quality	Acid Tartrate of Potassium per cent.	Tartrate of Calcium per cent.
Alsace	White	77·50 84·95 85·10	4·6 7·3 9·9
Switzerland	"	73·50 85·90	7·7 18·3
Burgundy	Red	32·10	46·25
Tuscany	White	84·50 85·20 88·50	9·20
Hungary	"	67·30	45·20
Spain	Red	24·20	

The best tartars come from Italy and the South of France.

Tartar is used for the manufacture of tartaric acid, and of carbonate of potassium (iv. 713). For the first mentioned purpose, the presence of a large amount of mucilaginous or other organic matter is very objectionable. To remove this impurity, a considerable proportion of the argol sent to this country is previously submitted to a simple process of purification, which consists in redissolving it in hot water, and adding a small quantity of clay in fine powder. The clay becomes mixed with the flocculent matter, and carries it down to the bottom of the vessel. The clear solution is concentrated and a crop of crystals obtained, which is then called tartar. The repetition of the process yields a proportionally purer article, and tartars are met with in this country, containing from 85 to 98 or 99 per cent. acid tartrate of potassium.

On the other hand, tartars are very often fraudulently adulterated with sulphate and chloride of potassium, sulphate and chloride of calcium, and other cheap materials; so that it is of importance to the manufacturer of tartaric acid to possess a ready method of ascertaining the quantity of tartaric acid contained in them. Now, the direct estimation of tartaric acid is difficult, as none of its salts are insoluble in water; hence it has been usual to estimate the proportion of it in tartars by determining the quantities of potash and lime present, and reckoning both bases as tartrates. Such a method, however, would clearly lead, in the case of adulterated tartars, to an over-estimation of the amount of tartaric acid present. Hence it is necessary to determine not only the amount of bases, but likewise that of the sulphuric, carbonic, or other acids present, besides the tartaric; to calculate the quantities of base required to saturate these acids; and reckon only the remainder as tartrates. An exact and ready method of ascertaining the commercial value of tartars is still a desideratum.

Tartrate of calcium can scarcely be regarded as an impurity in tartar intended for the manufacture of tartaric acid, inasmuch as the first step in the preparation of that acid is to convert the tartrate of potassium into tartrate of calcium. Nevertheless, the presence of a considerable quantity of calcic tartrate in the tartar is objectionable, because it quickly undergoes decomposition under the influence of damp, and is converted into carbonate. For this reason dry storing-places are of great importance for preserving tartars and argols, especially those containing much tartrate of calcium. (See Richardson and Watts's *Chemical Technology*, i. [5], 132, 168.)

TARTAR-EMETIC. Potassio-antimonious tartrate.

TARTARIC ACID. $C^4H^6O^6 = \left.\begin{matrix}(C^4H^2O^2)^{iv}\\ H^4\end{matrix}\right\}O^4$ or $\left.\begin{matrix}H^2\\ (C^4H^2O^2)^{iv}\\ H^2\end{matrix}\right\}O^4$.—This formula represents the composition of five different tetratomic and dibasic acids, some of which agree with one another in nearly all their chemical characters, though they are all distinguished by marked differences of physical properties, especially in their crystalline forms and their relations to polarised light. These five modifications of tartaric acid are:

1. Dextrotartaric or ordinary Tartaric acid, which forms anhydrous, hemihedral, rhombic crystals, and turns the plane of polarisation of a luminous ray to the right.

2. Lævotartaric or Antitartaric acid, which also forms anhydrous, hemihedral, rhombic crystals, but turns the plane of polarisation to the left.

3. Paratartaric or Racemic acid, which forms hydrated, holohedral, triclinic crystals, is optically inactive, and may be separated into dextrotartaric and lævotartaric acids (p. 35).

4. Inactive Tartaric or Mesotartaric acid, which is also without action on polarised light, but is not, like the preceding, resolvable into dextrotartaric and lævotartaric acids.

5. Metatartaric acid, a modification produced by the action of heat upon ordinary tartaric acid, is deliquescent and uncrystallisable; its salts differ from those of ordinary tartaric acid by their crystalline form and greater solubility.

Dextrotartaric and lævotartaric acids resemble one another exactly in specific gravity, solubility, and all their physical properties, excepting crystalline form, action on polarised light, and pyroelectrical relations. Their crystals are bounded by the same number of faces, inclined to one another at exactly the same angles; but they exhibit certain hemihedral faces, which, when the crystals are similarly placed, are situated to the right in the one crystal, and to the left in the other; so that the two crystals, though similar, are not superposible, but are related to one another like an object and its reflected image. Solutions of the two acids of the same strength deflect the plane of polarisation by exactly equal amounts—the one to the right, the other to the left: $[\alpha] = \pm 9{\cdot}6$ (see LIGHT, iii. 675). Both acids exhibit pyroelectricity, but in opposite directions, a crystal of either acid, when heated and left to cool, exhibiting positive electricity on the side on which the hemihedral faces are situated.

The same relations of crystalline form, optical rotatory power, and pyro-electricity, are exhibited by the corresponding metallic salts of dextrotartaric and lævotartaric acids.

When solutions of equal weights of dextro- and lævo-tartaric acids are mixed, the mixture yields by evaporation holohedral crystals of racemic acid. Mixtures of equal weights of the corresponding metallic salts also yield racemates, except in the case of the ammonio-sodic salts (iii. 675).

Dextro- and lævo-tartaric acids further resemble one another exactly in their chemical relations to all substances which have no action on polarised light; but when they come in contact with other optically active substances, this chemical identity no longer exists. In some cases, one of the acids easily forms compounds which cannot be produced with the other; in other cases, the two acids yield compounds identical in composition, but differing considerably in their properties. Thus, dextrotartaric acid combines readily with asparagine, forming a crystalline compound; but lævotartaric acid forms with it only an uncrystallisable syrup. The acid ammonium-salt of dextrotartaric acid forms a crystallisable double salt with the acid ammonium-salt of optically active malic acid; acid lævotartrate of ammonium, on the contrary, does not form a corresponding compound. Dextrotartrate of cinchonine contains 2 at. water of crystallisation, dissolves easily in absolute alcohol, gives off its water and begins to become coloured at 100°; the lævotartrate of cinchonine contains only ½ at. water, but bears a heat of 140° without alteration. The dextro- and lævo-tartrates of quinine, brucine, and strychnine exhibit similar differences (i. 683, 977; v. 24, 442).

The different reactions of the two opposite tartaric acids with optically active substances afford the means of resolving racemic acid into its component acids. When cinchonicine is dissolved in racemic acid, the solution, at a certain degree of concentration, deposits at first crystals of lævotartrate of cinchonicine; from a solution of quinicine in racemic acid, on the other hand, dextrotartrate of quinicine crystallises out first.

Racemic acid may also be decomposed by fermentation. When a few spores of *Penicillium glaucum* are introduced into a solution of racemic acid containing traces of an alkaline phosphate, fermentation is set up, the dextrotartaric acid is decomposed, and if the fermentation be interrupted after a certain time, the liquid contains nothing but lævotartaric acid.

When dextrotartrate of cinchonine is heated for some time to 170°, part of the dextrotartaric acid is converted into lævotartaric acid, and the two combine, forming racemic acid. Lævotartaric acid may be converted into racemic acid in the same manner. Racemic acid is also produced by the action of heat on ethylic tartrate (p. 35). (Pasteur, Ann. Ch. Pharm. lxxii. 164; lxxxiv. 157; lxxxviii. 211; Jahresb. 1847-48, pp. 31, 205; 1849, pp. 127, 307; 1852, p. 175; 1853, p. 423; 1858, p. 248; 1860, p. 250.)

Dextrotartaric Acid, $C^4H^6O^6$. *Ordinary Tartaric Acid. Dextroracemic Acid. Tartersäure. Tartrylsäure. Weinsäure. Weinsteinsäure. Sal essentiale tartari. Acide tartarique.*—This acid was first obtained in the free state by Scheele in 1770, but its existence in tartar had been previously suspected by Duhamel, Marggraf, and Rouelle. It is very widely diffused in the vegetable kingdom, occurring as frequently as citric and malic acid. Its existence in grape-juice, as acid tartrate of potassium, has long been known; the older chemists indeed, Van Helmont and others, were aware that the tartar deposited from wines existed ready-formed in the juice of the grape. It is also found in the free state, or as a potassium- or calcium-salt, in tamarinds, unripe mountain-ash berries, madder-root, potatoes, Jerusalem artichokes, sorrel, girkins, mulberries, pine-apples, black pepper, the leaves of *Chelidonium majus*, the bulbs of *Scilla maritima*, &c.

Dextrotartaric acid is artificially produced:—α. Mostly together with racemic acid, by the oxidation of saccharic acid, and of dextroglucose, cane-sugar, milk-sugar, starch, gum, and sorbin, with nitric acid (p. 35).—β. By boiling acid bromomalate of calcium (iii. 795) with lime-water. Acids having the composition of tartaric are also said to be produced.—γ. From citric acid, when lemon-juice is kept for a year in bottles (Schindler, Ann. Ch. Pharm. xxxi. 280).—δ. From a solution of pyroxylin in potash (Kerckhoff and Reuter, J. pr. Chem. xlvi. 284); but it is not stated whether these acids are identical in physical properties with dextrotartaric acid. The acid $C^4H^6O^6$, obtained by boiling the silver-salt of dibromosuccinic acid with water, or its calcium-salt with lime-water, is optically inactive. (Kekulé, p. 459.)

Preparation.—Tartaric acid is always prepared from acid tartrate of potassium—on the small scale from the purified salt (cream of tartar), on the large scale from partially purified tartars or crude argols. A boiling solution of the acid tartrate is first treated with pounded chalk or whiting, to convert it into insoluble sulphate of calcium and soluble neutral tartrate of potassium:

$$2C^4H^5KO^6 + Ca''CO^3 = C^4H^4K^2O^6 + C^4H^4Ca''O^6 + H^2O + CO^2.$$

The mixture is thrown on a filter; and the filtered solution of neutral potassic tartrate is mixed with solution of calcic chloride, or with precipitated calcic sulphate, obtained from a previous operation, whereby the whole of the tartaric acid is precipitated as tartrate of calcium. The two lime-precipitates are then boiled with a quantity of dilute sulphuric acid sufficient to convert the whole of the calcium into sulphate; and the filtered solution of tartaric acid is evaporated to a syrup at a gentle heat, then left to itself in a warm place, where it deposits an additional quantity of calcic sulphate, and finally transferred to the crystallising vessels. The presence of an excess of sulphuric acid greatly favours the crystallisation of the tartaric acid, but it acts injuriously during the subsequent evaporation of the mother-liquors, as it becomes more and more concentrated, and ultimately decomposes a considerable quantity of the tartaric acid still remaining in solution. (For details of the manufacturing process, see Richardson and Watts's *Chemical Technology*, vol. i. pt. v. p. 138.)

Lævotartaric Acid, $C^4H^6O^6$. *Antitartaric Acid. Lævoracemic Acid.*—The formation of this acid by the decomposition of racemic acid has already been mentioned. When equal weights of racemic acid are saturated, the one with soda, the other with ammonia, and mixed, the mixture deposits, on cooling or spontaneous evaporation, large beautiful crystals of a double salt, all of which are hemihedral, one half of them having the hemihedral forces oppositely situated to those of the other half; and on carefully separating these two kinds of crystals (the solutions of which exhibit equal and opposite actions on polarised light), purifying them by recrystallisation, precipitating the solutions by nitrate of lead, and decomposing the lead-salts with sulphuric or sulphydric acid, solutions are obtained which on evaporation yield crystals—the one of dextrotartaric acid, agreeing exactly in character with those obtained from tartar, as above described; the other of lævotartaric acid, agreeing with dextrotartaric acid in all respects, excepting in the opposite hemihedry of its crystals, and the opposition of its optical and pyro-electric properties. Respecting the preparation of lævotartaric acid by the fermentation of racemic acid, and by the action of heat on the racemates of cinchonicine and quinicine, see p. 673.

Properties.—Tartaric acid crystallises in monoclinic prisms, having the axes $a : b : c = 0{\cdot}7845 : 1 : 0{\cdot}8054$. Angle $b : c = 79° 43'$; $\infty P : \infty P$ (orthod.) $= 102° 52'$; $[P\infty] : [P\infty]$ (clinod.) $= 89° 26'$; $-P\infty : c = 45° 0'$; $+P\infty : c = 57° 30'$. Ordinary combination $\infty P . \infty P\infty . -P\infty . +P\infty$ (the last often wanting) . $[P\infty]$. The faces $[P\infty]$ are often developed only at one extremity of the orthodiagonal, and on one or the other side of the crystals, according as the acid is dextro- or lævo-rotatory. These faces are often greatly predominant.

The crystals are colourless and transparent, and do not contain any water of crystallisation; their specific gravity is 1·75 (Richter); 1·739 (Buignet, Jahresb. 1861, p. 15). They are very soluble in water and in alcohol, insoluble in ether; the aqueous solution becomes covered, after a while, with a fungous growth. The quantities of the crystallised acid contained in aqueous solutions of different densities are as follows (Schiff, Jahresb. 1859, p. 41):

Weight of crystallised acid in 100 pts. of solution.	Specific gravity of solution at 15°.
33	1·1654
22	1·1062
14·66	1·0690
11	1·0511
7·33	1·0337
3·67	1·0167

On mixing the concentrated solutions of dextro-, and lævo-tartaric acid, crystals of racemic acid are abundantly deposited, with evolution of heat quite perceptible to the hand.

Respecting the molecular rotatory power and the pyro-electricity of the two opposite tartaric acids, see p. 672. Their pyro-electricity is very strong, the heat of the hand developing it sufficiently to affect a sensitive electroscope.

The solution of tartaric acid forms white precipitates with the aqueous solutions of caustic *baryta, strontia, lime,* and *acetate of lead,* but it does not precipitate the chloride of barium, strontium, or calcium. Tartaric acid is distinguished from racemic acid by the greater solubility of its calcium-salt (p. 36).

Tartaric acid added in excess to the solution of a *potassium-salt* forms a white crystalline precipitate of acid potassic tartrate, provided the solution is not too dilute: the addition of alcohol renders the reaction much more delicate: the formation of the precipitate rated by stirring, and by rubbing the sides of the vessel with a glass rod. The precipitate is soluble in free alkalis, which convert it into neutral tartrate; hence, for detecting small quantities of tartaric acid in a solution, free potash should not be used, but rather chloride or nitrate of potassium, an excess of which does not dissolve the acid tartrate. Tartaric acid may be detected in presence of a considerable quantity of citric acid by mixing the solution with acetate of potassium, and an equal volume of strong alcohol. On the other hand, a small quantity of citric acid may be detected in the midst of a large quantity of tartaric acid, by removing the latter as above, evaporating the alcoholic filtrate, and treating the residue with chloride of calcium at the boiling heat (i. 995). (Spiller, Chem. Soc. Qu. J. x. 110; see also Schnitzer, Jahresb. 1862, p. 626.)

Decompositions.—1. Tartaric acid melts between 170° and 180°, and is gradually converted, without loss of water, into the isomeric compound, metatartaric acid (p. 688). By prolonged heating, water is eliminated, and tartralic or ditartaric acid, $C^8H^{10}O^{11} = 2C^4H^6O^6 - H^2O$, is produced; then tartrelic acid, $C^4H^4O^5 = C^4H^6O^6 - H^2O$; and ultimately insoluble tartaric anhydride, isomeric with the last. If the heat be increased, decomposition takes place, resulting in the formation of pyrotartaric and pyroracemic acids (iv. 769-771), together with acetic acid, formic acid, aldehyde, furfurol, ethylene, carbonic anhydride, &c.

2. Tartaric acid heated with fused *hydrate of potassium* is resolved into acetic and oxalic acids:

$$C^4H^6O^6 = C^2H^4O^2 + C^2H^2O^4.$$

3. By the *oxidation* of tartaric acid (*e.g.* by the action of chromates, permanganates, peroxide of manganese, peroxide of lead, minium, &c.), carbonic anhydride and formic acid are generally produced. The solution of the acid warmed with salts of *silver*, *gold*, and *platinum*, reduces the metals. By slow oxidation, especially by the spontaneous decomposition of nitrotartaric acid, an oxidation-product less removed from tartaric acid is formed—namely, tartronic acid:

$$\underset{\substack{\text{Tartaric}\\\text{acid.}}}{C^4H^6O^6} + O^3 = \underset{\substack{\text{Tartronic}\\\text{acid.}}}{C^3H^4O^5} + H^2O + CO^2.$$

4. By the action of *hydriodic acid* or *iodide of phosphorus*, tartaric acid is reduced to malic or to succinic acid:

$$\underset{\substack{\text{Tartaric}\\\text{acid.}}}{C^4H^6O^6} + 2HI = H^2O + I^2 + \underset{\substack{\text{Malic}\\\text{acid.}}}{C^4H^6O^5}.$$

$$\underset{\substack{\text{Tartaric}\\\text{acid.}}}{C^4H^6O^6} + 4HI = 2H^2O + 2I^2 + \underset{\substack{\text{Succinic}\\\text{acid.}}}{C^4H^6O^4}.$$

5. With *pentachloride of phosphorus*, tartaric acid yields chloromaleic chloride, $C^4HClO^2.Cl^2$. (Perkin and Duppa; see Maleic Acid, iii. 788.)

6. Pulverised tartaric acid, digested for several hours with *chloride of acetyl*, is converted into diacetotartaric anhydride, $C^8H^8O^7$ (Perkin, Chem. Soc. Qu. J. xx. 150):

$$C^4H^6O^6 + 2C^2H^3OCl = 2HCl + H^2O + C^4H^2(C^2H^3O)^2O^5.$$

7. Tartaric acid heated to 150° in a sealed tube, with an equivalent quantity of *benzoic acid*, yields benzotartaric acid, $C^{11}H^{10}O^7 = C^4H^5(C^7H^5O)O^6 = C^4H^6O^6 + C^7H^6O^2 - H^2O$. (Dessaignes, J. Pharm. [3] xxxii. 47.)

8. Tartaric acid is decomposed by strong *sulphuric acid* and by *nitric acid*. With very strong nitric acid it forms nitrotartaric acid.—*Chlorine* and *bromine* act but slightly upon the aqueous solution.

9. The *fermentation* of crude tartrate of calcium yields butyracetic acid. (Nöllner, i. 688.)

10. Tartaric acid heated with *alcohols*, monatomic or polyatomic, forms ethers, with elimination of water; in like manner with cane-sugar, glucose, dulcite, quercite, and other saccharoïdal substances. (See Tartaric Ethers.)

Tartrates.—Tartaric acid, as already observed, is tetratomic, and for the most part dibasic, 2 of the hydrogen-atoms in the molecule, $\left.\begin{matrix}H^2\\(C^4H^2O^2)^{iv}\\H^2\end{matrix}\right\}O^4$, being easily replaceable by metals, and the other two by alcoholic or acid radicles. With monatomic metals, it forms acid, neutral, and double salts, like the following:

$$\underset{\substack{\text{Acid potassic}\\\text{tartrate.}}}{\left.\begin{matrix}H^2\\C^4H^2O^2\\H.K\end{matrix}\right\}O^4} \qquad \underset{\substack{\text{Neutral potassic}\\\text{tartrate.}}}{\left.\begin{matrix}H^2\\C^4H^2O^2\\K^2\end{matrix}\right\}O^4} \qquad \underset{\substack{\text{Sodio-potassic}\\\text{tartrate.}}}{\left.\begin{matrix}H^2\\C^4H^2O^2\\Na.K\end{matrix}\right\}O^4}$$

With diatomic metals, it forms neutral salts, $C^4H^4M''O^6$, and double salts consisting of a double molecule of the acid, in which 2 at. hydrogen are replaced by a diatomic metal and 2 at. more by an alkali-metal; *e.g.*:

$$\left.\begin{matrix}H^2\\C^4H^2O^2\\Ba''\end{matrix}\right\}O^4 \qquad\qquad \left.\begin{matrix}H^4\\(C^4H^2O^2)^2\\Ba''K^2\end{matrix}\right\}O^8$$

Neutral baric tartrate. **Baric potassic tartrate.**

With triatomic metals, tartaric acid forms a peculiar class of salts—best known in the case of antimony—the constitution of which may be illustrated by the following formulæ:

$$\left.\begin{matrix}H^2\\(C^4H^2O^2)^{iv}\\H.Sb'''\end{matrix}\right\}\begin{matrix}O^4\\O\end{matrix} \qquad \left.\begin{matrix}H^2\\(C^4H^2O^2)^{iv}\\K.Sb'''\end{matrix}\right\}\begin{matrix}O^4\\O\end{matrix} \qquad \left.\begin{matrix}H^2\\(C^4H^2O^2)^{iv}\\\overset{'''}{Sb}{}^2\end{matrix}\right\}\begin{matrix}O^4\\O^2\end{matrix}$$

Acid antimonious tartrate. **Potassio-antimonious tartrate.** **Neutral antimonious tartrate.**

These formulæ are a typical expression of the idea that one of the three atomicities of the antimony takes the place of 1 at. of the typical hydrogen of the tartaric acid, binding instead of it one atomicity of the typical oxygen (Kekulé). The same salts may, however, be formulated similarly to the ordinary tartrates, by supposing 1 at. of the basic hydrogen to be replaced by the monatomic radicle antimonyl SbO; thus:

$$\left.\begin{matrix}H^2\\(C^4H^2O^2)^{iv}\\H.SbO\end{matrix}\right\}O^4 \qquad \left.\begin{matrix}H^2\\(C^4H^2O^2)^{iv}\\K.SbO\end{matrix}\right\}O^4 \qquad \left.\begin{matrix}H^2\\(C^4H^2O^2)^{iv}\\(SbO)^2\end{matrix}\right\}O^4$$

Acid antimonious tartrate. **Potassio-antimonious tartrate.** **Neutral antimonious tartrate.**

When these salts are heated to 160°—200°, they give off water, and form compounds which may be regarded either as tartrates in which the triatomic antimony replaces three-fourths of the typic hydrogen of the acid:

$$\left.\begin{matrix}(C^4H^2O^2)^{iv}\\H.Sb'''\end{matrix}\right\}O^4 \qquad\qquad \left.\begin{matrix}(C^4H^2O^2)^{iv}\\K.Sb'''\end{matrix}\right\}O^4;$$

or as antimonylic derivatives of the first anhydride of tartaric acid:

$$\left.\begin{matrix}(C^4H^2O^2)^{iv}\\H.SbO\end{matrix}\right\}O^3 \qquad \left.\begin{matrix}(C^4H^2O^2)^{iv}\\K.SbO\end{matrix}\right\}O^3 \qquad \left.\begin{matrix}(C^4H^2O^2)^{iv}\\(SbO)^2\end{matrix}\right\}O^2.$$

Tartaric acid forms similar compounds with arsenic and with boron. (Kekulé's *Lehrbuch*, ii. 201.)

The first of the formulæ above given for the antimony-salts dried at 160°—200° represents tartaric acid as tetrabasic; and this view is further in accordance with the known existence of a tetraplumbic tartrate (p. 682); but in most of its relations, tartaric acid, as already observed, is only dibasic.

The neutral tartrates of the *alkali-metals* are very soluble in water; the acid tartrates of potassium and ammonium are sparingly soluble; all tartrates are insoluble in alcohol. Hence, tartaric acid dissolved in alcohol does not decompose carbonates. The neutral tartrates of the *earth-metals* and *heavy metals* are, for the most part, insoluble or sparingly soluble in water, but dissolve in aqueous tartaric acid, also in hydrochloric and in nitric acid; also, with exception of the silver- and mercury-salts, in excess of potash or soda. Ammonia likewise dissolves all tartrates, excepting tartrate of mercury.

Tartaric acid added to the solutions of most metallic salts prevents their precipitation by alkalis. According to Aubel and Ramdohr (Ann. Ch. Pharm. ciii. 33; Jahresb. x. 572), metallic oxides may be divided, according to their behaviour with caustic potash or soda in presence of tartaric acid, into the three following groups:—*α*. Oxides soluble in the alkali in presence of tartaric acid, and not precipitated on boiling: alumina, bismuth-oxide, chromic oxide, cobaltous oxide, cupric oxide, ferric oxide, glucina, lead-oxide, nickel-oxide, platinic oxide, zinc-oxide.—*β*. Oxides precipitated on boiling from the alkaline solution, if moderately dilute: auric oxide (reduced on boiling), cadmium-oxide, manganous oxide, uranic oxide.—*γ*. Insoluble: mercuric oxide, silver-oxide (reduced on boiling), stannous oxide. (See further H. Grothe, J. pr. Chem. xcii. 175; Jahresb. 1864, p. 686.)

Most of the soluble tartrates crystallise easily, and some (especially the double salts) form large well-defined crystals. The crystals are invariably hemihedral, and their solutions turn the plane of a polarised ray to the right or to the left, according to the position of the hemihedral faces. The dextro- and lævo-tartrates are likewise opposite in their pyro-electric properties. In all their other characters they resemble one another exactly, and the solution of a dextrotartrate mixed with that of an equal weight of the corresponding lævotartrate forms a mixture which yields holohedral and optically inactive crystals of the corresponding racemate, excepting in the case of the sodio-ammonic salts, which crystallise out separately, as dextro- and lævo-tartrates (p. 674).

Tartrates calcined in contact with the air give off the odour of burnt sugar. Their dilute aqueous solutions become covered after a while with fungi.

The composition of the tartrates has been established chiefly by the analyses of Berzelius (Pogg. Ann. xix. 305, xxxvi. 4; Ann. Ch. Phys. [2], lxvii. 303), Dulk (Schw. J. lxiv. 180, 193), Werther (J. pr. Chem. xxxii. 383), and Dumas and Piria (Ann. Ch. Phys. [3] v. 353): see also *Gmelin's Handbook*, x. 273–326. The crystalline forms of a great number of tartrates have been determined by De la Provostaye (Ann. Ch. Phys. [3], iii. 129) and Pasteur, and their optical properties by Biot and Pasteur (see references, p. 673).

a. *Tartrates containing only Monatomic Metals.*

TARTRATES OF AMMONIUM.—The *neutral salt*, $C^4H^4(NH^4)^2O^6$, is obtained by evaporating a solution of the acid, neutralised with ammonia or carbonate of ammonium, in prismatic crystals, which are very soluble in water, and effloresce, with loss of ammonia, on exposure to the air. The crystals are monoclinic, having the axes $a : b : c = 0·868 : 1 : 1·244$. Angle $b : c = 88° 9'$; $[P\infty : P\infty]$ (clinod.) $= 69° 50'$; $+ P\infty : c = 39° 31'$. Ordinary combination, $oP . \infty P\infty . + P\infty . [P\infty]$; also with $+ P$ and $- P$ subordinate. Cleavage perfect parallel to oP. The faces $[P\infty]$ are present in only half the number required by the law of symmetry: the crystals are therefore hemihedral. Rotatory power $[\alpha]_r = \pm 29°$. Specific gravity of the crystals = 1·566. (Schiff, Jahresb. 1859, p. 16.)

The *acid salt*, or *bitartrate of ammonia*, $C^4H^5(NH^4)O^6$, is precipitated, on adding tartaric acid to the solution of the neutral salt, as a crystalline powder, exhibiting under the microscope beautiful shining laminæ, forming oblique-angled parallelograms or hexagonal plates, elongated and often hemitropic. It is slightly soluble in cold, very soluble in boiling water. The crystals are trimetric, and isomorphous with the acid potassium-salt. Axes $a : b : c = 0·6933 : 1 : 0·7086$. Angle $P : P$ (brach.) $= 127° 18'$; $P : P$ (macr.) $= 100° 20'$; $P : P$ (basal) $= 102° 24'$; $\infty P : \infty P$ (macr.) $= 69° 28'$; $\bar{P}\infty : \bar{P}\infty$ (basal) $= 70° 38'$; $2\breve{P}\infty : 2\breve{P}\infty$ (basal) $= 109° 36'$; $3\breve{P}\infty : 3\breve{P}\infty = 129° 36'$. The crystals exhibit the same faces as those of the acid potassium-salt (p. 678), and cleave most easily parallel to oP. They are hemihedral, the P-faces being always unequally developed; four of them, two at each end, being very small or non-existent, whilst the other four, which are much larger, are so situated as to form, by sufficient prolongation, the irregular tetrahedron $\frac{P}{2}$ (De la Provostaye). According to Hahn (Jahresb. 1859, p. 286), the crystals exhibit the combination $\infty P . \infty\breve{P}\frac{3}{2} . \infty\bar{P}2 . \infty\bar{P}\infty . P . \bar{P}\infty$; axes $a : b : c = 0·72988 : 1 : 0·83425$; angle $\infty P : \infty\breve{P}$ (macr.) $= 72° 15'$; $\bar{P}\infty : \bar{P}\infty$ (over c) $= 100° 20'$. The specific gravity of the crystals is 1·680. (Schiff.)

Acid dextrotartrate of ammonium combines with optically active acid malate of ammonium, forming the salt $C^4H^5(NH^4)O^6.C^4H^5(NH^4)O^5$, which crystallises in thick acuminated prisms (Pasteur). The acid lævotartrate does not form a similar compound.

TARTRATES OF CÆSIUM.—The *neutral tartrate* is very deliquescent (Bunsen).—The *acid salt*, $C^4H^5CsO^6$, crystallises in rhombic prisms, isomorphous with the rubidium-salt. Axes $a : b : c = 0·694 : 1 : 0·661$. Angle $P : P$ (brach.) $= 128° 50'$; $P : P$ (macr.) $= 103°$; $P : P$ (basal) $= 98° 30'$. Observed combination, $\infty\bar{P}\infty . \infty\breve{P}\infty . \infty P$ (the latter very subordinate and imperfect), together with the sphenoïds $+\frac{P}{2}$, $-\frac{P}{2}$, and $-\frac{\frac{4}{3}P3}{2}$. The crystals are dextro- or lævo-rotatory, according as one or the other of the sphenoïdal faces $\frac{P}{2}$ is absent or subordinate (they rarely occur together); the faces $-\frac{\frac{4}{3}P3}{2}$ occur only in lævo-rotatory crystals. Cleavage perfect parallel to $\infty\bar{P}\infty$ and $\infty\breve{P}\infty$, both of which faces are striated parallel to the principal axis. The striation and cleavage distinguish the crystals from those of acid potassic tartrate, to which they bear a general resemblance (J. P. Cooke, Sill. Am. J. [2], xxxvii. 70). They disolve in 10·3 pts. water at 25°, and in 1·02 pt. boiling water. (Allen, *ibid.* xxxiv. 367.)

TARTRATES OF LITHIUM.—The *neutral salt* is white, deliquescent, and uncrystallisable.—The *acid salt*, $2C^4H^5LiO^6.3H^2O$, forms small crystals, very soluble in water. (Dulk.)

TARTRATE, MERCUROUS.—This salt is obtained, by precipitation, as a white crystalline powder, or in the form of shining needles or scales. It is insoluble in water, but very soluble in nitric acid. Boiling water decomposes and turns it grey.

TARTRATES OF POTASSIUM.—The *neutral salt*, $C^4H^4K^2O^6$, prepared by saturating the acid salt with carbonate of potassium, crystallises with difficulty in short monoclinic prisms, the faces of which have generally very little lustre. Axes $a : b : c = 0·4021 : 1 : 1·1085$. Angle $b : c = 75° 1 2'$; $\infty P : \infty P$ (orthod.) $= 134° 50'$; $+P\infty : c = 52° 5'$; $-P\infty : c = 37° 25'$. The most frequently occurring faces are: ∞P, oP, $\infty P\infty$, $[\infty P\infty]$, $+P\infty$, $-P\infty$; more rarely $+\frac{1}{2}P$ occurs. Cleavage parallel to $+P\infty$ and $-P\infty$.

One part of neutral potassic tartrate dissolves in 0·75 pt. water at 2°, in 0·66 pt. at 14°, in 0·63 pt. at 23°, and in 0·47 pt. at 64° (Osann). It is very slightly soluble in boiling alcohol. Most acids added to the solution of this salt precipitate the acid tartrate; bromine forms the same precipitate without attacking the tartaric acid.

The *acid salt, bitartrate of potash*, or *cream of tartar*, $C^4H^5KO^6$, is contained in grape-juice, and, being much less soluble in alcoholic liquids than in water, is deposited, during the vinous fermentation of the juice, in crystalline crusts, called crude tartar or argol. The same deposit is formed in many kinds of wine when kept in casks or bottles, and constitutes the well-known crust of port-wine. The salt likewise exists in many other vegetable juices. Crude tartar, when purified by recrystallisation, yields cream of tartar. The pure salt is also formed whenever tartaric acid is added in excess to the solution of a potassium-salt.

The crystals of acid potassic tartrate belong to the trimetric system, and are isomorphous with the acid ammonium-salt. Axes $a : b : c = 0·7115 : 1 : 0·7372$. Angle $P : P$ (brach.) $= 125° 46'$; $P : P$ (macr.) $= 100° 20'$; $P : P$ (basal) $= 103° 28'$; $\infty P : \infty P$ (macr.) $= 70° 52'$; $\breve{P}\infty : \breve{P}\infty$ (basal) $= 72° 48'$; $2\breve{P}\infty : 2\breve{P}\infty = 111° 42'$; $3\breve{P}\infty : 3\breve{P}\infty = 131° 20'$. Ordinary combination $P . \infty P$, with $\infty\breve{P}\infty$ and the above-mentioned brachydiagonal domes. One half of the crystals is generally sphenoïdically enlarged in comparison with the other half. Cleavage most distinct parallel to oP. Specific gravity of the crystals = 1·973 (Schiff); 1·956 (Buignot).

Acid tartrate of potassium is but slightly soluble in water, requiring for solution about 240 pts. of water at 10°, and 15 pts. of boiling water. It is insoluble in strong alcohol, but dissolves easily in concentrated mineral acids and in alkalis, which convert it into the neutral tartrate.

The following determinations of the solubility of acid potassic tartrate in water, at various temperatures, have been made by Alluard (Compt. rend. lix. 500; Jahresb. 1864, p. 94) and by Chancel (Compt. rend. lx. 408; Jahresb. 1865, p. 830), in pure water and in water containing 10·5 per cent. alcohol. Alluard's determinations were made under a barometrical pressure of 718 mm.:—

Solubility of Cream of Tartar, $C^4H^5KO^6$.

100	6·90		

A saturated aqueous solution boils at 99·6° (Alluard). The solubility of the salt in water or in dilute alcohol is not diminished by the presence of glucose. ([illegible]el.)

The aqueous solution reddens litmus-paper, and dissolves a considerable number of metallic oxides, forming double tartrates.

Cream of tartar, when calcined, emits a pungent odour like that of burnt bread, and leaves a residue of potassic carbonate, mixed with charcoal, the *Sal fixum tartari* of the older chemists; calcined with saltpetre, it yields, according to the proportions, the *black* or *white flux* used in metallurgical and assaying operations.

Cream of tartar is one of the mordants most frequently employed in the dyeing of wool. Mixed with pounded chalk and alum, it forms an excellent powder for cleaning silver.

Ammonio-potassic tartrate, $C^4H^4(NH^4)KO^6$, obtained by saturating cream of tartar with ammonia or its carbonate, forms monoclinic crystals isomorphous with neutral potassic tartrate. They alter quickly in the air, giving off ammonia, and are very soluble in water.

Lithio-potassic tartrate, $C^4H^4LiKO^6.H^2O$, is very soluble in water, and, according to Zepharovich (Wien. Akad. Ber. xli. 520), crystallises in large rhombic prisms, having the axes $a : b : c = 0{\cdot}5477 : 1 : 0{\cdot}4430$; angle $\infty P : \infty P$ (brach.) = 122° 34′; $P : \infty P$ = 132° 41′. They exhibit the combination $\infty P \,.\, \infty\breve{P}\frac{3}{2} \,.\, \infty\breve{P}2 \,.\, \infty\breve{P}\infty \,.\, P \,.\, oP$, hemihedral from predominance or exclusive development of four of the P-faces. Cleavage imperfect parallel to oP.

TARTRATES OF RUBIDIUM.—The *neutral salt* has not been described.—The *acid salt*, $C^4H^5RbO^6$, is isomorphous with the acid cæsium-salt, exhibiting the same faces with the exception of $-\frac{4P3}{2}$, also the same striation and cleavage. Axes $a : b : c = 0{\cdot}726 : 1 : 0{\cdot}695$. Angle $P : P$ (brach.) = 126° 43′; $P : P$ (macr.) = 103° 40′; $P : P$ (basal) = 99° 34′ (J. P. Cooke). The crystals are permanent in the air, at ordinary temperatures, and at 100° they dissolve in 8·45 pts. water at 25°, and in 8·5 pts. of boiling water. The great difference of solubility between this and the cæsium-salt affords a means of separating the two metals by fractional crystallisation of their acid tartrates. (Allen.)

TARTRATE OF SILVER, $C^4H^4Ag^2O^6$.—This salt is obtained, as an amorphous curdy precipitate, on mixing a cold dilute solution of silver-nitrate with a dilute solution of Rochelle-salt slightly acidulated with nitric acid: if the solutions are mixed at the boiling heat, the mixture turns brown, and deposits brown laminæ of metallic silver. If a hot moderately strong solution of Rochelle-salt be added to a dilute solution of silver-nitrate, and the liquid heated to 80°, till the precipitate begins to be permanent (a certain quantity of the silver-nitrate remaining undecomposed), the filtered solution, on cooling, yields tartrate of silver, in white scales having a metallic lustre.

Tartrate of silver is nearly insoluble in water. It blackens on exposure to light, and, when heated, gives off carbonic anhydride and pyrotartaric acid, leaving a spongy shining residue of metallic silver. The dry salt is quickly decomposed by chlorine, yielding chloride of silver and empyreumatic products. When chlorine is passed into water in which tartrate of silver is suspended, carbonic anhydride is given off, and chloride of silver is obtained, together with unaltered tartaric acid.

A solution of tartrate of silver in ammonia deposits metallic silver at the boiling heat, while the liquid retains in solution a peculiar ammoniacal salt, which is less soluble in water than tartrate of ammonium, and crystallises on cooling.—Caustic *potash* and *soda* decompose tartrate of silver at ordinary temperatures, oxide of silver being separated, and the liquid apparently retaining potassio-argentic or sodio-argentic tartrate. (Liebig and Redtenbacher, Ann. Ch. Pharm. xxxviii. 132.—Erdmann, J. pr. Chem. xxv. 504.)

TARTRATES OF SODIUM.—The *neutral salt*, $C^4H^4Na^2O^6.2H^2O$, crystallises in trimetric prisms having the axes $a : b : c = 0{\cdot}7696 : 1 : 0{\cdot}3366$. Angle $\infty P : \infty P$ (brach.) = 104° 50′; $\infty P : \breve{P}\infty$ = 108° 31′; $\breve{P}\infty : \breve{P}\infty$ (basal) = 132° 44′; $\infty P : \infty\bar{P}\infty$ = 142° 25′; $\infty P : \infty\breve{P}\infty$ = 127° 35′. Ordinary combination $\infty P \,.\, \infty\breve{P}\infty \,.\, \infty\bar{P}\infty \,.\, \breve{P}\infty$ (De la Provostaye). The crystals have a specific gravity of 1·794 (Buignet). They are limpid, permanent in the air, soluble in 5 pts. of cold water, very soluble in hot water, insoluble in absolute alcohol. When heated, they melt in their water of crystallisation. By rapid crystallisation the salt is obtained in tufts of needles.

The *acid salt*, $C^4H^5NaO^6.H^2O$, is formed on mixing a hot solution of the neutral salt with ½ pt. tartaric acid, and separates in crystals on cooling. It dissolves in 9 pts. of cold and 1·8 pt. boiling water, but is insoluble in alcohol. It is difficult to obtain this salt in large crystals, but, by leaving a drop of the hot solution to evaporate under the microscope, small beautifully defined crystals soon make their appearance, having the form of right rhombic prisms ∞P, bevelled at each end by the hemihedral faces $\frac{P}{2}$.

Ammonio-sodic tartrate, $C^4H^4Na(NH^4)O^6.4H^2O$, is obtained by saturating acid tartrate of ammonium with carbonate of sodium, and concentrating the solution; also by mixing the warm solutions of equivalent quantities of the sodium- and ammonium-salts of racemic acid, and cooling the solution, or leaving it to evaporate, dextro- and lævo-tartrate of sodium and ammonium being then deposited in equal quantities. The crystals, which are often of considerable size, are trimetric, and isomorphous with those of the potassio-sodic salt. Axes $a : b : c = 0{\cdot}8233 : 1 : 0{\cdot}4200$. Angle $\infty P : \infty P$ (macr.) = 78° 36′; $\infty\bar{P}2 : \infty\bar{P}2$ (macr.) = 44° 44′; $\bar{P}\infty : \bar{P}\infty$ (basal) = 54° 4′; $\breve{P}\infty : \breve{P}\infty$ (basal) = 45° 34′; $2\breve{P}\infty : 2\breve{P}\infty$ (basal) = 80° 4′. Ordinary combination $\infty P \,.\, \infty\bar{P}2$ (often predominant) $.\ \infty\bar{P}\infty \,.\, \infty\breve{P}\infty \,.\, \bar{P}\infty \,.\, 2\breve{P}\infty \,.\, \breve{P}\infty \,.\, oP \,.\, \pm\frac{P}{2}$, the hemihedral faces being situated on one side or the other of the crystals, according as the salt is dextro- or lævo-rotatory. Rotatory power $[\alpha]_j = \pm 26°$. Specific gravity of the crystals = 1·587. (Schiff.)

Lithio-sodic tartrate, $C^4H^4LiNaO^6.2H^2O$, resembles the lithio-potassic salt.

Potassio-sodic tartrate, *Rochelle* or *Seignette salt*, $C^4H^4KNaO^6.4H^2O$.—This splendid salt is prepared by adding, in small portions and successively, 4 pts. cream of tartar, and about 3 pts. of crystallised sodic carbonate, to 12 pts. of boiling water. When the whole has been added, the liquid must be tested, to ensure that it is slightly alkaline, and then concentrated by evaporation. On cooling, it deposits fine large crystals of the double salt, and the mother-liquors yield an additional quantity; after a certain time, however, they deposit nothing but needles of sodic tartrate; but by redissolving these, and adding cream of tartar, an additional quantity of Rochelle-salt may be obtained. The crystals, which are often very large, are rhombic prisms, isomorphous with the preceding salt. Axes $a : b : c = 0{\cdot}8317 : 1 : 0{\cdot}4296$. Angle $\infty P : \infty P$ (macr.) = 79° 30′; $\infty\bar{P}2 : \infty\bar{P}2$ (macr.) = 45° 10′; $\bar{P}\infty : \bar{P}\infty$ (basal) = 54° 38′; $\breve{P}\infty : \breve{P}\infty$ (basal) = 46° 30′; $2\breve{P}\infty : 2\breve{P}\infty$ (basal) = 81° 20′. The crystals exhibit, for the most part, the same faces as the ammonio-sodic salt; $\breve{P}\infty$, however, is usually but slightly developed. Specific gravity = 1·767 (Schiff); 1·790 (Buignet).

The crystals melt in their water of crystallisation between 70° and 80°, forming a transparent liquid, which begins to boil at 120°, the ebullition continuing till the temperature rises to 215°, by which time all the water (amounting to 25·1 per cent.) is driven off. The residue is a viscid mass, which remains transparent when cold, and absorbs moisture from the air (Fresenius, Ann. Ch. Pharm. liii. 234).—The dry salt dissolves in 2·62 pts. water at 6° (Fresenius). The crystals dissolve in 3·3 pts. water at 3°, in 2·4 pts. at 11°, and in 1·5 pt. at 26° (Osann); in 2 pts. at 5·6°, in 1·2 pts. at 12·5°, in 0·42 pt. at 25°, and in 0·3 pt. at 37·5° (Brandes). The solution saturated at 8° has a density of 1·254.

Rubidio-sodic tartrate, $C^4H^4RbNaO^6.4H^2O$.—The solution of this salt, when left to evaporate spontaneously, solidifies to a transparent jelly; but, by slow cooling of a hot solution, crystals are obtained isomorphous with Rochelle-salt, and exhibiting the same faces, with addition of $2\bar{P}2$ and $2\bar{P}\infty$. (Piccard, Jahresb. 1864, p. 125.)

TARTRATES OF THALLIUM.—The *neutral salt*, $C^4H^4Tl^2O^6$, is slightly soluble in water and in alcohol. The crystals, which usually occur as twins, appear to be trimetric, but different in form from the neutral ammonium- and potassium-salts. De la Provostaye gives, as approximate measurements of the angles, $\infty P : \infty P$ (macr.) = 60°; $\infty P : \infty\breve{P}$, = 120°; . $\infty\breve{P}\infty : \breve{P}\infty$ = 131°; $\infty P : \breve{P}\infty$ = 110°. The crystals are anhydrous alterable in the air, become carbonised at 170°, and at higher temperatures leave yellow oxide of thallium, with a small quantity of reduced metal.

The *acid salt*, $C^4H^5TlO^6$, is precipitated, on adding tartaric acid to a solution of the neutral salt, in small flat prisms, which are difficult to measure. De la Provostaye gives, as approximate angular values, $\infty\bar{P}\infty : \infty P$ = 123°; $\breve{P}\infty : \breve{P}\infty$ = 108° to 110°; $\infty\breve{P}\infty : \breve{P}\infty$ = 125° to 126°; these angles are nearly the same as in the acid tartrates of ammonium and potassium. This salt is less soluble than the neutral tartrate of thallium. (Kuhlmann, Jahresb. 1862, p. 188.)

β. *Tartrates containing Diatomic Metals.*

TARTRATE OF BARIUM, $C^4H^4Ba''O^6$, is precipitated, on mixing tartrate of potassium with chloride of barium, or tartaric acid with baryta-water, in white flocks, which become crystalline when left at rest; it is insoluble in excess of tartaric acid.

Potassio-baric tartrate, $C^8H^8Ba''K^2O^{12}.2H^2O$, or $C^4H^4Ba''O^6.C^4H^4K^2O^{12}.2H^2O$, is obtained, as a sparingly soluble pulverulent precipitate, on evaporating a solution of cream of tartar with baryta-water.—*Sodio-baric tartrate*, $C^8H^8Ba''Na^2O^{12}.2H^2O$, is precipitated on mixing a solution of Rochelle-salt with chloride of barium; if, however, the solutions are dilute, it separates, after some time only, in the form of needles; it lightly soluble in water, more soluble in solution of Rochelle-salt.

Tartrate of Cadmium forms woolly needles, nearly insoluble in water.

Tartrates of Calcium.—The *neutral salt*, $C^4H^4Ca''O^6.4H^2O$, exists in several plants, especially in grapes, and is sometimes found in small crystals in the tartar deposited from the juice. It is precipitated, as a white crystalline powder, on mixing tartrate of potassium with a solution of calcic chloride; if the liquors are dilute, the precipitate does not appear for some minutes. Tartaric acid forms, with lime-water, copious white flocks, which gradually become crystalline; the precipitate redissolves in excess of tartaric acid; and the solution, when left at rest, deposits crystals of neutral calcic tartrate. The hard shining crystals of this salt are right rhomboïdal prisms, ∞P, having the basal summits modified by the octahedral face P. Angle $\infty P : \infty P = 97° 30'$; $P : P = 122° 15'$. (Pasteur.)

Tartrate of calcium is very slightly soluble in cold, rather more soluble in boiling water. According to F. Mohr (Jahresb. 1865, p. 393), it requires for solution 6,265 pts. of water at 15°, and 352 pts. of boiling water. Mineral acids, acetic acid, and cream of tartar dissolve it easily. The solutions, unless very concentrated, are not immediately precipitated by ammonia, but the mixture, after some time, deposits crystals of neutral calcic tartrate. The flocculent precipitate formed in a solution of calcic chloride by neutral potassic tartrate, dissolves in sal-ammoniac, and the liquid gradually deposits crystals of calcic tartrate.

Crude tartar containing tartrate of calcium, when kept in a moist warm place, often passes into a state of fermentation, induced by vegetable organisms present in it, the tartaric acid being converted into butyracetic acid. This change is especially liable to take place during the preparation of tartaric acid in warm weather, after the crude tartar has been mixed with lime.

Acid tartrate of Calcium, $C^8H^{10}Ca''O^{12}$, or $C^4H^4Cu''O^6.C^4H^6O^6$, appears to exist in the juice of *Rhus Typhinum*, and is produced (according to Dulk) on adding tartaric acid to lime-water till the precipitate redissolves: the solution, if left to itself, deposits crystals of neutral calcic tartrate, but if evaporated immediately, it yields rhomboïdal octahedrons of the acid tartrate, having the angles of the terminal edges = 82° 50′ and 153°. The crystals are transparent, redden litmus, are slightly soluble in cold water, more soluble in boiling water.

Potassio-calcic tartrate appears to be obtained, in the crystalline state, by spontaneous evaporation of a mixture of cream of tartar and lime-water. Neutral tartrate of calcium dissolves at a gentle heat in caustic potash, and the saturated solution deposits part of the neutral salt on addition of water. When boiled, it is converted into a thick pasty mass, but becomes clear again on cooling. Tartrate of calcium dissolves when boiled with solution of neutral potassic tartrate, and the liquid, evaporated to a syrupy consistence, solidifies on cooling to a mass of needles.

Sodio-calcic tartrate is precipitated in flocks, on mixing a solution of Rochelle-salt with chloride of calcium; if the solutions are dilute, it is gradually deposited in small needles. It is slightly soluble in water, more soluble in excess of Rochelle-salt, still more in chloride of calcium.

Caustic soda reacts with tartrate of calcium like caustic potash.

Tartrate of Cobalt is a red crystallisable salt.—*Potassio-cobaltous tartrate* forms large rhomboïdal prisms.

Tartrates of Copper.—*Cupric tartrate*, $C^4H^4Cu''O^6.3H^2O$, is a light-green crystalline powder, precipitated on mixing the neutral potassium-salt with cupric sulphate or nitrate. It dissolves in 1,715 pts. of cold water, and in 310 pts. of boiling water; also in nitric acid, but is insoluble in tartaric acid.

Potassio-cupric tartrate is obtained in blue crystals by boiling cupric oxide or carbonate with cream of tartar. Cupric tartrate dissolves in caustic potash, forming a blue liquid. Cupric salts mixed with tartaric acid are not precipitated by alkalis.

A solution of cupric sulphate mixed with potash, and a sufficient quantity of tartaric acid to prevent precipitation, is reduced by boiling with many organic substances, especially glucose, and is used for the estimation of the latter (ii. 860).

When a solution of potassio-cupric tartrate is exposed to the action of chlorine, or mixed with an alkaline hypochlorite, not in excess, a yellow precipitate is formed, consisting of a compound of 2 at. cuprous formate ($CHCu'O^2$) with 1 at. sodic carbonate (CNa^2O^3); afterwards cuprous oxide is separated. (E. Millon, Compt. rend. lv. 513; Jahresb. 1862, p. 216.)

A basic *sodio-cupric tartrate*, $C^8H^8Na^2Cu''O^{12}.2CuO.7H^2O$ (?), is obtained by dissolving cupric tartrate in a boiling solution of sodic carbonate; the blue liquid, when concentrated, deposits the double salt in mammellated groups of small tabular crystals, very soluble in water. If the boiling be too much prolonged, a precipitate of cuprous oxide is formed.

Ammoniacal Cupric Tartrates.—The *tetrammoniated salt*, $4NH^3.C^4H^4Cu''O^6$, or *tartrate of ammocuprammonium*, $C^4H^4[N^2H^4(NH^4)^2Cu'']''O^6$, remains, on evaporating a solution of cupric tartrate in ammonia, as an uncrystallisable, hard, vitreous mass, permanent in the air. Its aqueous solution is also very permanent, does not act upon cellulose, and is not reduced by heating with glucose. At 150° it gives off all its ammonia; between 100° and 110° only half, leaving *tartrate of cuprammonium*, $2NH^3.C^4H^4Cu''O^6 = C^4H^4(N^2H^6Cu'')''O^6$.

Cupric tartrate dissolves easily also in aqueous *ethylamine*, forming a dark-blue liquid, which, on evaporation, leaves a blue, vitreous, deliquescent salt, approximating in composition to the formula $C^4H^4\left[\begin{matrix}NH^3\\ NH^2(C^2H^5)\end{matrix}\right\}Cu''\Big]\overset{''}{O}{}^6$. (Schiff, Jahresb. 1862, p. 204.)

Tartrate, Ferrous.—White or pale-green crystalline powder, precipitated on mixing a solution of ferrous sulphate with tartaric acid or neutral potassic tartrate, or on dissolving metallic iron in tartaric acid. It dissolves easily in caustic alkalis, forming a solution which oxidises quickly on exposure to the air.

Tartrates of Lead.—The *monoplumbic* or *dibasic salt*, $C^4H^4Pb''O^6$, is a white crystalline precipitate, obtained by mixing nitrate or acetate of lead with tartaric acid. It is very soluble in nitric acid and in excess of tartaric acid; also in tartrate of ammonium, the concentrated solution solidifying to a gelatinous mass. When treated with chloride of acetyl, it yields chloride of lead and a thick yellowish syrup, which decomposes at 130°, with evolution of carbonic oxide and carbonic anhydride. (Schützenberger, Jahresb. 1861, p. 439.)

A *diplumbic* or *tetrabasic salt*, $C^4H^2\overset{''}{Pb}{}^2O^6$, is obtained by boiling an ammoniacal solution of the monoplumbic salt. (Erdmann, Ann. Ch. Pharm. xxi. 19.—Heintz, Zeitschr. Ch. Pharm. 1861, p. 17.)

Tartrates of Magnesium.—The *neutral salt*, $C^4H^4Mg''O^6.4H^2O$, is obtained in crystalline crusts, by evaporating a solution of magnesium-carbonate in tartaric acid. It dissolves in 122 pts. of water at 16°.—The *acid salt*, $C^8H^{10}Mg''O^{12}$ (crystallised), is formed in the preparation of the neutral salt when an excess of tartaric acid is used. It forms crystalline crusts, soluble in 52 pts. water at 16°.

Potassio-magnesic tartrate, $C^8H^8Mg''K^2O^6.4H^2O$, is obtained, in crystals, by boiling cream of tartar with water and carbonate of magnesium.—An *ammonio-magnesic salt* of corresponding composition is obtained in a similar manner.—The *sodio-magnesic salt*, $C^8H^8Mg''Na^2O^6.5H^2O$, is deposited, on evaporating a mixture of Rochelle-salt and carbonate of magnesium, in monoclinic prisms having the angles $\infty P : \infty P = 129°$; $oP : \infty P\infty = 103°$. Ammonia throws down from the solution of either of these salts a basic tartrate of magnesium, $C^4H^4Mg''O^6.Mg''O.2H^2O$, the formation of which interferes considerably with the use of tartaric acid in Otto's method of separating phosphoric acid from certain bases: hence citric acid is preferable for this purpose. (See Phosphoric Acid, iv. 547.)

Tartrate of Manganese.—A solution of neutral potassic tartrate, mixed with manganous chloride, first deposits acid tartrate of potassium, and then colourless crystals of manganous tartrate, which are decomposed by boiling water into a soluble acid salt and an insoluble basic salt. By dissolving manganous carbonate in cream of tartar, a very soluble salt is obtained, difficult to crystallise.

Tartrate, Mercuric.—White precipitate, insoluble in water, very soluble in weak nitric acid.

Ammonio-mercuric tartrate, obtained by boiling acid tartrate of ammonium with mercuric oxide, forms small prisms soluble in water.—*Tartrate of mercurammonium* is obtained, by digesting mercuric tartrate with ammonia, as a white powder insoluble in water. It appears also to be formed when mercuric oxide is heated with neutral tartrate of ammonium: the oxide then dissolves, with evolution of ammonia; and if an excess of it be used, a white compound separates; the filtered liquid, when concentrated, deposits needles, and, on addition of water, a white precipitate, containing $C^8H^{10}(N^2H^2\overset{''}{Hg}{}^3)''O^{12}.6H^2O$. (Harff, Brandes' Arch. v. 259.—Burckhardt, *ibid.* [2] xi. 257.)

Potassio-mercuric tartrate is obtained, in small slightly soluble prisms, by digesting mercuric oxide with cream of tartar.—When cream of tartar is boiled with chloride of mercurammonium (white precipitate), a large quantity of carbonic anhydride is evolved; the filtered liquid deposits, on evaporation, sparingly soluble salts containing mercury; and the mother-liquors yield needles, apparently consisting of the compound $4C^4H^5KO^6.Hg''Cl^2.6H^2O$.

Tartrate of Nickel.—Precipitated as a green crystalline powder, nearly insoluble in water, on saturating a boiling solution of tartaric acid with hydrate or carbonate of nickel. It dissolves easily in a hot solution of caustic potash or soda, or in sodic carbonate, the solution solidifying to a pasty mass on cooling. Nickel-salts mixed with tartaric acid are not precipitated by alkalis.

Tartrate of Nickel and Potassium, $C^8H^8Ni''K^2O^{12}$ (at 110°), is produced by heating carbonate of nickel with finely-pulverised cream of tartar and water. The resulting green solution is decomposed by boiling, but, when evaporated over oil of vitriol, it yields an apple-green crystalline powder, which effloresces in the air, and dissolves completely in water.

TARTRATE OF PALLADIUM.—Light-yellow precipitate, formed on mixing nitrate of palladium with an alkaline tartrate.

TARTRATES OF STRONTIUM.—The *neutral salt*, $C^4H^4Sr''O^6.4H^2O$, is deposited, on mixing a cold solution of potassic tartrate with nitrate of strontium, in monoclinic prisms, having the angle $oP : \infty P = 92° 35'$; $\infty P : \infty P = 125° 20'$ (De la Provostaye). It dissolves in 147 pts. of water at 16°, and is moderately soluble in solution of sal-ammoniac.—According to Marignac (Ann. Min. [5], xv. 280; Jahresb. 1859, p. 286), a solution of strontium-carbonate in excess of hot aqueous tartaric acid deposits the neutral salt on cooling in trihydrated crystals, $C^4H^4Sr''O^6.3H^2O$, having the form of monoclinic prisms, $\infty P\infty \,.\, [\infty P\infty] \,.\, oP \,.\, +P\infty \,.\, -P\infty$, in which ∞P occurs with only two faces, situated to the right when the crystal is placed with the clinodiagonal directed towards the observer, and the obtuse angle of the inclined axis to the front and above; also a face of $+P$ and a face of $-P$ to the left. Angle $\infty P\infty : \infty P = 140° 1'$; $oP : \infty P\infty = 102°$; $\infty P\infty : +P\infty = 123° 43'$; $\infty P\infty : -P\infty = 137° 32'$; $oP : +P = 128° 4'$; $oP : -P = 138° 20'$. The crystals do not give off any water at 100°.

Tartrate of Strontium and Ammonium, $C^8H^8Sr''(NH^4)^2O^6.12H^2O$, separates from the mother-liquor of the neutral strontium-salt, on neutralisation with ammonia, in thin rectangular laminæ, which are trimetric combinations, $\infty\breve{P}\infty \,.\, \infty P \,.\, \infty\breve{P}2 \,.\, \breve{P}\infty$, with four P-faces occurring hemihedrally. Angle $\infty\breve{P}\infty : \infty P = 124° 58'$; $\infty\breve{P}\infty : \breve{P}\infty = 124° 20'$; $\infty P : P = 140°$. (Marignac, *loc. cit.*).

Tartrate of Strontium and Potassium, $C^8H^8Sr''K^2O^{12}.2H^2O$, is obtained like the corresponding barium-salt (p. 680).—The *sodium-salt*, $C^8H^8Sr''Na^2O^{12}$ (after drying), is obtained, as a gummy very soluble mass, by saturating strontia-water with acid tartrate of sodium, and evaporating.

TARTRATE OF TIN. STANNOUS TARTRATE, $C^4H^4Sn''O^6$.—Prepared by pouring a boiling solution of tartaric acid into a concentrated solution of stannous acetate. It forms white microscopic crystals, consisting of prisms with rectangular base, soluble in cold water, more soluble and without decomposition in boiling water, still more in water acidulated with tartaric acid, the solution not being precipitated by ammonia. When strongly heated, it leaves a residue of stannic oxide.

By treating the acid tartrates of ammonium and potassium with stannous oxide, salts are formed which crystallise well, and appear to be perfectly stable in presence of water.

TARTRATE, URANOUS.—Tartaric acid throws down from uranous chloride a greyish-green precipitate, consisting of a basic salt, $2C^4H^4U''O^6.U''H^2O^2$, which is very soluble in hydrochloric acid, and is not precipitated by ammonia.

TARTRATES OF YTTRIUM.—The *neutral salt*, $C^4H^4Y''O^6.4H^2O$, is formed, on adding neutral tartrate of potassium to acetate of yttrium, as a bulky precipitate soluble in excess of the potassium-salt. Its solution in an equivalent quantity of tartaric acid deposits after a while a crystalline precipitate, insoluble in water, consisting of the *acid salt*, $C^8H^{10}Y''O^{12}$. (Popp, Jahresb. 1864, p. 205.)

TARTRATE OF ZINC.—Hot concentrated solutions of zinc-sulphate and neutral potassic tartrate, yield a yellowish-white crystalline precipitate, very slightly soluble in water, easily soluble in caustic potash or soda. Cream of tartar digested with excess of zinc or its oxide, forms a solution which deposits a white powder, and dries up to a gummy mass.

γ. *Tartrates containing Triatomic Metals and Metalloïds.*

TARTRATE OF ALUMINIUM.—This salt occurs in *Lycopodium clavatum*. Its solution, when evaporated, leaves a gummy non-deliquescent mass.

The solution of neutral potassic tartrate dissolves a large quantity of alumina without becoming alkaline; the liquid, on addition of alcohol, deposits oily drops, the aqueous solution of which dries up by evaporation to a gummy mass, containing both potash and alumina. Acid tartrate of potassium likewise dissolves alumina, forming an amorphous mass, which is not precipitated by alkalis.

TARTRATES OF ANTIMONY. (Respecting the several views of the constitution of these salts, see p. 676).—*Neutral antimonious tartrate*, $C^4H^4(SbO)^2O^6.H^2O$, is the

Ammoniacal Cupric Tartrates.—The *tetrammoniated salt*, $4NH^3.C^4H^4Cu''O^6$, or *tartrate of ammocuprammonium*, $C^4H^4[N^2H^4(NH^4)^2Cu'']''O^6$, remains, on evaporating a solution of cupric tartrate in ammonia, as an uncrystallisable, hard, vitreous mass, permanent in the air. Its aqueous solution is also very permanent, does not act upon cellulose, and is not reduced by heating with glucose. At 150° it gives off all its ammonia; between 100° and 110° only half, leaving *tartrate of cuprammonium*, $2NH^3.C^4H^4Cu''O^6 = C^4H^4(N^2H^6Cu'')''O^6$.

Cupric tartrate dissolves easily also in aqueous *ethylamine*, forming a dark-blue liquid, which, on evaporation, leaves a blue, vitreous, deliquescent salt, approximating in composition to the formula $C^4H^4\left[\left.\begin{matrix}NH^3\\NH^2(C^2H^5)\end{matrix}\right\}Cu''\right]\overset{''}{O}{}^6$. (**Schiff**, Jahresb. 1862, p. 204.)

Tartrate, Ferrous.—White or pale-green crystalline powder, precipitated on mixing a solution of ferrous sulphate with tartaric acid or neutral potassic tartrate, or on dissolving metallic iron in tartaric acid. It dissolves easily in caustic alkalis, forming a solution which oxidises quickly on exposure to the air.

Tartrates of Lead.—The *monoplumbic* or *dibasic salt*, $C^4H^4Pb''O^6$, is a white crystalline precipitate, obtained by mixing nitrate or acetate of lead with tartaric acid. It is very soluble in nitric acid and in excess of tartaric acid; also in tartrate of ammonium, the concentrated solution solidifying to a gelatinous mass. When treated with chloride of acetyl, it yields chloride of lead and a thick yellowish syrup, which decomposes at 130°, with evolution of carbonic oxide and carbonic anhydride. (**Schützenberger**, Jahresb. 1861, p. 439.)

A *diplumbic* or *tetrabasic salt*, $C^4H^2\overset{''}{Pb}{}^2O^6$, is obtained by boiling an ammoniacal solution of the monoplumbic salt. (**Erdmann**, Ann. Ch. Pharm. xxi. 19.—**Heintz**, Zeitschr. Ch. Pharm. 1861, p. 17.)

Tartrates of Magnesium.—The *neutral salt*, $C^4H^4Mg''O^6.4H^2O$, is obtained in crystalline crusts, by evaporating a solution of magnesium-carbonate in tartaric acid. It dissolves in 122 pts. of water at 16°.—The *acid salt*, $C^8H^{10}Mg''O^{12}$ (crystallised), is formed in the preparation of the neutral salt when an excess of tartaric acid is used. It forms crystalline crusts, soluble in 52 pts. water at 16°.

Potassio-magnesic tartrate, $C^8H^8Mg''K^2O^6.4H^2O$, is obtained, in crystals, by boiling cream of tartar with water and carbonate of magnesium.—An *ammonio-magnesic salt* of corresponding composition is obtained in a similar manner.—The *sodio-magnesic salt*, $C^8H^8Mg''Na^2O^6.5H^2O$, is deposited, on evaporating a mixture of Rochelle-salt and carbonate of magnesium, in monoclinic prisms having the angles $\infty P : \infty P = 129°$; $oP : \infty P\infty = 103°$. Ammonia throws down from the solution of either of these salts a basic tartrate of magnesium, $C^4H^4Mg''O^6.Mg''O.2H^2O$, the formation of which interferes considerably with the use of tartaric acid in Otto's method of separating phosphoric acid from certain bases: hence citric acid is preferable for this purpose. (See Phosphoric Acid, iv. 547.)

Tartrate of Manganese.—A solution of neutral potassic tartrate, mixed with manganous chloride, first deposits acid tartrate of potassium, and then colourless crystals of manganous tartrate, which are decomposed by boiling water into a soluble acid salt and an insoluble basic salt. By dissolving manganous carbonate in cream of tartar, a very soluble salt is obtained, difficult to crystallise.

Tartrate, Mercuric.—White precipitate, insoluble in water, very soluble in weak nitric acid.

Ammonio-mercuric tartrate, obtained by boiling acid tartrate of ammonium with mercuric oxide, forms small prisms soluble in water.—*Tartrate of mercurammonium* is obtained, by digesting mercuric tartrate with ammonia, as a white powder insoluble in water. It appears also to be formed when mercuric oxide is heated with neutral tartrate of ammonium: the oxide then dissolves, with evolution of ammonia; and if an excess of it be used, a white compound separates; the filtered liquid, when concentrated, deposits needles, and, on addition of water, a white precipitate, containing $C^8H^{10}(N^2H^2\overset{''}{Hg}{}^3)''O^{12}.6H^2O$. (**Harff**, Brandes' Arch. v. 259.—**Burckhardt**, *ibid.* [2] xi. 257.)

Potassio-mercuric tartrate is obtained, in small slightly soluble prisms, by digesting mercuric oxide with cream of tartar.—When cream of tartar is boiled with chloride of mercurammonium (white precipitate), a large quantity of carbonic anhydride is evolved; the filtered liquid deposits, on evaporation, sparingly soluble salts containing mercury; and the mother-liquors yield needles, apparently consisting of the compound $4C^4H^5KO^6.Hg''Cl^2.6H^2O$.

Tartrate of Nickel.—Precipitated as a green crystalline powder, nearly insoluble in water, on saturating a boiling solution of tartaric acid with hydrate or carbonate of nickel. It dissolves easily in a hot solution of caustic potash or soda, or in sodic carbonate, the solution solidifying to a pasty mass on cooling. Nickel-salts mixed with tartaric acid are not precipitated by alkalis.

Tartrate of Nickel and Potassium, $C^8H^8Ni''K^2O^{12}$ (at 110°), is produced by heating carbonate of nickel with finely-pulverised cream of tartar and water. The resulting green solution is decomposed by boiling, but, when evaporated over oil of vitriol, it yields an apple-green crystalline powder, which effloresces in the air, and dissolves completely in water.

TARTRATE OF PALLADIUM.—Light-yellow precipitate, formed on mixing nitrate of palladium with an alkaline tartrate.

TARTRATES OF STRONTIUM.—The *neutral salt*, $C^4H^4Sr''O^6.4H^2O$, is deposited, on mixing a cold solution of potassic tartrate with nitrate of strontium, in monoclinic prisms, having the angle $oP : \infty P = 92° 35'$; $\infty P : \infty P = 125° 20'$ (De la Provostaye). It dissolves in 147 pts. of water at 16°, and is moderately soluble in solution of sal-ammoniac.—According to Marignac (Ann. Min. [5], xv. 280; Jahresb. 1859, p. 286), a solution of strontium-carbonate in excess of hot aqueous tartaric acid deposits the neutral salt on cooling in trihydrated crystals, $C^4H^4Sr''O^6.3H^2O$, having the form of monoclinic prisms, $\infty P\infty . [\infty P\infty] . oP . +P\infty . -P\infty$, in which ∞P occurs with only two faces, situated to the right when the crystal is placed with the clinodiagonal directed towards the observer, and the obtuse angle of the inclined axis to the front and above; also a face of $+P$ and a face of $-P$ to the left. Angle $\infty P\infty : \infty P = 140° 1'$; $oP : \infty P\infty = 102°$; $\infty P\infty : +P\infty = 123° 43'$; $\infty P\infty : -P\infty = 137° 32'$; $oP : +P = 128° 4'$; $oP : -P = 138° 20'$. The crystals do not give off any water at 100°.

Tartrate of Strontium and Ammonium, $C^8H^8Sr''(NH^4)^2O^6.12H^2O$, separates from the mother-liquor of the neutral strontium-salt, on neutralisation with ammonia, in thin rectangular laminæ, which are trimetric combinations, $\infty\breve{P}\infty . \infty P . \infty\breve{P}2 . \breve{P}\infty$, with four P-faces occurring hemihedrally. Angle $\infty\breve{P}\infty : \infty P = 124° 58'$; $\infty\breve{P}\infty : \breve{P}\infty = 124° 20'$; $\infty P : P = 140°$. (Marignac, *loc. cit.*).

Tartrate of Strontium and Potassium, $C^8H^8Sr''K^2O^{12}.2H^2O$, is obtained like the corresponding barium-salt (p. 680).—The *sodium-salt*, $C^8H^8Sr''Na^2O^{12}$ (after drying), is obtained, as a gummy very soluble mass, by saturating strontia-water with acid tartrate of sodium, and evaporating.

TARTRATE OF TIN. STANNOUS TARTRATE, $C^4H^4Sn''O^6$.—Prepared by pouring a boiling solution of tartaric acid into a concentrated solution of stannous acetate. It forms white microscopic crystals, consisting of prisms with rectangular base, soluble in cold water, more soluble and without decomposition in boiling water, still more in water acidulated with tartaric acid, the solution not being precipitated by ammonia. When strongly heated, it leaves a residue of stannic oxide.

By treating the acid tartrates of ammonium and potassium with stannous oxide, salts are formed which crystallise well, and appear to be perfectly stable in presence of water.

TARTRATE, URANOUS.—Tartaric acid throws down from uranous chloride a greyish-green precipitate, consisting of a basic salt, $2C^4H^4U''O^6.U''H^2O^2$, which is very soluble in hydrochloric acid, and is not precipitated by ammonia.

TARTRATES OF YTTRIUM.—The *neutral salt*, $C^4H^4Y''O^6.4H^2O$, is formed, on adding neutral tartrate of potassium to acetate of yttrium, as a bulky precipitate soluble in excess of the potassium-salt. Its solution in an equivalent quantity of tartaric acid deposits after a while a crystalline precipitate, insoluble in water, consisting of the *acid salt*, $C^8H^{10}Y''O^{12}$. (Popp, Jahresb. 1864, p. 205.)

TARTRATE OF ZINC.—Hot concentrated solutions of zinc-sulphate and neutral potassic tartrate, yield a yellowish-white crystalline precipitate, very slightly soluble in water, easily soluble in caustic potash or soda. Cream of tartar digested with excess of zinc or its oxide, forms a solution which deposits a white powder, and dries up to a gummy mass.

γ. *Tartrates containing Triatomic Metals and Metalloïds.*

TARTRATE OF ALUMINIUM.—This salt occurs in *Lycopodium clavatum*. Its solution, when evaporated, leaves a gummy non-deliquescent mass.

The solution of neutral potassic tartrate dissolves a large quantity of alumina without becoming alkaline; the liquid, on addition of alcohol, deposits oily drops, the aqueous solution of which dries up by evaporation to a gummy mass, containing both potash and alumina. Acid tartrate of potassium likewise dissolves alumina, forming an amorphous mass, which is not precipitated by alkalis.

TARTRATES OF ANTIMONY. (Respecting the several views of the constitution of these salts, see p. 676).—*Neutral antimonious tartrate*, $C^4H^4(SbO)^2O^6.H^2O$, is the white granular precipitate formed on adding alcohol to a solution of antimonious oxide in aqueous tartaric acid. It is insoluble in water, gives off its water of crystallisation at 100°, and an additional atom of water at 190°, leaving the salt $C^4H^2(SbO)''O^5$, analogous in composition to the first anhydride of tartaric acid.—*Acid antimonious tartrate*, $C^4H^5(SbO)O^6$, or $C^4H^4(SbO)^2O^6.C^4H^6O^6$ (?), appears to be formed on adding alcohol to the concentrated solution of the hyperacid salt. At 160° it gives off 1 at. water, leaving the salt $C^4H^3(SbO)O^5$.—The *hyperacid salt*, $C^4H^4(SbO)^2O^6.3C^4H^6O^6.5H^2O$, is deposited, after some time, from a syrupy solution of antimonious oxide in excess of tartaric acid, in large crystals derived from a right rectangular prism. It is very soluble in water, deliquesces in moist air, and gives off 23·1 per cent. water at 160°. (Péligot, Ann. Ch. Phys. [3] xx. 289.)

Ammonio-antimonious tartrate, $C^4H^4(NH^4)(SbO)O^6.\frac{1}{2}H^2O$, is produced by boiling antimonious oxide with solution of acid tartrate of ammonium. The filtered solution, evaporated to a stiff jelly, gradually yields rather large octahedral crystals belonging to the trimetric system, in which the axes $a : b : c = 0·8923 : 1 : 1·0801$. Angle P : P (brach.) = 110° 58′; P : P (macr.) = 101° 8′; P : P (basal) = 116° 42′. Ordinary combination, P . oP . 2P . ∞P, the P-faces being predominant, and four of them, so situated as to form by extension a rhombic sphenoïd, being more developed than the other four. Cleavage parallel to oP. The crystals are isomorphous with those of ordinary tartar-emetic, and more soluble than the latter. They effloresce on exposure to the air, and give off ammonia when heated a little above 100°.

When the octahedral crystals just described have been removed from the mother-liquor, this liquid yields, in a short time, fine prismatic crystals, much more efflorescent than the octahedral crystals, and containing $\frac{5}{2}$ at. water (15·3 per cent.), which they give off at 100°. These crystals are rhombic prisms, having the angle ∞P : ∞P = 127°, and hemihedral from having two only of the edges of each base replaced by the octahedral faces $\frac{P}{2}$, forming an angle of 85° 30′, and situated alternately on the two bases. (Pasteur.)

Potassio-antimonious tartrate, $C^4H^4K(SbO)O^6.\frac{1}{2}H^2O$. *Tartar-emetic. Tartarus emeticus. Tartarus stibiatus. Brechweinstein. Spiessglanzweinstein.*—This salt was known to the older chemists. It is generally said to have been discovered by Mynsicht (about 1631), but it had been previously mentioned by Basil Valentine, about the end of the fifteenth century. It is prepared by boiling 3 pts. antimonious oxide for about half an hour with 4 pts. cream of tartar, renewing the water as it evaporates, and filtering the solution while still hot. Instead of antimonious oxide, the oxychloride (algaroth-powder) or oxysulphide (glass of antimony) may be used.

Potassio-antimonious tartrate forms octahedral crystals isomorphous with the corresponding ammonium-salt, and exhibiting the same faces and direction of cleavage. Axes $a : b : c = 0·9556 : 1 : 1·054$. Angle P : P (brach.) = 108° 16′; P : P (macr.) = 104° 22′; P : P (basal) = 116°. Optical rotatory power $[\alpha]^j = +156° 2′$. Specific gravity of the crystals = 2·607 (Schiff); 2·588 (Buignet).

Tartar-emetic gives off part of its water of crystallisation on exposure to the air, the crystals then becoming opaque, and the whole at 100°. When heated to 200°, it gives off another atom of water, and leaves the salt $C^4H^2K(SbO)O^5$, analogous in constitution to the first anhydride of tartaric acid.

Tartar-emetic dissolves in 14·5 pts. of cold and 1·9 pt. of boiling water. The solution yields a crystalline precipitate with alcohol, reddens litmus, and has a nauseous metallic taste. It is used in medicine; from 5 to 10 centigrammes are sufficient to excite vomiting; in large doses it is poisonous. It is also used externally as an ingredient of pommades and plasters for the treatment of skin-diseases, chronic catarrh, &c.

Sulphuric, *hydrochloric*, and *nitric acids* form, with solution of tartar-emetic, white precipitates consisting of basic antimony-salts, soluble in excess of those acids, and in tartaric acid.—*Ammonia* forms, in the concentrated aqueous solution, a white precipitate of antimonious oxide insoluble in excess of ammonia.—*Potash* forms a similar precipitate, soluble in excess.—*Mercuric chloride* forms a precipitate of calomel.—*Sulphydric acid* throws down orange-red antimonious sulphide; *infusion of galls* throws down white flocks, and produces a cloud even in dilute solutions.

Tartar-emetic is reduced at a white heat, yielding an alloy of antimony and potassium, mixed with charcoal, which decomposes water with evolution of hydrogen, and, when brought in contact with a few drops of water, sometimes produces violent explosions.

An *acid potassio-antimonious tartrate*, $C^4H^4K(SbO)O^6.C^4H^6O^6.\frac{5}{2}H^2O$, is usually contained in the mother-liquors of ordinary tartar-emetic, and is likewise produced by mixing 9 pts. of the latter with 4 pts. of tartaric acid, and evaporating at a gentle heat. The solution first deposits crystals of common tartar-emetic, then (when it has attained a syrupy consistence) confused crystals of the acid salt, having the form of oblique rhomboïdal prisms, which effloresce on exposure to the air, and give off 9·22 per cent. water at 100°. Alcohol, added to the solution of this salt, throws down tartar-emetic, leaving tartaric acid in solution. (Knapp, Ann. Ch. Pharm. xxxii. 76.)

A compound of *tartar-emetic and cream of tartar*, $C^4H^4K(SbO)O^6.3C^4H^5KO^6$, is obtained by boiling equal weights of the two salts with water. On adding carbonate of potassium to the solution as long as effervescence takes place, and evaporating, mammellated groups of needles are obtained, resembling wavellite in appearance, and probably consisting of a compound of tartar-emetic with neutral tartrate of potassium. They are very soluble in water, and tartaric acid added to the solution throws down scales of the preceding salt. (Knapp.)

Potassio-antimonic tartrate, probably $C^8H^4K(SbO^2)O^6.\,xH^2O$, is prepared, like tartar-emetic, with antimonic oxide and cream of tartar. The solution, which is not precipitated by hydrochloric acid, dries up on evaporation to a gummy mass. (Geiger and Reimann, Mag. Pharm. xvii. 18.—Mitscherlich, Pogg. Ann. lxxiii. 396.)

Rubidio-antimonious tartrate, $C^4H^4Rb(SbO)O^6.\frac{1}{2}H^2O$.—Prepared like tartar-emetic. The solution, filtered at the boiling heat, first deposits crystalline crusts containing but little antimony (probably impure acid tartrate of rubidium), and, when further concentrated and left to itself, crystals of the double salt, isomorphous with tartar-emetic. (Grandeau, Ann. Ch. Phys. [3] lxvii. 155.)

Sodio-antimonious tartrate, $C^4H^4Na(SbO)O^6.\frac{1}{2}H^2O$, is prepared in the same manner as the potassium-salt. The crystals, which absorb moisture from the air, are trimetric, having the axes $a : b : c = 0·9217 : 1 : 1·08$. Angle $\infty P : \infty P = 85° 20'$; $\infty P : \infty\breve{P}\infty = 137° 20'$. Ordinary combination $\infty P \,.\, \infty\breve{P}\infty \,.\, \infty\bar{P}\infty \,.\, oP \,.\, \bar{P}\infty \,.\, \frac{1}{2}P\infty$.

Double Salts, analogous to Tartar-emetic, obtained by Precipitation.—The solution of tartar-emetic forms, with salts of barium, calcium, strontium, cadmium, lead, and silver, precipitates consisting of tartar-emetic in which the potassium is replaced by the other metal.—The *argentic salt* has the composition $C^4H^4Ag(SbO)O^6$.—The other salts are represented by the general formula $C^8H^8M''(SbO)^2O^{12}$.—The *barium-salt* is precipitated in white scales, containing 2 at. water, which they give off at 150°.—The *cadmium-salt*, $C^8H^8Cd''(SbO)^2O^{12}$ (at 100°), gives off 2 at. water at 200°, leaving the salt $C^8H^4Cd''(SbO)^2O^{10}$ (Schiff, Jahresb. 1857, p. 221).—A compound of *calcio-antimonious tartrate with calcic nitrate*, $4C^8H^8Ca''(SbO)^2O^{12}.Ca''N^2O^6.6H^2O$, crystallises from a solution of tartar-emetic mixed with excess of calcic nitrate, in trimetric combinations $oP \,.\, \infty\breve{P}\infty \,.\, \infty P \,.\, \breve{P}\infty \,.\, \frac{1}{2}\breve{P}\infty \,.\, \bar{P}\infty \,.\, \frac{P}{2}$ (sphenoïdally hemihedral), which, when oP and $\infty\breve{P}\infty$ are predominant, and ∞P and $\bar{P}\infty$ equally developed, present the appearance of quadratic forms with the faces ∞P and P predominating. Angle $\infty P : \infty P$ (brach.) $= 124° 6'$; $\bar{P}\infty : \bar{P}\infty$ (basal) $= 124° 40'$; $oP : \breve{P}\infty = 134° 39'$. The compound, when recrystallised, is partially decomposed, with separation of pulverulent calcio-antimonious tartrate (Marignac, Ann. Min. [5] xv. 280; Jahresb. 1859, p. 287).—*Strontio-antimonious tartrate*, $C^8H^8Sr''(SbO)^2O^{12}$, first prepared by Kessler, is obtained by dissolving pulverised tartar-emetic in a cold solution of excess of strontium-nitrate; and separates, on warming the liquid, in hexagonal combinations of ∞P with P, $2P$ or oP. Angle $P : P$ (terminal) $= 138° 26'$; $2P : 2P$ (terminal) $= 126° 48'$; $\infty P : P = 135° 12'$; $\infty P : 2P = 153° 36'$ (Marignac, *loc. cit.*). By digesting 1 pt. of strontium-nitrate with 2 pts. water and an excess of strontio-antimonious tartrate at 30°—35°, and leaving the filtrate to evaporate, large very soluble crystals are obtained, consisting of the compound $C^8H^8Sr''(SbO)^2O^{12}.Sr''N^2O^6.H^2O$, the solution of which deposits strontio-antimonious tartrate on boiling. (Kessler, Pogg. Ann. lxxv. 410.)

Double Salts of Antimonious Tartrate containing Organic Bases.—These salts are prepared by boiling the acid tartrates of the several bases with antimonious oxide, or the bases themselves with tartar-emetic.—The *berberine-salt*, $C^4H^4(C^{20}H^{18}NO^4)(SbO)O^6$, crystallises like wavellite, is very slightly soluble in cold water, and may be recrystallised without decomposition from alcohol (Stenhouse, Jahresb. 1863, p. 452).—The *brucine-salt*, $C^4H^4(C^{23}H^{27}N^2O)(SbO)O^6$, forms short very brittle crystals (Stenhouse, *ibid.* p. 447).—The *cinchonidine-salt* crystallises in prisms easily soluble in water and in alcohol (Hesse, *ibid.* 1865, p. 445).—The *morphine-salt* forms nodular groups of crystals, sparingly soluble in cold water, and decomposed by prolonged boiling with water (Decharme, *ibid.* 1853, p. 445).—The *strychnine-salt* forms brittle needles or laminæ, very slightly soluble in water. (Stenhouse.)

TARTRATES OF ARSENIC.—Arsenious and arsenic oxide dissolve in acid tartrates of alkali-metal, forming double salts analogous to tartar-emetic. (Mitscherlich, *Lehrbuch.*—Pelouze, Ann. Ch. Phys. [3] vi. 63.—Marignac, *loc. cit.*)

Ammonio-arsenious tartrate, $C^4H^4(NH^4)(AsO)O^6.\frac{1}{2}H^2O$, is prepared by boiling arsenious oxide for a long time with acid tartrate of ammonium, the filtered liquid first depositing crusts of the latter salt with a little arsenious oxide, and afterwards, when strongly concentrated, large efflorescent crystals of the double salt, which are trimetric combinations having the axes $a : b : c = 0{\cdot}8760 : 1 : 0{\cdot}6941$. Angle $P : P$ (brach.) = 122° 54′; $P : P$ (macr.) = 113° 52′; $P : P$ (basal) = 93°; $\infty P : \infty P$ (macr.) = 82° 26′; $2\breve{P}\infty : 2\breve{P}\infty$ (basal) = 108° 28′. Observed combination $\infty P . \infty\breve{P}\infty . P . 2\breve{P}\infty . oP$ (Marignac).—The corresponding *potassium-* and *sodium-salts* are obtained in like manner, but do not crystallise so well. Marignac obtained the potassium-salt in rhombic prisms of 92° 50′ with dihedral summits of 85° 10′, resting on the acute prismatic edges.

Potassio-arsenic tartrate, $C^4H^4K(AsO^2)O^6.\frac{5}{2}H^2O$, is obtained by adding 1 pt. of cream of tartar to a solution of rather more than 1 pt. arsenic oxide (As^2O^5) in 5 or 6 pts. of water, and raising the liquid to the boiling heat—or, better, mixing it with alcohol, the double salt then separating as a crystalline powder. It is very soluble in water, which however quickly decomposes it, liberating acid tartrate of potassium. It parts with its water of crystallisation at 100°, but does not give off any more water at higher temperatures without undergoing complete decomposition. (Pelouze.)

A compound of *strontio-arsenious tartrate* with *nitrate of ammonium*, $2C^8H^8Sr''(AsO)^2O^{12}.(NH^4)NO^3.12H^2O$, separates from a mixture of the component salts in large trimetric crystals, $\infty P . \infty\bar{P}2 . \infty\bar{P}\infty . \infty\breve{P}\infty . \breve{P}\infty . \frac{1}{2}\breve{P}\infty$. Angle $\infty P : \infty P$ (brach.) = 113° 58′; $\breve{P}\infty : \breve{P}\infty$ (brach.) = 113°. The form of the crystals resembles that of a dimetric or quadratic combination, in which $\infty\breve{P}\infty$ would form the end-face; but the crystals are not optically uniaxial. (Marignac.)

TARTRATES OF BISMUTH, $C^{12}H^{12}Bi^2O^{18}.6H^2O = Bi^2O^3.3C^4H^4O^5.6H^2O$.—When a hot concentrated solution of 4 pts. tartaric acid is added to a hot, moderately strong solution of 5 pts. bismuth-oxide in nitric acid, the mixture first remains limpid, but, when left at rest, deposits a considerable quantity of bismuth-tartrate in small crystals, forming a hard white crust at the bottom of the liquid; they must be washed with aqueous tartaric acid, as pure water decomposes them. (R. Schneider, Pogg. Ann. lxxxviii. 55.)

Tartrate of Bismuth and Potassium is produced by boiling a solution of cream of tartar with excess of bismuth-oxide, and is deposited, on concentrating the liquid, as a perfectly white powder, containing (at 100°) $C^4H^2K(BiO)O^5$, analogous therefore to tartar-emetic dried at 200°. (Schwarzenberg, Ann. Ch. Pharm. lxi. 244.)

TARTRATES OF BORON. (Meyrac, J. Pharm. iii. 8.—Soubeiran, *ibid.* iii. 399; xi. 560; xxxv. 241.—Soubeiran and Capitaine, *ibid.* xxv. 741.—Duflos, Schw. J. lxiv. 333.—Vogel, J. Pharm. iii. 1.—Robiquet, *ibid.* [3] xxi. 197.—Wackenroder, Arch. Pharm. [2] lviii. 4.—Wittstein, Repert. Pharm. [3] vi. 1, 177.—*On the optical characters of these salts:* Biot, Ann. Ch. Phys. [3] xi. 82.)—Tartaric acid forms, with boron and the alkali-metals, salts analogous to tartar-emetic, the group BO taking the place of hydrogen, or a metal, just like the group SbO.

Tartaric and boric acids, triturated together, form a mixture which appears to be a definite compound, inasmuch as it deliquesces in moist air—a property not exhibited either by tartaric or by boric acid alone. Boric acid also dissolves in water containing tartaric acid more easily than in pure water, the boric acid being, however, deposited on evaporation.

Boropotassic tartrate, $C^4H^4K(BO)O^6$ (at 100°)—also called *Borotartrate of potassium*, or *Soluble Cream of Tartar*—is obtained by evaporating to dryness, 1 pt. boric anhydride, 2 pts. cream of tartar, and 24 pts. of water, and treating the mass with alcohol, which takes up the excess of boric acid. It is a white amorphous mass, very soluble in water, but insoluble in alcohol. Mineral acids added to its solution, do not throw down either boric acid or cream of tartar. At 180° it gives off 1 at. water, leaving the salt $C^4H^2K(BO)O^5$, and behaves in other respects like tartar-emetic. Soluble cream of tartar is used in medicine as a purgative, and externally as a lotion for ulcers.

By boiling, for some hours, 1 pt. boric acid and 12 pts. cream of tartar with a large quantity of water, removing the deposit of cream of tartar which settles down on cooling, then evaporating to dryness, taking up the residue with a little cold water, removing the new deposit of cream of tartar (if any), repeating these operations till cold water no longer separates the latter salt, and finally treating the product with boiling alcohol, a salt is obtained, containing 11·4 per cent. of boric anhydride (B^2O^3), and apparently consisting of a compound of potassio-boric tartrate with cream of tartar, $C^4H^4K(BO)O^6.C^4H^5KO^6$.

Sodio-boric tartrate appears to be obtained in the same manner as the potassium-salt. Acid tartrate of sodium forms a gummy deliquescent salt with borax, also with borate of ammonium; 1 pt. borax and 3 pts. cream of tartar, dissolved together, yield on evaporation a gummy deliquescent salt, called *tartarised borax*, containing (according to Duflos and Vogel) 3·6 per cent. borax, and agreeing with the formula $2C^4H^4K(BO)O^6.C^4H^4Na(BO)O^6.6H^2O$.

Calcio-boric tartrate is formed, in combination with tartrate of calcium, by precipitating a solution of cream of tartar neutralised with ammonia, with chloride of calcium.

TARTRATES OF CHROMIUM.—The solution of chromic hydrate in tartaric acid dries up to a violet mass, probably consisting of neutral chromic tartrate.

Potassio-chromic tartrate, or *Chromotartrate of potassium*, $C^4H^4K(CrO)O^6 . \frac{1}{2}H^2O$, is formed on adding pulverised tartaric acid to a hot aqueous solution of potassic dichromate, as long as carbonic acid continues to be evolved; it is precipitated by alcohol from its dark-green aqueous solution. The same solution, mixed with a strong solution of neutral potassic tartrate, deposits dark-green crystalline grains, containing 1 at. potash (K^2O) to 3 at. chromic oxide. Potassio-chromic tartrate forms, with acetate of lead, a bluish-green precipitate, which, when, decomposed by sulphuretted hydrogen, yields a tartrate of chromium, probably consisting of chromotartaric acid, $C^4H^3(CrO)O^6$. (Berlin, *Berz. Lehrbuch.*—Malaguti, Compt. rend. xvi. 457.—Lœwel, *ibid.* xvi. 862.)

TARTRATES OF IRON (*ferricum*).—Tartaric acid dissolves recently precipitated ferric hydrate, and the solution, evaporated below 50°, yields an amorphous mass, apparently consisting of ferric tartrate. The solution, which is not precipitated by alkalis, probably contains originally normal ferric tartrate, $C^{12}H^{12}\overset{'''}{Fe}{}^2O^{18}$, which is resolved, on evaporation, into a basic and an acid salt, the latter being partly converted, by the prolonged action of warmth and light, into ferrous tartrate, which remains in solution mixed with free tartaric acid; this acid is, however, partially oxidised at the same time. (Ludwig, Jahresb. 1861, p. 434.)

Ammonio-ferric tartrate, $C^4H^4(NH^4)(FeO)O^6 + 4$ to $5H^2O$, is obtained by dissolving recently precipitated ferric hydrate in acid tartrate of ammonium, and evaporating, in garnet-coloured scales, soluble in rather more than 1 pt. of water. The solution is precipitated by alcohol.

Potassio-ferric tartrate, $C^4H^4K(FeO)O^6$ (at 100°).—This salt, which constitutes the essential part of the *Tartarus chalybeatus* or *Mars solubilis*, and the *Globuli martiales* of the pharmacopœias, is prepared by digesting cream of tartar with water and recently precipitated ferric hydrate, or with iron filings in a vessel exposed to the air; in either case, however, the product is frequently contaminated with ferrous salt. Pure potassio-ferric tartrate forms shining scales of a brown or nearly black colour, exhibiting a fine red tint by transmitted light. The salt decomposes at 150°, giving off water and carbonic acid. Acids precipitate from its solution a basic ferric salt, soluble in excess of the acid. (*Gmelin's Handbook*, x. 316.)

Rubidio-ferric tartrate is formed by boiling ferric oxide with acid tartrate of rubidium, and separates on evaporation in right rhombic prisms with hemihedral faces. (Grandeau, Jahresb. 1863, p. 184.)

TARTRATES OF URANYL, OR URANIC TARTRATES. *Neutral Uranic Salt*, $C^4H^4(UO)^2O^6 + H^2O$ and $4H^2O$.—The yellow solution of uranic oxide in tartaric acid yields, by concentration, crystals containing 1 at. water, and by spontaneous evaporation in a vacuum, crystals containing 4 at. water. The last give off 3 at. water at 150°: the salt does not experience any further loss by drying at 200° (Péligot, Ann. Ch. Phys. [3] xii. 463).—Uranic salts are precipitated by alkalis, even when mixed with tartaric acid. (H. Rose.)

Antimonio-uranic tartrate, $C^4H^4(SbO)(UO)O^6.4H^2O$, is obtained, in yellow silky needles, on mixing the aqueous solutions of tartar-emetic and uranic nitrate, and redissolving the gelatinous precipitate in boiling water. This salt, when dried at 100°, exhibits the composition $C^4H^2(SbO)(UO)O^5$, analogous to that of the first anhydride of tartaric acid. (Péligot.)

ACIDS ISOMERIC WITH TARTARIC ACID.

Racemic or Paratartaric Acid has been already described (p. 34).

Inactive Tartaric Acid, or **Mesotartaric Acid.**—This is a modification of tartaric acid, inactive to polarised light, but differing from racemic acid in not being separable into dextro- and lævo-tartaric acids. It is obtained, as above mentioned (p. 672), by heating racemate or tartrate of cinchonine to 170° for several hours. On dissolving the product in water, adding chloride of calcium, filtering immediately from the racemate of calcium which separates out, and leaving the filtrate to itself, the calcium-salt of inactive tartaric acid separates out. The acid crystallises well, and most of its salts are quite equal in beauty to the corresponding tartrates and racemates. (Pasteur, Ann. Ch. Pharm. lxxxviii. 212.)

The inactive tartaric acid prepared from dibromosuccinic acid is probably the same modification.

Mesotartaric acid, obtained by Dessaignes (Compt. rend. lv. 769; Jahresb. 1862, p. 305), together with dextrotartaric, racemic, and aposorbic acids, by oxidising sorbin with nitric acid, also by boiling tartaric or racemic acid for a long time (at least 400 hours) with hydrochloric acid, appears also, from comparative experiments of Pasteur (Bull. Soc. Chim. 1862, p. 107), to be identical with inactive tartaric acid.

a. It is separated from the oxidation-products of sorbin by first removing the tartaric and racemic acid as acid ammonium-salts, precipitating the acid filtrate with chloride of calcium, and decomposing the calcium-salt with sulphuric acid.—*β*. In preparing it from tartaric acid, the greater part of the unaltered tartaric acid, and a certain quantity of racemic acid, likewise formed in the reaction, must first be removed by crystallisation, the hydrochloric acid expelled by evaporation over the water-bath, and the remaining liquid half neutralised with ammonia, whereby nearly all the tartaric acid is precipitated as acid ammonium-salt. The filtrate, when concentrated, yields large well-defined crystals of acid mesotartrate of ammonium.—*γ*. In preparing it from racemic acid, the unaltered racemic acid is removed by crystallisation, the hydrochloric acid expelled by evaporation, the remaining liquid half neutralised with ammonia, and then precipitated with acetate of calcium.

Mesotartaric acid is very soluble in water (10 pts. dissolving in 8 pts. of water at 15°). It usually crystallises in rectangular plates containing 1 at. water of crystallisation: $C^4H^6O^6.H^2O$. These crystals effloresce in a vacuum, and give off their water of crystallisation at 100°. If the residue be then dissolved in water, and the solution evaporated to the crystalline point, large anhydrous crystals are obtained, resembling those of ordinary tartaric acid. The solution of these crystals, however, if left to itself, gradually yields the hydrated acid.

Mesotartaric acid melts at 140°; at 200° it is partly decomposed, giving off pyrotartaric acid; the remaining portion is partly converted into racemic acid. It is also transformed into racemic acid by prolonged boiling with hydrochloric acid. (Dessaignes, Bull. Soc. Chim. 1865, i. 34; Jahresb. 1865, p. 393.)

The mesotartrates for the most part resemble the tartrates, but the acid ammonium- and potassium-salts are moderately soluble in water, and the acid does not precipitate a solution of gypsum.—The *calcium-salt*, $C^4H^4Ca''O^6.4H^2O$, dissolves in hydrochloric acid, and is precipitated from the solution by ammonia; it also reacts with potash in the same way as tartrate of calcium.—The *lead-salt* contains $C^4H^4Pb''O^6.H^2O$; the *silver-salt*, $C^4H^4Ag^2O^6.H^2O$.

Metatartaric Acid. This isomer of tartaric acid, discovered in 1831 by Braconnot (Ann. Ch. Phys. [2] lxviii. 299), and further examined by Erdmann (Ann. Ch. Pharm. xxi. 9), and by Laurent and Gerhardt (*ibid.* lxx. 848), is produced by quickly heating tartaric acid to 170°—180°, and keeping it at that temperature till completely fused. The product is a transparent gummy mass, which gradually becomes opaque and crystalline. If the heat be continued longer, ditartaric acid is also produced.

Metatartaric acid is deliquescent. While still hot and liquid, it turns the plane of polarisation strongly to the right; but as it cools and solidifies, the dextrorotatory power becomes weaker, and at 3·5° perceptible lævorotation is produced.

The metatartrates have the same composition as the tartrates, but are for the most part distinguished from them by their crystalline forms, and by greater solubility. By boiling their aqueous solutions, they are gradually converted into tartrates.

The *acid ammonium-salt*, $C^4H^5(NH^4)O^6$, separates from very concentrated solutions in groups of microscopic needles, usually exhibiting the form of spindles, somewhat thickened in the middle. It is more soluble than the acid tartrate, and is further distinguished therefrom by not giving any precipitate with chloride of calcium. Its solution, saturated with ammonia, is precipitated by chloride of calcium only when highly concentrated; and the crystalline *metatartrate of calcium* thus obtained, $C^4H^4Ca''O^6.4H^2O$, is distinguished from the tartrate by the form of its crystals, which appear, under the microscope, as irregular lenticular grains, or small prisms unsymmetrical at the two ends, whereas the tartrate forms small often elongated octahedrons. Metatartrate of calcium gives off half its water of crystallisation at 160°, and the rest at 230°. When once deposited in the crystalline state, it dissolves but very slowly in boiling water, being at the same time converted into tartrate; but it dissolves easily in cold water, especially if slightly acidulated with nitric or hydrochloric acid. The liquid neutralised with ammonia again, after a while, deposits metatartrate of calcium, with its characteristic crystalline form; but if the metatartrate dried at 220° be dissolved in hydrochloric acid, the solution, neutralised with ammonia, yields octahedral crystals of calcic tartrate. (Laurent and Gerhardt.)

Acid metatartrate of potassium, $C^4H^5KO^6$, resembles the acid tartrate in appearance and in its reactions. On neutralising metatartaric acid with potash, and adding alcohol, a limpid oil is precipitated, which crystallises slowly, in the form of neutral potassic tartrate, and the solution of which yields with calcium-salts octahedral crystals of calcic tartrate.

Glycotartaric Acid, $C^4H^6O^6$. (A. Schöyen, Ann. Ch. Pharm. cxxxii. 168.)—Glyoxal, $C^2H^2O^2$, unites with 2 at. hydrocyanic acid, forming a black amorphous substance, which, when heated with alkalis, gives off ammonia, and is converted into glycotartaric acid. This acid is deliquescent, alterable at 100°, and, when more strongly heated, gives off the same odour as tartaric acid.

The glycotartrates of the *alkali-metals*, even the acid potassium-salt, are easily soluble, and their solutions are precipitated by chloride of barium, chloride of calcium, acetate of lead, and nitrate of silver.—The *barium-salt* contains $C^4H^4Ba''O^6.H^2O$; the *lead-salt*, $C^4H^4Pb''O^6.H^2O$.

Acids derived from Tartaric Acid by substitution of Acid Radicles for the Alcoholic Hydrogen.

Diacetotartaric Acid, $C^8H^{10}O^8 = \left.\begin{matrix}(C^2H^3O)^2\\(C^4H^2O^2)^{iv}\\H^2\end{matrix}\right\}O^4$, and **Diacetotartaric Anhydride,** $C^8H^8O^7 = \left.\begin{matrix}(C^2H^3O)^2\\(C^4H^2O^2)^{iv}\end{matrix}\right\}O^3$. (Ballik, Wien. Akad. Ber. xxix. 26.—Pilz, *ibid.* xliv. [2] 7; Jahresb. 1861, p. 368.—Perkin, Chem. Soc. Qu. J. xx. 149).—The anhydride is produced by heating pulverised tartaric acid with chloride of acetyl:

$$C^4H^6O^6 + 2C^2H^3OCl = C^8H^8O^7 + 2HCl + H^2O.$$

It is a tough crystalline solid, melting at 126°—127° C. When distilled, it undergoes a considerable amount of decomposition, especially if the distillation be carried on slowly. It boils above 250° C, but no fixed point can be obtained, acetic anhydride coming over during the distillation, as well as other products, some of which affect the eyes like acrolein; a residue of carbon is left in the retort. If heated gently, it sublimes in beautiful but small prisms. It is slightly soluble in benzene, and crystallises from this solvent in slender white needles. It also crystallises from acetic anhydride. (Perkin.)

Diacetotartaric acid, $C^8H^{10}O^8 = C^8H^8O^7.H^2O$, is formed by the direct combination of the anhydride with water. The aqueous solution, evaporated in a vacuum, leaves the acid as a transparent, gummy, deliquescent substance, having a very acid taste. When strongly heated, it decomposes, without previous formation of the anhydride. Heated with caustic potash or soda, it is resolved into tartaric and acetic acids:

$$C^8H^{10}O^8 + 2H^2O = C^4H^6O^6 + 2C^2H^4O^2.$$

Diacetotartaric acid is dibasic, forming acid and neutral salts; they are all very soluble, and somewhat difficult to obtain pure; they are prepared by dissolving the several carbonates in the aqueous acid.

The *neutral potassium-* and *sodium-salts* are very deliquescent.—The *acid potassium-salt*, $C^8H^9KO^8$, is a crystalline powder, very soluble, but not deliquescent; it has an acid taste, and reddens litmus powerfully.—The *barium-salt*, $C^8H^8Ba''O^8$, crystallises from a syrupy solution, in slender deliquescent needles, sometimes half an inch long.—The *calcium-salt*, $C^8H^8Ca''O^8$, dries up, on evaporation, to an opaque, friable, deliquescent mass.—The *cupric salt*, $C^8H^8Ca''O^8$, forms blue crystals.—The *mercurous salt* is a gelatinous precipitate, soluble in acetic acid.—The *silver-salt*, $C^8H^8Ag^2O^8$, is a white crystalline mass, very slowly acted upon by light. (Perkin.)

Paratartaric (*racemic*) *acid*, heated with chloride of acetyl, yields diacetoparatartaric anhydride, as a beautiful crystalline body, isomeric with diacetotartaric anhydride, which it resembles in melting-point and other properties. In contact with water, it yields diacetoparatartaric acid, which is resolved by heating with alkalis into acetic and paratartaric acids. (Perkin.)

Benzotartaric Acid, $C^{11}H^{10}O^7 = \left.\begin{matrix}H.C^7H^5O\\(C^4H^2O^2)^{iv}\\H^2\end{matrix}\right\}O^4$. (Dessaignes, J. Pharm. [3]

xxxii. 47; Jahresb. 1847, p. 307.)—Produced by heating 1 at. tartaric acid and 1 at. benzoic acid to 150° in a sealed tube:

$$C^4H^6O^6 + C^7H^6O^2 = H^2O + C^{11}H^{10}O^7.$$

A brown liquid is thereby formed, which, when dissolved in hot water, deposits benzoic acid; the residue, left on evaporating the mother-liquor to dryness, dissolves partially in carbonate of sodium; and the solution, decolorised with charcoal and slightly supersaturated with hydrochloric acid, deposits benzotartaric acid, in warty groups of microscopic crystals (Dessaignes). It is also formed, together with ethylbenzotartaric acid, by the action of dilute alcoholic potash on benzotartaric ether, and remains in the mother-liquor after the ethylbenzotartaric acid has separated out. (Perkin, p. 695.)

Benzotartaric acid is more soluble than benzoic acid in water, but less soluble in alcohol. It remains unaltered at the temperature at which benzoic acid melts and sublimes: at a higher temperature, it melts and gives off benzoic acid, the residue turning brown, and emitting the odour of burnt tartar. A cold saturated solution of the acid forms no precipitate with ferric chloride, lime-water, or silver-nitrate, but a slight precipitate with basic acetate of lead. When saturated with ammonia, it forms a pale-yellow precipitate with ferric chloride, none with chloride of calcium. In a solution of the acid one-fourth saturated with ammonia, nitrate of silver forms a white precipitate, consisting of *argentic benzotartrate*, $C^{11}H^8Ag^2O^7$.

Dibromotartaric Acid, $C^4H^4Br^2O^6$, is formed by the action of bromine, at 100°, on bromomaleic acid (iii. 788); probably thus:

$$C^4H^3BrO^4 + Br^4 + 2H^2O = 3HBr + C^4H^4Br^2O^6.$$

It is very deliquescent. (Kekulé, Jahresb. 1861, p. 363.)

Nitrotartaric Acid, $C^4H^4N^2O^{10} = \left.\begin{matrix}(NO^2)^2\\(C^4H^2O^2)^{iv}\\H^2\end{matrix}\right\}O^4$. (Dessaignes, Ann. Ch. Pharm. lxxxii. 362; lxxxix. 339.)—This acid is formed by adding 1 pt. of pulverised tartaric acid to 4½ pts. of very strong nitric acid; then adding, with stirring, an equal volume of strong sulphuric acid; pressing the pasty mass between porous tiles; dissolving it in a small quantity of lukewarm water; cooling to 0°, and pressing the crystals between paper.

Nitrotartaric acid dissolves in absolute alcohol, and remains, on spontaneous evaporation, in distinct prisms. It is optically active, like tartaric acid (Chautard). It is very unstable, its aqueous solution, even at a few degrees above 0°, continually giving off nitric oxide and carbonic anhydride. By spontaneous evaporation, it yields tartronic acid (p. 698), and, when heated to 40°—50°, oxalic acid.—By *sulphide of ammonium* it is reconverted into tartaric acid.

The nitrotartrates have not been much examined.—The *acid ammonium-salt*, $\left.\begin{matrix}H\\NH^4\end{matrix}\right\}C^4H^2(NO^2)^2O^6$, forms small, very soluble crystals.—The *neutral ammonium-salt* yields, with nitrate of silver, an easily soluble silver-salt, containing $Ag^2C^4H^2(NO^2)^2O^6$.

TARTARIC AMIDES. See TARTRAMIC ACID and TARTRAMIDE.

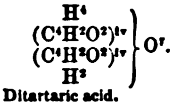
TARTARIC ANHYDRIDES. Since tartaric acid contains four atoms of replaceable hydrogen, it should be capable of yielding two anhydrides, by the loss of H^2O and $2H^2O$ respectively: thus—

$$\underset{\text{Tartaric acid.}}{\left.\begin{matrix}(C^4H^2O^2)^{iv}\\H^4\end{matrix}\right\}O^4.} \qquad \underset{\text{First anhydride.}}{\left.\begin{matrix}C^4H^2O^2)^{iv}\\H^2\end{matrix}\right\}O^3.} \qquad \underset{\text{True anhydride.}}{(C^4H^2O^2)^{iv}.O^2.}$$

But as the four typic hydrogen-atoms of tartaric acid are not all of the same character (two being alcoholic and two basic), it is further possible that the first anhydride may exhibit three isomeric modifications, according as the alcoholic or basic hydrogen-atoms of the acid are eliminated in its formation: thus—

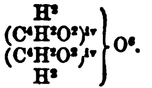
$$\underset{\text{Dibasic acid.}}{\left.\begin{matrix}(C^4H^2O^2)^{iv}\\H^2\end{matrix}\right\}O^3.} \qquad \underset{\text{Monobasic acid.}}{\left.\begin{matrix}H\\(C^4H^2O^2)^{iv}\\H\end{matrix}\right\}O^3.} \qquad \underset{\text{Neutral anhydride.}}{\left.\begin{matrix}H^2\\(C^4H^2O^2)^{iv}\end{matrix}\right\}O^3.}$$

Further, two or more molecules of tartaric acid may unite together in giving up water, thereby producing compounds analogous to the polyethylenic alcohols (ii. 570), the polyglycerins (ii. 894), and the polylactic acids (iii. 461). The simplest, and therefore the most probable of these compounds, would be ditartaric acid, which, by further elimination of water, might yield corresponding anhydrides: thus—



$$\left.\begin{matrix}H^4\\(C^4H^2O^2)^{iv}\\(C^4H^2O^2)^{iv}\\H^2\end{matrix}\right\}O^7.$$

Ditartaric acid.



$$\left.\begin{matrix}H^2\\(C^4H^2O^2)^{iv}\\(C^4H^2O^2)^{iv}\\H^2\end{matrix}\right\}O^6.$$

Ditartaric anhydride.

All these compounds might possibly be produced by the action of heat upon tartaric acid. Only a few of them have, however, been actually obtained; and, moreover, the statements of different chemists, who have investigated the decompositions of tartaric acid by heat, do not quite agree. (See especially Braconnot, Ann. Ch. Pharm. ii. 315.—Frémy, *ibid.* xix. 197; xxix. 142; lxxviii. 297.—Erdmann, *ibid.* xxi. 9.—Laurent and Gerhardt, *ibid.* lxx. 348.) But, as already observed (p. 675), it appears most probable that the first effect of heat on tartaric acid is to convert it into the isomeric compound, metatartaric acid; and that afterwards, by successive elimination of water, there are formed—first, ditartaric acid, then a soluble modification of the first anhydride, $C^4H^4O^5$, called by Frémy tartrelic acid; and, finally, the neutral insoluble modification of the same anhydride. The true anhydride of tartaric acid, $C^4H^2O^2.O^2$, is not known. (Kekulé, *Lehrbruch*, ii. 199.)

Ditartaric Acid, $C^8H^{10}O^{11} = 2C^4H^6O^6 - H^2O$.—This acid (called *Tartralic acid* by Frémy, *Isotartaric acid* by Laurent and Gerhardt) is produced by melting tartaric acid, and keeping it at a temperature of 170°, till it no longer gives a precipitate of calcic tartrelate with lime, or with calcic acetate (Frémy); also by adding tartaric anhydride to melting tartaric acid (Schiff, Zeitschr. Ch. Pharm. 1862, p. 375). It is very soluble in water, and not crystallisable. Its salts, $C^8H^9M'O^{11}$ and $C^8H^8M''O^{11}$, even the calcium-salt, are also very soluble in water, and are precipitated by alcohol in the form of syrup or of bulky flocks. By boiling with water, they are converted, first into acid metatartrates, and then into tartrates.

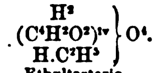
Gerhardt (*Traité*, ii. 15, 51) regards tartralic acid as isomeric with tartaric and metatartaric acids, on the ground that tartaric acid may be converted into it without loss of weight, even in presence of water. According to this view, the composition of the tartralates, which are neutral, is the same as that of the acid tartrates and metatartrates; but analysis shows that the composition of these salts agrees more nearly with the formula of the ditartrates above given.

Tartrelic Acid, $C^4H^4O^5 = C^4H^6O^6 - H^2O$. *Soluble Tartaric Anhydride.*—Obtained by quickly heating small quantities of tartaric acid till the fused mass swells up. It is a yellowish, tumefied, deliquescent mass, which dissolves in water, forming an acid solution.

Chloride or acetate of calcium added to this solution, throws down *tartrelate of calcium*, $C^8H^6Ca''O^{10}$, as a syrupy mass, which is insoluble in water, and becomes crystalline by contact with alcohol. The *barium-* and *strontium-salts*, which are similar in composition, and prepared in like manner, are also syrupy masses, insoluble in water. Tartrelic acid, heated with lead-oxide to 150°, yields a *lead-salt* containing $C^4H^4Pb''O^5$.—In contact with *alkalis*, it forms tartralates or ditartrates. By boiling with water, it is converted, first into metatartaric, then into tartaric acid.

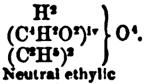
Insoluble Tartaric Anhydride, $C^4H^4O^5$, is formed by heating tartaric acid for some time to 150°, exhausting the product with cold water, and drying it in a vacuum. It is a white powder, insoluble in water, alcohol, and ether; and is converted by water, slowly in the cold, quickly on boiling, into tartaric acid. (Frémy.)

TARTARIC ETHERS. Tartaric acid, like other dibasic acids, forms, with monatomic acids, both acid and neutral ethers, the former of which are monobasic acids; *e.g.*:



$$\left.\begin{matrix}H^2\\(C^4H^2O^2)^{iv}\\H.C^2H^5\end{matrix}\right\}O^4.$$

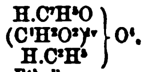
Ethyltartaric acid.



$$\left.\begin{matrix}H^2\\(C^4H^2O^2)^{iv}\\(C^2H^5)^2\end{matrix}\right\}O^4.$$

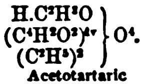
Neutral ethylic tartrate.

The two alcoholic hydrogen-atoms in these ethers are also replaceable by acid-radicles, forming compounds like the following:



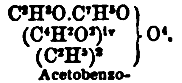
$$\left.\begin{matrix}H.C^7H^5O\\(C^4H^2O^2)^{iv}\\H.C^2H^5\end{matrix}\right\}O^4.$$

Ethylbenzotartaric acid.



$$\left.\begin{matrix}H.C^2H^3O\\(C^4H^2O^2)^{iv}\\(C^2H^5)^2\end{matrix}\right\}O^4.$$

Acetotartaric ether.



$$\left.\begin{matrix}C^2H^3O.C^7H^5O\\(C^4H^2O^2)^{iv}\\(C^2H^5)^2\end{matrix}\right\}O^4.$$

Acetobenzotartaric ether.

Closely related to these ethers are also certain dibasic acids, derived from tartaric acid by the substitution of acid-radicles for one or both of its alcoholic hydrogen-atoms (p. 689); *e.g.*:

$$\left.\begin{matrix} H.C^7H^5O \\ (C^4H^2O^2)^{iv} \\ H^2 \end{matrix}\right\} O^4. \qquad \left.\begin{matrix} (C^2H^3O)^2 \\ (C^4H^2O^2)^{iv} \\ H^2 \end{matrix}\right\} O^4. \qquad \left.\begin{matrix} (NO^2)^2 \\ (C^4H^2O^2)^{iv} \\ H^2 \end{matrix}\right\} O^4.$$

Benzotartaric acid. Diacetotartaric acid. Dinitrotartaric acid.

The constitution of these compounds shows that tartaric acid may be regarded as a diatomic alcohol, as well as a dibasic acid.

The acid tartaric ethers are formed by the direct action of tartaric acid on the alcohols; the neutral ethers by passing hydrochloric acid gas into a solution of the acid in the respective alcohols. The derivatives of these ethers containing acid radicles, are formed by treating them with alcoholic chlorides.

A few ethers are also known, produced by the action of tartaric acid on polyatomic alcohols.

Neutral Tartaric Ethers, containing Monatomic Alcohol-radicles.

Ethylic Tartrate, or **Tartaric Ether,** $C^8H^{14}O^6 = C^4H^4(C^2H^5)^2O^6$. (Demondesir, Ann. Ch. Pharm. lxxx 301.)—This ether is a liquid which acts on polarised light. It bears a somewhat high temperature without decomposition, but, when heated to a certain point, gives off considerable quantities of pyrotartaric acid. It mixes in all proportions with *water*, *alcohol*, and common *ether*.—With *ammonia* it yields tartramic acid or tartramide, according to the time for which the action is continued.

Tartaric ether is decomposed by *sodium*, with evolution of hydrogen; the action is slow, on account of the viscidity of the ether, but may be made to go on very rapidly, by mixing it with five or six times its volume of anhydrous benzene. On separating the excess of sodium, and evaporating, a pale yellowish-brown, uncrystalline, but friable residue, is obtained, probably consisting of sodiotartaric ether—$\left.\begin{matrix} H.Na \\ C^4H^2O^2 \\ (C^2H^5)^2 \end{matrix}\right\} O.$

By the continued action of the sodium, a gelatinous product is also formed, probably disodiotartaric ether, $\left.\begin{matrix} Na^2 \\ C^4H^2O^2 \\ (C^2H^5)^2 \end{matrix}\right\} O^4.$ (Perkin.)

Acetotartaric Ether, $C^{10}H^{16}O^7 = C^4H^3(C^2H^3O)(C^2H^5)^2O^6$. (Perkin, Chem. Soc. J. xx. 145.)—Produced by the action of acetylic chloride on an equivalent quantity of tartaric ether; the action takes place at ordinary temperatures, large quantities of hydrochloric acid being evolved, and the mixture becoming hot. The oily product is purified by agitating it with water, dissolving in ether, agitating the ethereal solution with dry carbonate of sodium, filtering, and evaporating to dryness over the water-bath.

Acetotartaric ether is an oily liquid, having about the consistence of olive-oil, heavier than water, and slightly soluble therein, but quite insoluble in saline solutions. It is perfectly neutral to test-paper, and has a rather bitter taste. When somewhat strongly heated in a retort, it decomposes, giving off acetic acid: at about 287°, an oil passes over, and finally a carbonaceous residue is left. It is decomposed by aqueous ammonia, the solution, when evaporated, yielding a yellowish syrupy product, having a bitter and slightly burning taste. Heated with *chloride of benzoyl*, it gives off hydrochloric acid, and forms a thick colourless oil, probably benzacetotartaric ether.

Acetotartaric ether is rapidly decomposed by *sodium*, especially when diluted with benzene, hydrogen-gas being evolved, and a transparent gummy substance formed, probably consisting of sodacetotartaric ether, $C^4H^2Na(C^2H^3O)(C^2H^5)^2O^6$.

Diacetotartaric Ether, $C^{12}H^{18}O^8 = C^4H^2(C^2H^3O)^2(C^2H^5)^2O^6$. (Perkin, Chem. Soc. J. xx. 147.)—Produced by treating 1 at. tartaric ether with 2 at. chloride of acetyl, and, after the reaction has abated, heating the product for a short time to 100° in a sealed tube. When purified like the preceding, it solidifies to a beautiful crystalline mass, which may be separated from a small quantity of oily acetotartaric ether by strong pressure between bibulous paper, and then crystallised from water.

Diacetotartaric ether dissolves in all proportions in *alcohol* and common *ether*, and is precipitated from its alcoholic solution by water. When it is boiled with water, a considerable quantity dissolves, and the solution, on cooling, deposits it in splendid prismatic crystals more than 1½ inch long. It is slightly soluble in cold water, but on the addition of a strong solution of chloride of sodium, the liquid becomes cloudy, and the diacetotartaric ether crystallises out on standing.

Diacetotartaric ether melts to a colourless oil at 67°, and does not resolidify on cooling; but as soon as a small particle of the solid product is thrown into it, it begins to crystallise in tufts of needles, and in a few moments becomes perfectly solid. During crystallisation, it evolves heat sufficient to become quite hot to the hand. When strongly heated, it distils with only slight decomposition. It boils between 294° and 298°.

Diacetotartaric ether is not quickly decomposed by *aqueous potash*, or by cold *alcoholic ammonia.* It is scarcely acted upon by *sodium*, either in the fused state, or when dissolved in benzene.

Paratartaric (*racemic*) *ether* treated with chloride of acetyl yields acetoparatartaric and diacetoparatartaric ether, isomeric with the tartaric ethers just described. Monacetoparatartaric ether is a colourless oil. Diacetoparatartaric ether is a solid body, melting at 50·5°, boiling at about 298°, and distilling with slight decomposition. It dissolves in alcohol or ether in all proportions. It is deposited from its boiling aqueous solution, on cooling, in small tufts of needles, and, after long standing, sometimes forms short but very brilliant prisms on the sides of the vessel.

Benzotartaric Ether, $C^{15}H^{18}O^7 = C^4H^3(C^7H^5O)(C^2H^5)^2O^6$. (Perkin, Chem. Soc. J. xx. 139.)—Produced by heating chloride of benzoyl with a slight excess of tartaric ether to 100° for two or three hours. When purified, like the preceding compound, by agitation with carbonate of sodium, solution in ether, &c., it forms a viscid transparent oil, which, on standing (especially under water) for two or three weeks, is almost wholly converted into a mass of colourless prismatic crystals, which may be freed from oil by pressure.

Benzotartaric ether, when pure, is a white inodorous solid, heavier than water, and easily pulverised. It melts at 64°, and cools to a viscid oil, which does not solidify until it has stood for some considerable time; but the introduction of a minute piece of the solid product immediately causes it to commence crystallising; and this takes place with a very considerable elevation of temperature. It crystallises in transparent prisms. If strongly heated, it distils with decomposition. It is soluble in all proportions in *alcohol* and *ether*; slightly soluble in boiling *water*, the solution becoming milky and depositing oily drops on cooling; afterwards beautiful but small prismatic crystals separate. Its aqueous solution has a slightly bitter taste. Its solutions do not change the colour of litmus-paper.—Aqueous *potash* appears to be without action upon it. With *sodium* it liberates hydrogen, and appears to form a sodium-compound. When heated in a sealed tube to 100° with alcoholic *ammonia*, it slowly decomposes, and is apparently converted into benzoic acid, tartramide, benzotartramide, and alcohol.

Alcoholic potash quickly decomposes benzotartaric ether, yielding, if in excess, tartaric and benzoic acids; but if dilute solutions are used, and the quantity of potash present is not sufficient to produce complete decomposition, benzotartaric and ethylbenzotartaric acids are produced (p. 695). The formation of these products is represented by the following equations:

$$\underset{\text{Benzotartaric ether.}}{\left.\begin{matrix}C^2H^5\\C^2H^5\end{matrix}\right\}C^4H^3(C^7H^5O)O^6} + H^2O = \underset{\text{Alcohol.}}{C^2H^6O} + \underset{\text{Ethylbenzotartaric acid.}}{\left.\begin{matrix}H\\C^2H^5\end{matrix}\right\}C^4H^3(C^7H^5O)O^6}.$$

$$\left.\begin{matrix}C^2H^5\\C^2H^5\end{matrix}\right\}C^4H^3(C^7H^5O)O^6 + 2H^2O = 2C^2H^6O + \underset{\text{Benzotartaric acid.}}{\left.\begin{matrix}H\\H\end{matrix}\right\}C^4H^3(C^7H^5O)O^6}.$$

$$\left.\begin{matrix}C^2H^5\\C^2H^5\end{matrix}\right\}C^4H^3(C^7H^5O)O^6 + 3H^2O = 2C^2H^6O + \underset{\text{Tartaric acid.}}{\left.\begin{matrix}H\\H\end{matrix}\right\}C^4H^4O^6} + \underset{\text{Benzoic acid.}}{C^7H^6O^2}.$$

Benzotartaric ether is not converted into dibenzotartaric ether by heating with chloride of benzoyl; neither does this compound appear to be produced by heating tartaric ether with 2 at. chloride of benzoyl.

Paratartaric ether heated with chloride of benzoyl, yields benzoparatartaric ether isomeric with benzotartaric ether, but melting at a much lower temperature, viz. 57°, and not crystallising so readily.

Acetobenzotartaric Ether, $C^{17}H^{20}O^8 = C^4H^2(C^2H^3O)(C^7H^5O)(C^2H^5)^2O^6$. (Perkin, Chem. Soc. J. xx. 145.)—Prepared by heating benzotartaric ether with a slight excess of chloride of acetyl to 140°—150°, in a sealed tube for three or four hours. It is a very thick colourless oil, heavier than water, showing no tendency to solidify, neutral to test-paper, very soluble in alcohol and ether.—Heated with *alcoholic potash*, it is completely resolved into alcohol, and acetic, benzoic, and tartaric acids:

$$C^{17}H^{20}O^8 + 4H^2O = 2C^2H^6O + C^2H^4O^2 + C^7H^6O^2 + C^4H^6O^6.$$

Succinotartaric Ether, $C^{20}H^{30}O^{14} = C^8H^6(C^4H^4O^2)''(C^2H^5)^4O^{12}$. (Perkin, Chem. Soc. J. xx. 143.)—This body, formed by the substitution of 1 at. succinyl for 2 at. hydrogen in a double molecule of tartaric ether, is prepared by heating 2 at. tartaric ether with 1 at. chloride of succinyl in a test-tube to 100°, as long as hydrochloric acid continues to go off:

$$2C^4H^4(C^2H^5)^2O^6 + (C^4H^4O^2)''Cl^2 = 2HCl + C^8H^6(C^4H^4O^2)''(C^2H^5)^4O^{12}.$$

The product, purified like the preceding, is an extremely thick oil, generally of a pale-yellow colour. It dissolves freely in *alcohol* and *ether*, forming neutral solutions. It is decomposed by alcoholic potash, and cannot be distilled without decomposition.

Methylic Tartrate, $C^6H^{10}O^6 = C^4H^4(CH^3)^2O^6$. *Methyltartaric Ether.*—Prepared like ethyltartaric ether, which it resembles. (Demondesir.)

β. *Acid Tartaric Ethers containing Monatomic Alcohol-radules.*

These are monobasic acids, produced by the direct action of alcohols on tartaric acid.

Amyltartaric Acid, $C^9H^{16}O^6 = C^4H^5(C^5H^{11})O^6$. *Tartramylic Acid.*—This acid, discovered by Balard (Ann. Ch. Phys. [3] xii. 309), and more fully investigated by Breunlin (Ann. Ch. Pharm. xci. 314), is prepared by digesting 150 pts. finely-pulverised tartaric acid, for several days (at about 130°), with 88 pts. rectified amylic alcohol. A syrupy liquid is then formed, which, by slow cooling, solidifies to warty masses of unctuous crystals, having an intensely bitter taste. They melt at a gentle heat, and dissolve in a small quantity of water, but a larger quantity of water separates the amyltartaric acid in oily drops. (Breunlin.)

The amyltartrates, $C^4H^4M(C^5H^{11})O^6$ and $C^8H^8M''(C^5H^{11})^2O^{12}$, are for the most part soluble in water. Most of them remain unaltered when their aqueous solutions are boiled, but they decompose when dried at 100°.

Amyltartrate of Barium, prepared by saturation, separates from its concentrated solution, in colourless, nacreous, crystalline laminæ, containing $C^8H^8Ba''(C^5H^{11})^2O^6.2H^2O$, which become dull when dried at a gentle heat, and are decomposed at 100°. They dissolve in alcohol, and, on adding water to the solution, the anhydrous salt, $C^8H^8Ba''(C^5H^{11})^2O^{12}$. is precipitated in white amorphous flakes.—The *calcium-salt*, $C^8H^8Ca''(C^5H^{11})^2O^{12}$, likewise obtained by neutralisation, remains, on evaporating its solution over oil of vitriol, as a friable saline mass, which dissolves very readily in water, and is not decomposed at 100°.—The *lead-salt*, obtained by precipitating the potassium-salt with acetate of lead, appears to be a basic salt.—The *potassium-salt*, obtained by decomposing the barium-salt with carbonate of potassium, separates, on evaporation and cooling, as a white crystalline mass, containing $C^4H^4K(C^5H^{11})O^6.H^2O$. It is sparingly soluble in cold, easily in boiling water, and gives off its water of crystallisation at 100°.—The *sodium-salt*, $C^2H^4Na(C^5H^{11})O^6$, prepared in like manner, separates, by evaporation over oil of vitriol, in soft, nodular, anhydrous crystals. The *silver-salt*, $C^4H^4Ag(C^5H^{11})O^6$, separates on cooling from a hot concentrated solution of the potassium-salt mixed with nitrate of silver, in tufts of needles having an adamantine lustre. (Breunlin.)

Ethyltartaric Acid, $C^6H^{10}O^6 = C^4H^5(C^2H^5)O^6$.—*Tartrethylic* or *Tartrovinic Acid.* (Marian, Trommsd. J. xiii. 2, 43.—Trommsdorff, *ibid.* xxiv. 1, 11.—Guérin-Varry, Ann. Ch. Phys. [2] lxii. 57.)—When absolute alcohol is boiled for some time with tartaric acid, and the liquid, after dilution with water, saturated with carbonate of barium, insoluble tartrate of barium is formed, together with a solution of the ethyltartrate, which is deposited in crystals on concentrating the liquid. This salt, decomposed with an equivalent quantity of sulphuric acid, yields ethyltartaric acid.

This acid crystallises in elongated prisms, with oblique bases; it is colourless, inodorous, tastes both sweet and sour, and quickly absorbs moisture from the air. It is very soluble in alcohol and in ether. Its aqueous solution is completely decomposed, by prolonged boiling, into alcohol and tartaric acid. It dissolves zinc and iron, with evolution of hydrogen.

Ethyltartaric acid is decomposed, by dry distillation, into alcohol, water, acetic ether, acetic acid, ethylene-gas, pyrotartaric acid, and other products.—*Nitric acid* converts it into acetic, carbonic, and oxalic acids.

The solution of ethyltartaric acid gives no precipitate with *potash* or *soda*, in whatever proportion the alkali may be added.—When added by drops to *baryta-water*, it forms a precipitate, which disappears, with the exception of a slight turbidity, as the liquid approaches neutrality, but reappears on adding an excess of the acid. These characters distinguish ethyltartaric acid from tartaric acid.—With *lime-water*, it forms a precipitate soluble in excess of the acid.

The ethyltartrates, $C^4H^4M(C^2H^5)O^6$ and $C^8H^8M''(C^2H^5)^2O^{12}$, usually crystallise well; they are unctuous to the touch, and without odour. Almost all of them are very soluble in water, less soluble in alcohol. On boiling their solutions, they are resolved into alcohol and tartrates.

The *ammonium-salt* is obtained, in silky fibres, by spontaneous evaporation of a solution of the acid saturated with carbonate of ammonium.—The *potassium-salt*, $C^4H^4K(C^2H^5)O^6$, forms colourless rhombic prisms, usually exhibiting the combination $\infty\breve{P}2 . \infty\breve{P}\infty . \breve{P}\infty . P$. Axes $a : b : c = 0{\cdot}2879 : 1 : 0.4174$. Angle $\infty\breve{P}2 : \infty\breve{P}2$ (brach.) $= 120° 8$; $\infty\breve{P}2 : \infty\breve{P}\infty = 101° 5'$; $\breve{P}\infty : \breve{P}\infty = 134° 41'$. Cleavage easy parallel to $\infty\breve{P}\infty$. Its aqueous solution, when boiled, deposits acid tartrate of potassium.—The *sodium-salt* forms laminæ, sometimes rhomboïdal, sometimes rectangular.

The *barium-salt*, $C^8H^8Ba''(C^2H^5)^2O^{12}.2H^2O$, prepared as already described (p. 694), forms beautiful fan-shaped groups of crystals, apparently belonging to the trimetric system.

The *calcium-salt*, $C^8H^8Ca''(C^2H^5)^2O^{12}.5H^2O$, prepared like the barium-salt, forms rectangular prisms or laminæ, which melt in their water of crystallisation at 100°.

The *cupric salt*, $C^8H^8Cu''(C^2H^5)^2O^{12}.6H^2O$, obtained by dissolving cupric oxide in the aqueous acid, forms blue, silky, efflorescent needles.

The *lead-salt* separates, on adding ethyltartaric acid to acetate of lead, in small nacreous prisms, insoluble in excess of the acid.

The *silver-salt*, $C^4H^4Ag(C^2H^5)O^6$, obtained by precipitation, crystallises in prisms, sometimes tumefied in the middle. It is slightly soluble in cold water, and may be heated to 100° without decomposition.

The *zinc-salt* forms groups of rectangular prisms, unctuous to the touch.

Ethylbenzotartaric Acid, $C^{13}H^{14}O^7 = C^4H^3(C^7H^5O)(C^2H^5)O^6$. (Perkin, Chem. Soc. J. **xx.** 142.)—Produced, together with benzotartaric acid and other products, by treating a dilute alcoholic solution of benzotartaric ether with a quantity of dilute alcoholic potash, not sufficient to resolve it completely into benzoic and tartaric acids (p. 693). On gently heating the resulting liquid to expel the excess of alcohol, adding water to separate oily products, passing the solution through a wet filter, acidulating with hydrochloric acid, which separates an oil consisting of benzoic and ethylbenzoic acids, together with a little neutral oil, smelling like benzoic ether, and placing the clear filtrate in a vacuum over oil of vitriol, ethylbenzoic acid separates, after a few days, in beautiful tufts of hard needles, which may be completely purified by washing with water. The mother-liquor contains benzotartaric acid (p. 690).

Ethylbenzotartaric acid is sparingly soluble in water, but extremely soluble in alcohol and ether, and is deposited from its alcoholic or ethereal solution, on evaporation, in fan-shaped groups of crystals. Its aqueous solution reddens litmus-paper. It is easily decomposed by potash, and its salts appear to be rather unstable.

Methyltartaric Acid, $C^5H^8O^6 = C^4H^5(CH^3)O^6$. *Tartromethylic Acid.* (Dumas and Péligot, Ann. Ch. Phys. [2] lxi. 200.—Guérin-Varry, *ibid.* lxii. 77.—Dumas and Piria, *ibid.* [3] v. 373.)—Tartaric acid dissolves in methylic more easily than in ethylic alcohol, and converts it with greater facility into the acid ether. To prepare this compound, tartaric acid is dissolved in an equal weight of methylic alcohol at the boiling heat; the solution is evaporated to a syrup at a temperature below 100°; the syrup left to evaporate freely, and the resulting crystals dried in a vacuum.

Methyltartaric acid crystallises in colourless rectangular prisms, heavier than water, fusible, inodorous, but having an acid taste. It is scarcely altered by the moisture of the air, dissolves very easily in cold water, and in all proportions of boiling water; is easily soluble also in alcohol and wood-spirit, but insoluble in ether.

The aqueous solution of methyltartaric acid, when boiled, takes up 1 at. water, reproducing tartaric acid and methylic alcohol. The crystals, when heated, give off water, methylic alcohol, and methylic acetate, together with other products.

The aqueous acid dissolves *zinc* and *iron*, with evolution of hydrogen. With *baryta-water* and *lime-water* it forms precipitates, soluble in a slight excess of the acid. It does not precipitate sulphate of potassium, but forms a pulverulent precipitate with *acetate of lead.*

The methyltartrates are converted, by boiling their aqueous solutions, into methylic alcohol.—The *potassium-salt*, $C^5H^7KO^6$, crystallises in right rectangular prisms, which (according to Dumas and Piria) are anhydrous, but (according to Guérin-Varry) give off 4·2 per cent. water in a vacuum over oil of vitriol. It is much more soluble in hot than in cold water.—The *sodium-salt* is sparingly soluble in water, and separates, as a granular precipitate, on pouring methyltartaric acid into caustic soda.—The *barium-salt*, $C^{10}H^{14}Ba''O^{12}.H^2O$ (?), is obtained by saturating a solution of the acid in methylic alcohol with carbonate of barium, and crystallises, by spontaneous evaporation, in white rectangular prisms, much more soluble in hot than in cold water. It decomposes at about 160°, yielding a syrupy alliaceous liquid, containing water, methylic alcohol, methylic acetate, and a crystallisable substance, which may be obtained from it by evaporation.—The *lead-salt* and the *silver-salt* are obtained by precipitation.

Acids isomeric with Methyltartaric Acid.

Citratartaric Acid, $C^5H^8O^6$. (Carius, Ann. Ch. Pharm. cxxix. 159; Jahresb. 1864, p. 393.)—An acid produced by boiling a neutral salt of chlorocitramalic acid with water:

$$\underset{\text{Chlorocitramalate.}}{C^5H^5K^2ClO^5} + H^2O = KCl + \underset{\text{Citratartrate.}}{C^5H^7KO^6}.$$

To prepare it, a solution of chlorocitramalate of barium * is repeatedly evaporated to dryness, with excess of baryta. On carefully decomposing the resulting barium-salt with dilute sulphuric acid, evaporating the filtrate, and decolorising with animal charcoal, citratartaric acid is obtained, as a transparent, amorphous, deliquescent mass, which melts above 100°, and becomes carbonised, with evolution of acid vapours.

Citratartaric acid is dibasic. Its *potassium-* and *ammonium-salts* have the composition $C^5H^6M^2O^6$: the former crystallises in needles. The free acid is precipitated by acetate of lead; the solutions of the neutral alkali-metal salts form, with lead- and silver-salts, precipitates which are soluble both in the free acid and in excess of the alkaline salt; no precipitate with chloride of barium, calcium, copper, or zinc. Citratartaric acid reduces an ammoniacal silver-solution at the boiling heat, and prevents the precipitation of ferric oxide by alkalis.

Citratartrate of barium contains $C^5H^6Ba''O^6$; the *neutral lead-salt*, $C^5H^6Pb''O^6$; the *basic lead-salt*, $C^5H^6Pb''O^6.Pb''O$.

Dibasic acids having the same composition, and perhaps identical with the preceding, are produced:—*α*. By the reduction of oxalic ether with sodium-amalgam, the pasty amalgam being covered with alcohol of 80 per cent., and the oxalic ether gradually added.† This acid, Löwig's glycomalic acid, is uncrystallisable, but its acid barium-salt may be obtained in crystals. (Löwig, Jahresb. 1862, p. 311.)

β. By the action of silver-oxide on dibromopyrotartaric acid (iv. 774):

$$C^5H^6Br^2O^4 + Ag^2O + H^2O = 2AgBr + C^5H^8O^6.$$

The acid thus produced (homotartaric acid) is very soluble in water, and the syrupy solution yields crystals after long standing. Its salts are almost all soluble in water.—The *neutral barium-salt*, $C^5H^6Ba''O^6$ (at 150°), is insoluble in alcohol. (Kekulé, Ann. Ch. Pharm. Suppl. i. 346; *Lehrbuch*, ii. 213.)

γ. Tartaric Ethers containing Polyatomic Alcohol-radicles.

These ethers are formed by heating tartaric acid, in various proportions, with glycerin, mannite, dulcite, pinite, glucose, &c. Their composition and properties have already been described. See Ethers (ii. 521, 522); Glucosotartaric Acid (ii. 872); Glycerotartaric Acids (ii. 893).

TARTARIN. Native sulphate of potassium, also called *Arkanite* and *Glaserite.*

TARTARUS. A general pharmaceutical name for salts of tartaric acid:—*Tartarus ammoniatus* is ammonio-potassic tartrate.—*T. boraxatus*, or tartarised borax, is the gummy salt obtained by evaporating a mixture of 1 pt. borax and 3 pts. cream of tartar (p. 687).—*T. chalybeatus* is potassio-ferric tartrate.—*T. emeticus*: potassio-antimonious tartrate.—*T.* (*ferratus* or *ferruginosus*), *T. kalico-ferricus*, and *T. martialis* or *martiatus*, are various preparations containing ferric tartrate.—*T. regeneratus*: acetate of potassium.—*T. solubilis*: neutral tartrate of potassium.—*T. solubilis ammoniacalis*: ammonio-potassic tartrate.—*T. stibiatus*: tartar-emetic.—*T. tartarisatus*: neutral tartrate of potassium.—*T. vitriolatus*: sulphate of potassium.—*T. vitriolatus acidus*: acid sulphate of potassium.

TARTRALIC ACID. Syn. with Ditartaric Acid (p. 691).

TARTRAMETHANE. Ethylic tartramate.

---

* This salt is prepared by treating a cold solution of citraconate of barium with hypochlorous acid, produced by passing chlorine into water containing mercurous oxide in suspension. (Jahresb. 1863, p. 386.)

† The reduction of ethylic oxalate by sodium-amalgam, under different conditions, yields racemocarbonic or desoxalic acid, $C^5H^6O^8$ (p. 40).

TARTRAMIC ACID. $C^4H^7NO^5 = C^4H^5(NH^2)O^5 = \left.\begin{matrix}H^2\\(C^4H^2O^2)^{iv}\\H.H^2\end{matrix}\right\}\begin{matrix}O^3\\N\end{matrix}$. (Laurent, Compt. Chim. 1845, p. 153.—K. Grote, Ann. Ch. Pharm. cxxx. 262.)—The ammonium-salt of this acid is produced:—1. By passing ammonium-gas over tartaric anhydride moistened with alcohol. Two layers of liquid are then formed, the upper consisting of alcohol, and the lower of tartramate of ammonium (Laurent).—2. Together with tartaric acid, by heating tartaric ether with strong aqueous ammonia to 100°. The resulting solution first deposits efflorescent crystals of tartrate of ammonium, then hard crusts of the tartramate. The longer the action is continued, the greater is the quantity of tartrate produced, and in about a week the whole of the tartramate is converted into tartrate. (Grote.)

Tartramate of calcium is precipitated on mixing the solution of the ammonium-salt with chloride of calcium, and adding alcohol. It is very soluble in water, insoluble in alcohol, and forms large tetrahedral crystals, containing $C^8H^{12}Ca''N^2O^{10}.6H^2O$. Its solution, mixed with acetate of lead and ammonia, yields a precipitate, consisting of a *basic lead-salt*, $C^8H^8\overset{''}{Pb}{}^3N^2O^{10}$—The *barium-salt*, $C^8H^{12}Ba''N^2O^{10}.8H^2O$, forms crystalline crusts, which give off half their water at 100.°—The *free acid*, separated from the calcium-salt by sulphuric acid, is syrupy. (Grote.)

Ethylic Tartramate, Tartramic Ether, or *Tartramethane*, is obtained by the action of alcoholic ammonia on tartaric ether. When cautiously treated with alkalis, it yields tartramic acid. Ammonia converts it into tartramide. (Demondesir, Compt. rend. xxxiii. 229.)

PHENYLTARTRAMIC, or TARTRANILIC ACID, $C^{10}H^{11}NO^5 = C^4H^6(C^6H^5)NO^5$. (Arppe, Ann. Ch. Pharm. xciii. 352; Jahresb. 1855, p. 477.)—This compound is obtained by boiling tartranil with aqueous ammonia. On evaporating the excess of ammonia at a gentle heat, adding an excess of baryta-water, decomposing the washed precipitate with sulphuric acid, and filtering, the tartranilic acid separates in light red warty masses and shining laminæ, which may be rendered colourless by treatment with animal charcoal.

Tartranilic acid is very soluble in *water* and in *alcohol*, less soluble in *ether*; it melts at 180°, and decomposes with loss of water.—Its *ammonium-salt* remains, on evaporation, as a very efflorescent, easily soluble, crystalline mass. The aqueous acid is not precipitated by *lime-water*, even on addition of ammonia; but on addition of potash, a cloudiness is produced, and a precipitate on boiling; neither is the aqueous acid precipitated by *chloride of barium* or *calcium*, even on addition of ammonia; with *baryta-water* it forms a copious precipitate, and with *ferric chloride*, a yellow precipitate.

Tartranilate of Barium, $C^{20}H^{20}Ba''N^2O^{10}$, is moderately soluble in boiling water, and crystallises in shining spangles.—The *silver-salt*, $C^{10}H^{10}AgNO^5$, is a white somewhat soluble powder.

TARTRAMIDE. $C^4H^8N^2O^4 = C^4H^4(NH^2)^2O^4 = \left.\begin{matrix}H^2\\(C^4H^2O^2)^{iv}\\H^4\end{matrix}\right\}\begin{matrix}O^2\\N^2\end{matrix}$. (Demondesir, *loc. cit.*—Pasteur, Compt. rend. xxxv. 176.—Grote, *loc. cit.*)—Produced by passing dry ammonia-gas into an alcoholic solution of tartaric ether. It usually crystallises from pure water in holohedral crystals; but if a few drops of ammonia are added to the hot solution, the crystals deposited on cooling exhibit hemihedral faces, often very fully developed. Its solution exhibits dextro- or lævo-rotation, according to the kind of tartaric acid from which it has been prepared. Both varieties unite with ordinary active *malamide*, forming compounds which have the same composition, but differ in crystalline form and in solubility, the compound containing lævotartramide being much more soluble than the other. (Pasteur.)

A hot solution of *mercuric oxide* in tartramide deposits crystalline crusts of mercurotartramide, $C^{16}H^{16}\overset{''}{Hg}{}^3N^8O^{16}$ (?), insoluble in water, soluble in hydrochloric acid, not attacked by iodide of ethyl. (Grote.)

Oxide of silver is easily reduced by tartramide. (Grote.)

DIPHENYLTARTRAMIDE, or TARTRANILIDE, $C^{16}H^{16}N^2O^4 = C^4H^6(C^6H^5)^2N^2O^4$. (Arppe, Ann. Ch. Pharm. xciii. 352.)—Produced, together with tartranil (phenyltartrimide), by the action of heat on tartrate of aniline. This salt, heated to 130°—140°, gives off aniline (the neutral salt being partly converted into the acid salt); and at 150°, the mass fuses, and then no longer gives the reaction of aniline with chloride of lime:

$$\underset{\text{Neutral tartrate of aniline.}}{C^4H^4(C^6H^8N)^2O^6} - 2H^2O = \underset{\text{Tartranilide.}}{C^{16}H^{16}N^2O^4}.$$

$$\underset{\text{Acid tartrate of aniline.}}{C^4H^5(C^6H^8N)O^6} - 2H^2O = \underset{\text{Tartranil.}}{C^{10}H^9NO^4}.$$

Boiling water dissolves out the tartranil; the brown residue dissolves in boiling alcohol; and the solution, on cooling, deposits crystals of tartranilide.

Tartranilide crystallises in colourless, nacreous, slender, interlaced needles, insoluble in water, slightly soluble in ether, moderately soluble in alcohol. It may be heated to 250° without decomposition, melts and decomposes at a higher temperature, but by careful heating to somewhat below its melting-point, it may be sublimed in shining laminæ. It is not altered by boiling with alkaline solutions. It is dissolved with difficulty by hot hydrochloric acid, with partial decomposition by nitric acid, easily by sulphuric acid.

TARTRAMYLIC ACID. Syn. with Amyltartaric Acid (p. 694).

TARTRANIL. Syn. with Phenyltartrimide (*infra*).

TARTRANILIC ACID. Syn with Phenyltartramic Acid (p. 697).

TARTRANILIDE. Syn. with Phenyltartramide (p. 697).

TARTRATES. See Tartaric Acid (p. 675).

TARTRELIC ACID. Soluble tartaric anhydride (p. 691).

TARTRETHYLIC ACID. Syn. with Ethyltartaric Acid (p. 694).

TARTRIMIDE. $C^4H^5NO^4 = \left.\begin{matrix}H^2\\(C^4H^2O^2)''\\H\end{matrix}\right\}\begin{matrix}O^2\\N\end{matrix} = C^4H^4(NH^4)O^6$ (acid ammonium-tartrate) $-2H^2O$.—This compound has not been obtained; but phenyltartrimide or tartranil, $C^{10}H^9NO^4 = C^4H^4(C^6H^5)NO^4$, is produced, as above described, together with tartranilide, by the dehydration of tartrate of aniline. It may be purified by recrystallisation and treatment with animal charcoal, and separates, on cooling from hot solutions, as a white granular powder, or in nacreous laminæ. It dissolves easily in water and in alcohol, sparingly in ether. It may be heated to somewhat above 200° without decomposition (the granular variety becoming crystalline, and partly volatilising as a woolly sublimate), but melts, and decomposes at 230°. It is tasteless, but reddens litmus-paper distinctly. (Arppe, *loc. cit.*)

TARTROGLYCERIC ACID. Syn. with Glycerotartaric Acid (ii. 893).

TARTROMETHYLIC ACID. Syn. with Methyltartaric Acid (p. 695).

TARTRONIC ACID. $C^3H^4O^5$. (Dessaignes, Compt. rend. xxxiv. 731; xxxviii. 44.)—A dibasic acid, produced by the spontaneous decomposition of nitrotartaric acid (p. 690); also, according to Baeyer (Jahresb. 1864, p. 641), by the action of sodium-amalgam on mesoxalic acid, $C^3H^2O^5$ (iii. 932). It crystallises in rather large prisms, which melt at 160°, and decompose with formation of glycollide (ii. 919):

$$C^3H^4O^5 = C^2H^2O^2 + CO^2 + H^2O.$$

The tartronates of the alkali-metals are soluble in water: the *acid ammonium-salt* crystallises in prisms: the *silver-salt* contains $C^3H^2Ag^2O^5$.—The aqueous acid forms precipitates with argentic, plumbic, and mercurous salts, and with the acetates of barium, calcium, and copper.

TARTROVINIC ACID. Syn. with Ethyltartaric Acid (p. 694).

TARTRYL. $C^4H^2O^2$.—The radicle of tartaric acid.

TARTRYLIC ACID. Syn. with Tartaric Acid.

TASMANITE. A fossil resin occurring, in small scales or plates, between the layers of a rock containing alumina and ferric oxide, occurring on the Mersey River in Tasmania. The resin, which forms from 30 to 40 per cent. of the entire deposit, is translucent and reddish-brown, has a specific gravity of 1·18, hardness = 2, and a conchoïdal fracture. It is not dissolved by alkalis, alcohol, ether, carbonic disulphide, benzene, or other hydrocarbons. It is slowly oxidised by nitric acid, with formation of sulphuric acid; oil of vitriol chars it, and eliminates sulphydric acid. By dry distillation, it yields oily and solid products, smelling like Canadian petroleum. It burns readily in the air, with a smoky flame and offensive odour. It gives by analysis (after deduction of 8 to 12 per cent. ash, consisting of silica, alumina, and a little ferric oxide), 79·34 per cent. carbon, 10·41 hydrogen, 5·32 sulphur, and 4·94 oxygen, agreeing nearly with the formula $C^{40}H^{62}O^2S$. (Church, Phil. Mag. [4] xxviii. 465.)

TAUNUS-SLATE. A clay-slate occurring in the Taunus range in Western Germany. It has a grey to violet colour, and silky iridescent lustre, and contains sericite or damourite (p. 235). A similar formation occurs at Göllnitz in Hungary.

TAURINE. $C^2H^7NSO^3$.—A neutral crystallisable substance obtained from bile, and resulting from the transformation of taurocholic acid under the influence of acids or of alkalis:

$$\underset{\substack{\text{Taurocholic}\\\text{acid.}}}{C^{26}H^{45}NSO^7} + H^2O = \underset{\text{Taurine.}}{C^2H^7NSO^3} + \underset{\substack{\text{Cholic}\\\text{acid.}}}{C^{24}H^{40}O^5}.$$

It was discovered in 1826 by L. Gmelin (Tiedemann u. Gmelin, *Die Verdauung*, i. 43, 60), who obtained it from ox-bile; it may also be prepared from the bile of most other animals—from all kinds of bile, indeed, which contain taurocholic acid (Strecker, Ann. Ch. Pharm. lxv. 132; lxvii. 34; xci. 101).—It is never found in the free state in healthy bile, or indeed in any other of the healthy secretions, at least in the higher animals; but it often occurs in diseased bile taken from the dead body, especially when the bile has an acid reaction. It is found also in certain molluscs (Valenciennes and Frémy, Compt. rend. xli. 735); in the muscles of the oyster, which close the shell; in the blood of the shark; in the liver, spleen, and kidneys of the ray (Städeler and Frerichs); in the pulmonary tissue of oxen, and sometimes in the kidneys (Clöetta, Ann. Ch. Pharm. xcix. 289). It has been especially studied by Demarçay (Ann. Ch. Pharm. xxvii. 286), by Dumas and Pelouze (*ibid.* xxvii. 292), and by Redtenbacher (*ibid.* lvii. 170), who first showed that it contains sulphur.

According to the formula above given, which was established by Redtenbacher, taurine is isomeric with acid sulphite of vinyl-ammonium, $\left.\begin{matrix}NH^3(C^2H^3)\\H\end{matrix}\right\}SO^3$, and is related to isethionic acid in the same manner as alanine to lactic acid:

$$\underset{\substack{\text{Lactate of}\\\text{ammonium.}}}{C^3H^5(NH^4)O^3} - H^2O = \underset{\text{Alanine.}}{C^3H^7NO^2}.$$

$$\underset{\substack{\text{Isethionate of}\\\text{ammonium.}}}{C^2H^5(NH^4)SO^4} - H^2O = \underset{\text{Taurine.}}{C^2H^7NSO^3}.$$

In accordance with this last relation, Strecker has shown that it may be produced from isethionate of ammonium by elimination of water, and an improved method of preparing it from isethionic acid has recently been given by Kolbe. (Ann. Ch. Pharm. cxxii. 33.)

Preparation.—1. From *Bile.*—Ox-bile (which is the kind most easily obtained in quantity) is mixed with hydrochloric acid, and the liquid filtered from the resulting precipitate is evaporated down at the boiling heat, till it has separated into a viscous resinous deposit and a clear watery liquid. The latter is poured off, the resin rinsed with water, and the united liquids concentrated. On cooling, they deposit a large quantity of common salt, together with crystals of taurine, which must be picked out and purified by recrystallisation.

Taurine is also easily prepared from putrid bile. The bile, mixed with a considerable quantity of water, is exposed for about three weeks to a summer temperature, till it acquires a distinct acid reaction. It is then precipitated with acetic acid; the filtered liquid is evaporated; the residue treated with strong alcohol; and the taurine, which remains undissolved, is crystallised from boiling water (Gorup-Besanez, Ann. Ch. Pharm. lix. 130). As taurine may be decomposed by prolonged contact with ferments, it is important not to allow the putrefaction to go on too long.

2. From *Isethionic Acid.*—*a.* Isethionate of ammonium is heated for some time to 210°, till it becomes solid; the residue is dissolved in water; and the solution mixed with a small quantity of alcohol, which throws down a brownish substance; then with a larger quantity, which precipitates taurine (Strecker). The product thus obtained is generally small, the greater part of the taurine suffering further decomposition.

β. Dry pulverised isethionate of potassium is mixed in a retort with 2½ times its weight of phosphoric pentachloride. The mixture immediately becomes warm, and gives off hydrochloric acid and phosphoric oxychloride, after which, on applying heat, chlorethylsulphuric chloride, $C^2H^4SO^2Cl^2$, distils over, together with more oxychloride. These two substances are separated by fractional distillation, and the chlorethylsulphuric chloride, which passes over at about 200°, is decomposed by prolonged heating with water in sealed tubes, into hydrochloric and chlorethylsulphuric acids. The resulting solution is neutralised with ammonia, and the salt left on evaporating it over the water-bath, is heated for some time to 100° in closed vessels with excess of strong aqueous ammonia, whereby taurine is produced, together with sal-ammoniac. The free ammonia is then evaporated off; the liquid heated with hydrate of lead as long as ammonia continues to escape; and the filtrate, freed from lead by sulphuretted hydrogen, is concentrated by evaporation: it then, on cooling, yields crystals of pure taurine (**Kolbe**). The series of reactions is represented by the following equations:—

$$\underset{\text{Isethionic acid.}}{C^2H^6SO^4} + 2PCl^5 = \underset{\text{Chlorethyl-sulphuric chloride.}}{C^2H^4SO^2Cl^2} + 2POCl^3 + 2HCl.$$

$$\underset{\text{Chlorethyl-sulphuric chloride.}}{C^2H^4SO^2Cl^2} + H^2O = HCl + \underset{\text{Chlorethyl-sulphuric acid.}}{C^2H^5ClSO^3}.$$

$$\underset{\text{Chlorethyl-sulphuric acid.}}{C^2H^5ClSO^3} + NH^3 = HCl + \underset{\text{Taurine.}}{C^2H^7NSO^3}.$$

Properties.—Taurine forms large, transparent, monoclinic crystals, having a vitreous lustre, and usually exhibiting the combination $\infty P \,.\, \infty P \infty \,.\, +P \,.\, -P$, like *fig.* 301 (ii. 155), also with oP and other faces. Axes $a : b : c = 1{\cdot}4648 : 1 : 0{\cdot}06648$. Angle $b : c = 86° 22'$; $\infty P : \infty P$ (orthod.) $= 68° 32'$; $oP : \infty P = 87°$; $+P : +P$ (clinod.) $= 137° 30'$; $-P : -P$ (clinod.) $= 139° 44'$. The crystals grate between the teeth, and have a pungent taste; they are neutral to vegetable colours, and permanent at 100°, but melt and carbonise at a higher temperature. By dry distillation, they yield a brown empyreumatic oil, together with a yellow slightly acid liquid, which contains an ammoniacal salt, and reddens ferric chloride (acetate of ammonium?).

Taurine is more soluble in hot than in cold water; 1 pt. dissolves in 15·5 pts. water at 12°. It is nearly insoluble in absolute alcohol.—Strong *sulphuric* and *nitric acids* dissolve it; but it is not decomposed by nitric or by nitromuriatic acid, even at the boiling heat, or by dry chlorine.—*Nitrous acid* converts it into isethionic acid, with evolution of nitrogen (**Gibbs**, Sill. Am. J. [2], xxv. 30). Its aqueous solution is not precipitated by salts of copper, mercury, or silver.—Melted with caustic *potash*, it yields a residue, which, when treated with dilute sulphuric acid, gives off sulphydric and sulphurous acids, and yields a deposit of sulphur. If evaporated slowly with caustic potash, it gives up all its ammonia at a certain stage, without blackening; and the cooled residue, if then treated with sulphuric acid, gives off sulphurous acid, without sulphydric acid or deposition of sulphur, and yields by distillation a mixture of acetic and sulphurous acids.

TAURISCITE. A variety of ferrous sulphate, found on the Windgälle, in the Canton Uri, Switzerland; it has the composition of ordinary green vitriol, but forms orthorhombic crystals, like those of magnesium-sulphate.

TAUROCHENOCHOLIC ACID. A sulphuretted acid contained in goose-bile. It has not been obtained quite pure, but, according to **Heintz** and **Wislicenus** (Pogg. Ann. cviii. 547), it consists of $C^{29}H^{49}NSO^3$, differing therefore in composition from taurocholic acid, and, when boiled with baryta-water, yields chenocholic acid, $C^{27}H^{44}O^4$, homologous with hyocholic acid, $C^{25}H^{40}O^4$. **Chenocholic acid** is insoluble in water, soluble in alcohol and ether, and separates from solution mostly as an amorphous mass, rarely in indistinct crystals. Its solution has an acid reaction, and gives, with sugar and sulphuric acid, the blood-red coloration characteristic of the biliary acids.—Its *barium-salt*, $C^{54}H^{86}Ba''O^8$, is insoluble in water and in ether, but soluble in absolute alcohol.—The *potassium-salt* dissolves easily in water and in alcohol, but not in dilute potash-ley.

TAUROCHOLIC ACID. $C^{26}H^{45}NSO^7$. *Choleic Acid. Sulphocholeic Acid.* (**Strecker**, Ann. Ch. Pharm. lxvii. 30; lxx. 169.—**Lieberkühn** and **Heintz**, *Lehrbuch der Zoochemie*, p. 367.—**Hoppe**, Arch. Path. Anat. xv. 126.—**Cloëtta** and **Vulpian**, N. Jahrb. Pharm. vii. 106.—**J. Parke**, Bull. Soc. Chim. 1866, ii. 242.)—An acid occurring as a sodium-salt in the bile of most animals. In the bile of serpents (*Boa*, *Python*), and in that of the dog, it occurs free from glycocholic acid; in that of fishes (*Pleuronectes*, *Gadus*, *Esox*, *Perca*), and of the sheep, wolf, goat, and domestic fowl, mixed with only a small quantity, and in that of the ox, with a large quantity of glycocholic acid.

Taurocholic acid may be prepared from dog's bile, by evaporating the decolorised alcoholic extract of the bile; digesting the residue with a small quantity of absolute alcohol, and adding ether, which precipitates the alkaline taurocholate in the crystalline state; mixing the aqueous solution of this salt with acetate of lead and a little ammonia; exhausting the washed precipitate with boiling alcohol; and saturating the hot filtered liquid with sulphydric acid gas. On evaporating the filtered liquid to a small bulk, and precipitating with excess of ether, the syrupy precipitate solidifies, after some time, into a mass of fine silky needles of pure taurocholic acid, which in contact with the air quickly changes to an amorphous transparent mass (Parke). Taurocholic acid may be prepared from bile containing also glycocholic acid, by first precipitating the latter with basic acetate of lead, and throwing down the taurocholic acid from the filtrate by adding more basic acetate of lead and ammonia. (Heintz.)

Taurocholic acid is easily soluble in water and in alcohol, less soluble in ether; it has a sweetish taste, with somewhat bitter aftertaste. It acts upon polarised light, its specific rotatory power being +24·9° for red, and +25·3° for yellow light (Hoppe-Seyler). In the dry state, it may be heated considerably above 100° without decomposition (Parke); but when boiled with *water*, or with *alkalis*, it is resolved into taurine and cholic acid:

$$C^{26}H^{45}NSO^7 + H^2O = C^2H^7NSO^3 + C^{24}H^{40}O^5.$$

By boiling with *acids*, it is resolved into taurine and dyslysin, $C^{24}H^{36}O^3$, together with other products:

$$C^{26}H^{45}NSO^7 = C^2H^7NSO^3 + C^{24}H^{36}O^3 + H^2O.$$

Taurocholates.—Taurocholic acid is monobasic. The taurocholates of the alkali-metals are easily soluble in water and in alcohol, but insoluble in ether, which precipitates them from their alcoholic solutions as pasty masses changing into crystals on standing. The aqueous solutions of the alkaline taurocholates froth like soap-water, and deposit the dissolved salt on addition of caustic potash. They give no precipitate with acetic acid, dilute mineral acids, or neutral acetate of lead.—*Basic acetate of lead* throws down white flocks, soluble in boiling water, and in excess of the lead-solution; on adding a few drops of ammonia, a more abundant precipitate is formed.—*Ferric chloride* produces a precipitate easily soluble in excess. No turbidity is produced by nitrate of silver or by mercuric chloride.—*Mercurous nitrate* and *stannous chloride* throw down white flocks. The solutions give no precipitate with acetate of barium, strontium, calcium, magnesium, or copper.

Taurocholate of Barium is obtained, by dissolving taurocholic acid in baryta-water, evaporating, dissolving in alcohol, and precipitating with ether, as a resinous mass, which quickly solidifies in the crystalline form.

Taurocholate of Lead.—The precipitate formed by basic acetate of lead in the solution of an alkaline taurocholate contains 52 at. carbon to 2½ at. lead.

Taurocholate of Potassium, $C^{26}H^{44}KNSO^7$, is contained in fish-bile, together with glycocholate of sodium. To obtain it pure, the bile is first precipitated by neutral acetate of lead; then the filtrate by basic acetate of lead and ammonia; the precipitate is decomposed by carbonate of potassium; and the solution is mixed with strong potash-ley, which precipitates the taurocholate of potassium. For further purification, it is dissolved in absolute alcohol; carbonic acid gas is passed into the solution; the liquid is filtered from the carbonate of potassium which separates; and the taurocholate is precipitated by ether. It then separates in colourless needles, grouped like crystals of wavellite.

Taurocholate of Sodium, $C^{26}H^{44}NaNSO^7$, is one of the chief constituents of ox-bile. It resembless the potassium-salt.

TAURYLIC ACID. $C^7H^8O^7$. (Stadeler, Ann. Ch. Pharm. lxxvii. 17.)—A compound obtained, together with phenol, from cows', horses', and human urine. It appears to be isomeric with anisol, benzylic alcohol, and cresol—perhaps identical with the latter; but its composition is not precisely known, as it has never been completely separated fron phenol.

To extract it, cows' urine is boiled with lime, and the decanted liquid is evaporated to an eighth of its bulk; supersaturated when cold with hydrochloric acid; left to stand for twenty-four hours; and then distilled, after separation of the hippuric acid deposited from it. The distillate, which contains thick greenish oily drops having a disagreeable odour, is mixed with a weighed quantity of potassium-hydrate and rectified (whereupon it gives off, together with ammonia, a neutral nitrogenous oil heavier than water, and having the odour of rosemary); the residue is mixed with a quantity of sulphuric acid sufficient to neutralise ⅝ths of the potash, and distilled, as long as the distillate is precipitated by basic acetate of lead; this distillate, which smells of phenol, is repeatedly rectified over common salt, till only a small quantity of watery liquid remains mixed with it, then repeatedly agitated with carbonate of sodium (to remove damolic and damaluric acids, ii. 301), and exhausted with ether; the ethereal solution is evaporated, the residue distilled, first with strong potash-ley to volatilise neutral oil, and then with acid carbonate of potassium; and this last oily distillate is dried over chloride of calcium and rectified, oil containing water then passing over at 180°, pure oil between 185° and 195°, and brownish oil at 200°.

The liquid which passes over between 185° and 195°, is a mixture of taurylic and phenic acids. It is a colourless oil, which smells like castoreum, remains liquid at 18°, and makes a white spot upon the skin. With an equal volume of strong sulphuric acid, it solidifies to a dendritic mass, the mother-liqour of which contains phenylsulphuric acid. When boiled with nitric acid, it yields a nitro-acid.

TAUTOCLINE. Breithaupt's name for a ferruginous bitter spar, from Freiberg, containing, according to Ettling (Ann. Ch. Pharm. xcix. 204), 49·07 per cent. $CaCO^3$, 33·28 $MgCO^3$, 14·89 $FeCO^3$, and 2·09 MnO^3 (= 99·33).

TAUTOLITE. A mineral allied to bucklandite, but regarded by Breithaupt as a distinct species, occurring in the volcanic rocks at Lake Laach, near Andernach. It is opaque, black, with vitreous lustre, and crystallised like bucklandite: hardness = 6·5; specific gravity = 3·865. It appears to consist mainly of the silicates of ferrosum, magnesium, and aluminium.

TAXIN. A resinous substance obtained from the leaves of the yew-tree (*Taxus baccata*), by treatment with alcohol and tartaric acid, two pounds of the leaves yielding 3 grains of taxin. It is slightly soluble in water, dissolves easily in alcohol, ether, and dilute acids, and is precipitated from the acid solutions by alkalis in white bulky flocks. It is not precipitated by tannic acid or tincture of iodine. Strong sulphuric acid dissolves it, with purple-red colour. (Lucas, Arch. Pharm. [2], lxxxv. 145.)

TAYUYIN. An amorphous, purgative, bitter substance, contained in the root of *Trianosperma ficifolia*, Mart., a climbing cucurbitaceous plant, indigenous in Brazil. (Peckolt, Arch. Pharm. [2], cxiii. 104.)

TCHA-LAN. A blue powder, containing copper, used by the Chinese for producing blue colours on porcelain. (Ebelmen and Salvétat, Ann. Ch. Phys. [3], xxxv. 338.)

TCHINGUEL-SAKESEY. A kind of caoutchouc, less elastic than the ordinary kind. It is said to flow from incisions in the stem of a tree cultivated in Kurdistan, and to harden in the air (*Handw. d. Chem.* viii. 525).

TEA. *Thé. Thee. Folia theæ.*—The dried leaves of the tea-plant, *Thea sinensis*. This plant is indigenous and extensively cultivated in China, Japan, and the northern parts of the eastern peninsula of India, and has been introduced more or less successfully into British India on the southern declivities of the Himalayas, Java, the Kong Mountains in Western Africa, Brazil, Madeira, and other countries of warm and temperate climates; it appears, indeed, to be capable of flourishing in all latitudes between 0° and 40°. It was formerly supposed that there were two species of the tea-plant, *Thea viridis*, yielding green, and *Thea Bohea*, yielding black tea; but it appears, from the recent observations of Mr. Fortune,* that either green or black tea may be obtained at pleasure from the same plant.

Green tea is prepared from the young leaves, which, within an hour or two after they have been gathered, are roasted in pans over a brisk wood-fire. After four or five minutes' roasting, the leaves become flaccid, and are rolled by the hands upon a wooden table; they are then again thrown into the drying-pans, where they are kept in rapid motion, and in about an hour, or an hour and a half, are completely dried.

Black tea is allowed to lie in heaps for ten or twelve hours after the leaves have been gathered; they are then tossed about for some time, till they become flaccid. At this stage they begin to emit a fragrant smell; they are next rolled in balls, with the hand, upon a wooden table, and a large quantity of liquid is expressed from them; after which they are shaken out, roasted for a few minutes, agained rolled, and, whilst still flaccid, are exposed to the air for some hours upon shallow bamboo trays: this alternate heating and rolling is repeated three or four times, and finally, the leaves are dried slowly over charcoal fires. A species of fermentation appears to occur during the drying of the leaf, in consequence of which a development of essential oil takes place, by which the agreeable aroma is occasioned: this aroma is wanting in the fresh leaf. The change of the leaf from green to black is mainly due to chemical alterations produced by the oxygen of the air upon the constituents of the leaf, and especially upon the astringent principle—this change being prevented in green tea by the rapid process of drying to which it is subjected.

Many kinds of green tea, intended for the European market, are coloured by dusting them with a finely-pulverised mixture of prussian-blue and gypsum, turmeric being also sometimes added; but the Chinese never colour tea intended for their own use. Teas for the foreign market are also frequently perfumed with various sweet-scented flowers—as roses, jasmine, orange, *Gardenia florida*, *Olea fragrans*, &c.

Tea is subjected to numerous adulterations. It is often mixed with various leaves

---

* "The Tea Districts of China and India," by R. Fortune (3rd edition, London, John Murray, 1857), i. 220; ii. 237.

(as those of the elm, willow, sloe, &c.), dried and prepared like true tea-leaves; or it is mixed, during the colouring process above mentioned, with graphite, talc, &c. In some instances, preparations of copper have actually been used to give a green colour to tea (**Günther**, J. pr. Chem. x. 279.—**Warington**, Chem. Gaz. 1852, p. 238).—A kind of adulteration, which has been much practised in this country, is the working up of spent tea-leaves, which are prepared in the Chinese fashion, so as to resemble black and green tea. Sometimes also products are sent into the market as tea, or mixed in considerable quantities with various kinds of tea, which do not consist of tea-leaves at all, but are artificial mixtures, made out of tea-dust, sand, and dirt of various kinds, united together with paste. A substance of this kind is prepared in China, and called by the Chinese "Lie-tea," by the English "gum and dust."

Chemical Constitution of Tea.—The most important constituents of tea are, an *essential oil*, to which it owes its peculiar aroma; two nitrogenised bodies, viz., *theine* or *caffeine*, and *legumin*; and a peculiar astringent substance, or *tannin*.

Mulder (Ann. Ch. Pharm. xxviii. 314) analysed four kinds of tea, from China and Java. He found the proportion of water in all of them nearly the same, whereas **Péligot** (*ibid.* xlvii. 358) found the average amount of water equal to 10 per cent. in green tea, and 8 per cent. in black:—

Composition of Dried Tea. (**Mulder**.)

	Chinese Tea.		Java Tea.	
	Green (Hyson).	Black (Congo).	Green (Hyson).	Black (Congo).
Volatile oil . . .	0·79	0.60	0·98	0·65

	104·34	104·04	105·18	103·06

The **volatile oil of tea** is obtained either by distillation, or by extraction with ether. It is lemon-yellow, lighter than water, easily solidifies, resinises quickly on exposure to the air, and possesses in a high degree the smell and taste of tea. It has a powerful stimulating action, and in rather large quantities produces giddiness and headache: in combination with tannin, however, it produces (according to **Mulder**) merely a diuretic and sudorific action.

The properties of **theine**, and the methods of extracting it from tea, have already been described under CAFFEINE (i. 707). The following are the proportions of it in various kinds of tea, as determined by **Stenhouse** (Ann. Ch. Pharm. xlv. 366; xlvi. 227; lxxxix. 245; cii. 126):—

Green Hyson tea	contains	1·05 per cent. theine.
Black Congo	„	1·02 „
„ Assam	„	1·37 „
Cheap green Twankay	„	0·98 „
Cheap black Bohea	„	0·70 „
Black tea (average) †	„	2·00 „
The same	„	2·13 „
Black Kumaon tea (Himalayas)	„	1·9 „

Péligot (Ann. Ch. Pharm xlvii. 361) found in Hyson tea 2·40 and 2·56 per cent. theine; in a mixture of equal parts of *Gunpowder*, *Hyson*, *Caper*, and *Kaisow tea*, 2·70; in *Gunpowder tea*, 3·5 and 4·1 per cent., and by a more complete method of extraction 6·21 per cent., of which 3·84 crystallised out from the concentrated solution, and 2·37 were obtained from the mother-liquor by precipitation with tannic acid.

The proportion of **nitrogen** in tea, dried at 100°, is (according to **Péligot**) in Pekoe tea 6·58, Gunpowder 6·15, Souchong 6·15, and Assam 6·10 per cent. The aqueous extract of 100 pts. dried Gunpowder tea yielded 4·30; of green Souchong, 4·70 per cent. nitrogen. The leaves, exhausted by hot water, contained, when dried, 4·6 per cent. (*Souchong*) and 4.40 per cent. (*Gunpowder*) nitrogen. The exhausted leaves contain casein (legumin), combined with tannin in the form of a compound insoluble in water, which may, however, be rendered soluble by addition of alkali. According to Péligot's determinations—

---

* Oxidised extractive matter, according to **Warington** (Ann. Ch. Pharm. lxxxi. 233).

† **Gram, Stenhouse**, and **Campbell** (Chem. Soc. Qu. J. ix. 33).

100 pts. of Gunpowder tea contain:

Water . . .	10	containing	Volatile oil . . .	0·5
Extract . . .	47		Theine . . .	6·0
Exhausted leaves .	43	„	Legumin . . .	12·
	100			

100 pts. Souchong tea contain:

Water . . .	8	containing	Volatile oil . .	0·5
Extract . . .	43		Theine . . .	6·0
Exhausted leaves .	49	„	Legumin . . .	14·0
	100			

In the way in which tea is generally used, namely, as a watery infusion, the legumin remains in the spent leaves which are thrown away; but among the Mongols and other tribes of Central and Northern Asia, tea is used more as an article of food than as a mere beverage. These people make use of a product called *brick-tea*, prepared in China from inferior teas, and from the stalks and other refuse of the better sorts, which are compressed into cakes, either alone, or more frequently with addition of sheep's or bullock's blood. These cakes are pounded and boiled with water containing common salt, carbonate of potassium, or other alkaline salt (to dissolve the legumin), and the whole, mixed with fat and flour, is consumed as a thin broth.

The **tannin** of tea-leaves is commonly said to be identical with gallotannic acid. Stenhouse, however, regards it as a peculiar kind of tannin distinct from the latter; he finds also that it is associated in tea-leaves with a small quantity of gallic acid. According to R. **Wagner** also, all tannins occurring in healthy vegetable organs are essentially distinct from those which, like gallotannic acid, are found only in diseased tissues like gall-nuts (see TANNIC ACID, p. 660). The tannin of tea-leaves produces a blue-black precipitate with iron-salts.

The proportion of **ash** in unadulterated commercial tea varies from 4·73 to 6·5 per cent.; in adulterated tea it is often much larger; in some of the Chinese "Lie-teas," Warington found from 34 to 45·5 per cent. ash. The ash of tea is especially distinguished by its large amounts of iron and manganese. **Fleitmann** (Liebig's *Chemische Briefe*, 4te Aufl. ii. 182) found in an infusion of 70 grms. of Pekoe tea, 0·104 grm. ferric oxide, and 0·20 grm. manganous oxide.[*] Lehmann found in the ash of tea-infusion 0·7 per cent. manganic oxide.

The following are analyses of **tea-ash**: *a* and *b* of "*Souchong*," by Spooner; *c*, "*Oolong*," by Tevis: *d*, "*Young Hyson*," by Hague; *e*, "*Ning Young*," by Homer;[†] *f*, dry aqueous extract of tea, by Lehmann[‡]:—

---

[*] There must be some error in these numbers.

[†] The analyses *a—e* were made under Horsford's direction (Sill. Am. J. [2], xi. 249). The enormous tions in the proportions of potash and soda are probably due to defective analysis.

[‡] Liebig's *Chemische Briefe*, 4te Aufl. ii. 182.

The physiological action of tea, when used as an infusion, depends chiefly on the theine, essential oil, tannin, and inorganic constituents. In general, it may be said that tea acts upon the nervous system: when taken in moderate quantity, it heightens the activity of the brain, accelerating the flow of thought, and producing a pleasurable mental excitement; in excess it occasions sleeplessness and uneasiness, which may amount to anxiety, trembling, spasmodic attacks, &c. It, moreover, increases the action of the heart, the excretion of urea, the perspiration by the skin, and the peristallic motion of the intestines (Liebig, *Chemische Briefe*, loc. cit.). Lehmann (*Lehrb. d. physiolog. Chemie*, i. 151) also found the excretion of urea increase after taking tea; Böcker, on the other hand (Archiv. f. wiss. Heilk. 1853, i. 2), found it diminished. Further and more extended experiments are required to decide whether the use of tea accelerates or retards the change of tissue in the organism. (See Knapp's *Chemische Technologie*, 1848, ii. 84.)

TEAK. *Tectona grandis.*—The wood of this tree, which grows in the South of India and other tropical countries, frequently exhibits cracks and cavities of considerable extent, lined with a white crystalline deposit, consisting chiefly of hydrocalcic orthophosphate, $Ca''HPO^4.H^2O$, with about 11·4 per cent. ammonio-magnesian phosphate. (Abel, Chem. Soc. Qu. J. xv. 91.)

TEARS. See Serous Fluids (p. 236).

TECTIZITE. A brown mineral, supposed to be a hydrated ferrous sulphate, occurring at Schwarzenberg in Saxony, and at Bräunsdorff in the Erzgebirge, in small pyramidal and acicular crystals, and massive. Hardness = 1·5 to 2. It is easily soluble in water, and attracts moisture readily. (Dana, ii. 388.)

TECTONA. See Teak.

TEETH. (Von Bibra, Chem. Untersuch. über die Knochen u. Zähne, 1844. Frémy, Ann. Ch. Phys. [3] xliii. 47.—Hoppe, Virch. Arch. v. 170; xxiv. 13.)——The typical mammalian tooth consists of *dentine*, *enamel*, and *cement*, or *crusta petrosa*. Under the microscope, a thin section of dentine presents the appearance of a number of fine tubules, following a wavy but nearly parallel course from the pulp-cavity towards the exterior of the tooth; these tubules give off minute branches from their sides, and, as they approach the periphery, rapidly subdivide. Enamel seems to be made up of short prismatic fibres, while cement differs from bone chiefly in the absence of Haversian canals. Among the different kinds of animals, very great variations in the arrangement and relative proportion of these three constituents are observable, and the teeth of some of the lower vertebrata present special modifications of tissue known by the names of *vasodentine*, &c. &c.

Each of these dental tissues consists, like bone, of certain inorganic matters united (in a definite ratio, there is reason to believe) with an organic basis. In *cement* the organic basis is identical with that of bone. The greater part of the organic matter of dentine is also resolved by prolonged boiling into gelatin, but the proper walls of the dentinal tubules appears to be composed of a material which cannot be so resolved. The organic basis of the enamel does not yield gelatin, but seems rather to be allied to the chemical basis of epithelium.

The proportion of inorganic to organic material, and the composition of the former, will readily be seen from the following analyses. Zalesky (Hoppe-Seyler, Untersuch. i. p. 40) found in the ash of the enamel of fossil rhinoceros-tooth ·592 per cent. of fluoride of calcium. Hoppe calls attention to the analogy between the inorganic portion of enamel and apatite. The enamel of undeveloped teeth contains a form of albumin:—

TEKORETIN. A resin found in fossil pine-stems in the bogs of Holtegaard in Denmark. It crystallises in large prisms, melting at 45°, insoluble in water, slightly soluble in alcohol, very soluble in ether. It distils without alteration near the boiling-point of mercury. Chlorine converts it into a crystalline substance. Nitric acid transforms it into oxalic acid and a brown resin, apparently containing nitrogen. It gave, as the mean of four analyses, 87·17 per cent. carbon and 12·84 hydrogen, agreeing approximately with the formula nC^5H^8. (Forchhammer, Ann. Ch. Pharm. xli. 39.)

TELAESIN or **TELESCIN.** A product formed, according to Rochleder (J. pr. Chem. lxxxvii. 22), by the action of aqueous acids or alkalis on argyræscin, aphrodæscin, and æscinic acid, constituents of the cotyledons of horse-chestnut seeds (iii. 172).

TELERYTHRIN. A product of the decomposition of orsellinic ether (iv. 236), formed, according to Kane (Ann. Ch. Pharm. xxxix. 36), when the ether dissolved in hot water is exposed to the air for several months; it is probably a mixture, chiefly consisting of orcin and erythromannite.

TELESIE. Syn. with Corundum (ii. 86).

TELLURAMYL. See Amyl, Telluride of (i. 206).

TELLURATES. See Tellurium, Oxides and Oxygen-acids of.

TELLURETHYL. See Ethyl, Telluride of (ii. 550).

TELLURHYDRIC ACID. H^2Te. See Hydrogen, Telluride of (iii. 204).

TELLURIC ACID. See Tellurium, Oxides and Oxygen-acids of.

TELLURIC BISMUTH. See Tellurides.

TELLURIC OCHRE. Native tellurous oxide.

TELLURIC SILVER. See Tellurides.

TELLURIDES and **TELLURHYDRATES.** Compounds analogous to the sulphides and sulphydrates, and to the selenides and selenhydrates. The tellurides belong to the class of metallic alloys: those of bismuth, gold, lead, and silver are found native; the others may be obtained by fusing the respective metals with tellurium, or (in the wet way) by precipitating solutions of the metals with tellurhydric acid or an alkaline tellurhydrate. The tellurides of potassium and sodium are prepared by heating powdered tellurium with an alkaline carbonate, containing finely-divided charcoal—black flux, for instance. The access of air to the mass must be prevented till it is quite cold, on account of its highly pyrophoric nature. It may then be exhausted with water in which the alkaline tellurides dissolve, being probably converted into tellurhydrates. They may also be formed by passing tellurhydric acid gas through solutions of caustic alkali. Tellurhydrate solutions have a portwine-colour, and deposit tellurium on exposure to the air.

Telluride of Bismuth.—This alloy occurs native in several localities, forming the mineral called *Telluric Bismuth*, *Tetradymite*, or *Bornite*. Some specimens contain only bismuth and tellurium, but generally the tellurium is partly replaced by sulphur and selenium. It forms crystals belonging to the hexagonal system, namely acute rhombohedrons, having the angles of the terminal edges = 66° 40′, combined (according to Haidinger) with the basal face oR, and aggregated in cruciform groups of four individuals. It cleaves perfectly parallel to the base, and thin laminæ are more or less flexible, also somewhat elastic. The mineral likewise occurs in granulo-laminar masses. Hardness = 1 to 2. Specific gravity = 7·2 to 7·9. Before the blowpipe it melts with tolerable facility, coating the charcoal with a yellow-and-white deposit, the reaction varying in character according to the proportion of sulphur or selenium present. It dissolves in nitric and in sulphuric acid.

The variations in composition of this mineral will be seen from the following analyses *:—

Selenium	. .	. .	. .	. .	1·5	
	99·4	98·6	99·6	93·1	99·6	98·5

The great variations in the proportion of tellurium to bismuth, and the fact that the crystalline forms of the mineral and its two constituents belong to the same system (bismuth, rhombohedral; tellurium, hexagonal), lead to the conclusion that it is not a definite compound, but an isomorphous mixture of tellurium and bismuth. It must be observed, however, that many of the analyses—namely, those by Genth of the specimens from Virginia and Georgia, which contain no sulphur and little or no selenium—agree nearly with the formula Bi^2Te^3 (requiring 59·9 per cent. bismuth, and 48·1 tellurium); and that those by Berzelius, Wehrle, and Hruschauer may be represented approximately by Bi^2Te^2S.

Telluride of Gold and Silver. See SYLVANITE (p. 647).

Telluride of Hydrogen. See HYDROGEN, TELLURIDE OF (iii. 204).

Telluride of Lead, PbTe. *Altaite. Cubic Tellurium.*—This mineral occurs in the mine of Savodinskoi, near Barnaoul in the Altai, usually massive, with cubic cleavage, rarely in cubic crystals. It has a metallic lustre and tin-white colour, like that of native antimony. Hardness = 3 to 3·5. Specific gravity = 8·159. Sectile. Before the blowpipe it volatilises in the reducing flame, leaving only a minute bead of silver, and colours the flame blue. It is soluble in nitric acid. It contains 38·37 per cent. tellurium, 60·35 lead, and 1·28 silver (G. Rose, Pogg. Ann. xviii. 68), and is therefore PbTe (38·3 tellurium, and 61·7 lead), mixed with a small quantity of silver-telluride.

Telluride of Silver, Ag^2Te. *Hessite. Petzite. Bitellurct of Silver.*—Occurs in the Savodinskoi mine in the Altai, at Nagyag in Transylvania, and at Retzbanya in Hungary, in coarse-grained masses and granular, with metallic lustre, lead-grey or steel-grey colour, and slightly malleable. Hardness = 2 to 3·5. Specific gravity = 8·3 to 8·9. Before the blowpipe on charcoal, it melts to a black globule, which on cooling, after being subjected to the action of the reducing flame, exhibits points or dendrites of silver on its surface. Heated in a tube, it melts, and colours the glass yellow. Fused with carbonate of sodium, it yields a globule of pure silver.

Analyses:—a, b. From the Savodinskoi mine (G. Rose, Pogg. Ann. xviii. 64).—*c.* From Nagyag (Petz, *ibid.* lvii. 470).—*d, e.* From Retzbanya (Rammelsberg, *Mineralchemie,* p. 15): *d.* massive; *e.* granular with green coating; after deduction of 15·25 per cent. insoluble matter:

	a.	*b.*	*c.*	*d.*	*e.*
Tellurium	36·96	36·89	37·76	. .	33·0
Silver	62·42	62·32	61·55	60·28	64·5
Gold	. .	. .	0·69		
Iron	0·24	0·50			
	99·62	99·71	100·00	. .	97·5

The formula Ag^2Te requires 37·27 per cent. tellurium, and 62·73 silver.

Tellurides, Organic. See AMYL, ETHYL, METHYL, TELLURIDES OF (i. 206; ii. 550; iii. 992).

The alcoholic tellurides obtained by Wöhler have the composition R^2Te.—Cahours has lately shown (Compt. rend. lx. 20, 1147; Jahresb. 1865. p. 447), that telluride of methyl unites directly with iodide of methyl, forming a crystalline compound, $(CH^3)^3TeI$, sparingly soluble in water, easily soluble in alcohol. This iodide, treated with oxide of silver, yields an alkaline product, which, when neutralised with hydrochloric acid, forms with platinic chloride, an orange-coloured double salt, $2(CH^3)^3TeCl.Pt^{iv}Cl^4$.

Telluride of ethyl unites in like manner with iodide of ethyl, forming the compound $(C^2H^5)^3TeI$; and corresponding compounds are formed by the sulphides and selenides of ethyl and methyl with the iodides of those radicles.

TELLURITES. See TELLURIUM, OXIDES AND OXYGEN-ACIDS OF.

TELLURIUM. *Symbol*, Te. *Atomic Weight*, 128. *Vapour-density*, obs. at 1390° = 9·00; calc. (1 vol.) = 8·86.

This element, though decidedly metallic, must be classed as a member of the sulphur family, as it approximates very closely in its chemical characters to sulphur, and still more to selenium. It was first identified as a distinct metal by Klaproth, in 1798, who gave it the name "tellurium," from *tellus*, the mythological name of the earth.

Tellurium is one of the rarer elements, being found in a few localities only, chiefly in Hungary and Transylvania, in the silver mine of Savodinskoi in the Altai, and in the State of Virginia. It occurs native in a state of considerable purity: a specimen from Nagyag was found by Petz to contain 97·22 per cent. tellurium and 2·78 gold; and Klaproth found in a specimen from the Maria Loretto mine, near Zalathna in Hungary, 92·53 tellurium, 0·25 gold, and 7·20 iron. The principal ores of tellurium are the tellurides of bismuth, lead, gold, and silver, already described (iv. 1; v. 707, 708).

Preparation.—Tellurium is separated from its ores by processes analogous to those which yield selenium (p. 221).—1. Native telluride of bismuth, freed as far as possible from its matrix, and made into a paste with pearlash and oil, is gradually raised in a covered crucible to a full white heat; and the fused mass when cold is treated with boiling water, which extracts telluride of potassium, forming a portwine-coloured solution, from which the tellurium is deposited in metallic scales, by passing a current of air through it, or by mere exposure to the air.—2. Finely pulverised foliated tellurium, or nagyagite (iv. 1), freed from sulphides of lead and antimony by repeated boiling with hydrochloric acid, and washing with water, is heated with strong nitric acid, whereby tellurous acid is obtained in solution. This is evaporated to dryness, and the residue, after solution in hydrochloric acid, is reduced by a current of sulphurous acid gas. For further details, see *Gmelin's Handbook*, iv. 393.

Properties.— Tellurium is a tin-white, shining, brittle metal, having a great tendency to crystallise. The crystals belong to the hexagonal system. Native tellurium occurs in rhombohedral crystals, isomorphous with those of antimony, arsenic, and bismuth, and exhibiting the faces R, with those of derived rhombohedrons; also oR and ∞R. Length of principal axis, for R = 1·3298; angle R : R in the terminal edges = 86° 57′. The opposite rhombohedrons +R and −R likewise occur together, forming a hexagonal pyramid (in combination with ∞P and oP), in which the angle P : P in the terminal edges = 130° 28′; in the lateral edges = 113° 52′. Cleavage perfect parallel to ∞R; in traces parallel to oR. According to H. Rose, tellurium separates from a solution of potassium-telluride, by spontaneous decomposition, in six-sided prisms with rhombohedral summits.

Tellurium conducts heat and electricity, though not very readily. Its specific gravity is 6·1 to 6·33; hardness of the native metal = 2 to 2·5. It melts at about 500°, volatilises at a higher temperature, and condenses in crystalline needles, or in drops. It may be purified by distillation in a current of hydrogen. Its vapour-density, as determined by Deville and Troost (Jahresb. 1863, p. 17), is 9·00 at 1390°, and 9·08 at 1439°. The vapour has a greenish-yellow colour, like that of chlorine-gas.

Tellurium, when strongly heated in the air, takes fire, burns with a lively blue flame edged with green, producing white fumes of tellurous acid, and emitting a peculiar odour, often partly due to the presence of traces of selenium. (Respecting the spectrum of its flame, see J. Werther, J. pr. Chem. lxxxviii. 180; Jahresb. 1863, p. 235).—Tellurium, like sulphur and selenium, dissolves to a slight extent in cold strong sulphuric acid, and is precipitated unchanged on dilution with water; but when heated with strong sulphuric acid, it is oxidised and dissolved as tellurous acid, while sulphurous anhydride is evolved as gas.—By strong *nitric acid*, it is quickly converted into tellurous acid.—*Hydrochloric acid* has no action upon it; but with *nitromuriatic acid*, it yields tellurous mixed with telluric acid.—By fusion with *saltpetre*, it yields tellurate of potassium.—Strong *potash-ley* dissolves tellurium at the boiling heat, forming a red liquid, containing telluride and tellurite of potassium. On cooling, or on dilution with water, however, the red colour disappears, and tellurium is separated, in consequence of the reducing action exerted by the potassium on the tellurous acid:

$$2K^2Te + K^2TeO^3 = 3K^2O + Te^3.$$

Tellurium, fused with *carbonate of potassium*, likewise yields a mixture of telluride and tellurite.

Tellurium, in its chemical relations, bears a very close analogy to sulphur and selenium. It forms two oxides—namely, tellurous oxide, TeO^2, and telluric oxide, TeO^3—which, in combination with water and with metallic bases, yield acids and salts analogous to those formed by the corresponding oxides of sulphur and selenium.—

With *hydrogen*, it forms a gaseous compound, H^2Te, analogous to sulphydric and selenhydric acids. It unites also with the *alcohol-radicles*, methyl, ethyl, and amyl, forming compounds represented by the general formula R^2Te, which are diatomic radicles, analogous to the selenides of the alcohol-radicles.—With *chlorine* it forms a tetrachloride, $TeCl^4$, analogous to $SeCl^4$, and a dichloride, $TeCl^2$, to which there does not appear to be any definite analogue among the sulphur- and selenium-compounds (pp. 223, 533); and similar compounds with *bromine* and *iodine*. The inorganic compounds of tellurium have been studied chiefly by Berzelius; the organic compounds by Wöhler.

TELLURIUM, ALLOYS OF. See TELLURIDES (p. 707).

TELLURIUM, BROMIDES OF. The dibromide, $TeBr^2$, is produced by distilling the tetrabromide with finely pulverised tellurium, and passes over as a violet vapour, which condenses to slender black needle-shaped crystals. It melts easily, and is decomposed by water with formation of tellurous acid. (Berzelius.)

The *tetrabromide*, $TeBr^4$, may be prepared by adding finely divided tellurium, with frequent agitation, to bromine contained in a tube cooled with ice, and distilling off the excess of bromine after all the tellurium is dissolved (Berzelius). According to v. Hauer (J. pr. Chem. lxxiii. 98), it is more easily prepared by covering small pieces of tellurium with hydrobromic acid in a flask, then adding bromine, and leaving the flask closed till all the bromine has disappeared, the action being assisted by shaking the flask from time to time. The ruby-coloured solution thus obtained yields the dry compound by evaporation over the water-bath.

Tetrabromide of tellurium forms a compact red-yellow mass, which melts at a gentle heat to a dark-red transparent liquid, and solidifies in the crystalline form on cooling. It may be sublimed without decomposition in pale-yellow needles. It dissolves without alteration in a small quantity of water, forming a yellow solution, which becomes colourless on dilution, the tetrabromide being thereby resolved into hydrobromic and tellurous acids. The yellow solution evaporated over the water-bath deposits the hydrated tetrabromide in ruby-coloured crystals.

Tetrabromide of tellurium forms cinnabar-red compounds with the bromides of the alkali-metals.—The *potassium-salt*, $2KBr.TeBr^4.3H^2O$, was first obtained by Berzelius, by evaporating a mixed solution of the component salts. According to v. Hauer, it is better prepared by mixing 1 at. finely pulverised tellurium with 2 at. bromide of potassium in a flask, and adding water till the bromide is completely dissolved; then adding bromine by small portions, with frequent agitation, and leaving the flask closed till all the bromine has disappeared. On warming the resulting dark-red solution, to expel the excess of bromine, decanting it from a yellowish deposit which forms, and leaving it to cool, the double salt separates in dark-red, opaque, shining crystals, which effloresce superficially in dry air. It is slightly soluble in cold, easily in hot water. When heated, it gives off its water of crystallisation without melting. The anhydrous salt, which is orange-yellow, decomposes at a higher temperature, giving off tetrabromide of tellurium.

TELLURIUM, CHLORIDES OF. The dichloride, $TeCl^2$, is formed by distilling a mixture of equal parts of finely divided tellurium and the tetrachloride (Berzelius), or by passing chlorine slowly over strongly heated tellurium, or native telluride of silver. It may be freed from admixed tetrachloride by fractional distillation (H. Rose). It is a black amorphous mass, having an earthy fracture; melts easily to a black liquid, and is much more volatile than the tetrachloride. Its vapour is purple when mixed with air; yellow when pure. When exposed to the air, it absorbs moisture, but does not fume. When mixed with water, it becomes milky from formation of tellurous acid. Hydrochloric acid decomposes it, separating half the tellurium in the metallic state, and dissolving the other half as tellurous acid. The dichloride may be fused in all proportions with metallic tellurium, or with the tetrachloride.

Tetrachloride of Tellurium, $TeCl^4$, is obtained by gently heating tellurium in a stream of chlorine-gas, till a dark-yellow liquid is produced. This liquid turns yellow on cooling, and crystallises to a white mass at the moment of solidification. The tetrachloride melts easily to a yellow liquid, turning red near its boiling point: it is not very volatile, but forms a dark-yellow vapour when strongly heated. It is very deliquescent, and is decomposed by cold water, with separation of a basic salt and tellurous acid. Boiling water dissolves it, the solution on cooling depositing crystals of tellurous acid. Dilute hydrochloric acid dissolves it without alteration.

By mixing a solution of the tetrachloride with *chloride of ammonium* or *chloride of potassium*, double salts are formed, which crystallise in lemon-yellow octahedrons.—A compound of the tetrachloride with *chloride of aluminium*, $2AlCl^3.TeCl^4$, is obtained, to R. Weber (J. pr. Chem. lxxvi. 313), by melting the two chlorides together, and expelling any excess of aluminium-chloride that may be present by gentle heating. This double chloride is a yellowish-white, easily fusible mass, very soluble in dilute sulphuric acid. When heated nearly to its boiling-point, which is very high, it is partially decomposed, leaving a residue richer in tellurium.

Tetrachloride of tellurium quietly absorbs *ammonia-gas* at ordinary temperatures, swelling up, and changing to a greenish-yellow mass of the compound $4NH^3.TeCl^4$. This compound is permanent in the air, but is decomposed by water into tellurous acid and sal-ammoniac. When heated, it gives off sal-ammoniac, hydrochloric acid, and nitrogen-gas, while tellurium is separated. (Espenschied, J. pr. Chem. lxxx. 480.)

TELLURIUM, DETECTION AND ESTIMATION OF. 1. *Blowpipe reactions.*—All compounds of tellurium are easily reduced on *charcoal* in the inner flame, the reduced metal being volatilised, and forming a white deposit of tellurous oxide on the charcoal. With *borax* and *microcosmic salt*, tellurous oxide gives a clear colourless bead, which, when heated on charcoal, is rendered grey and opaque by the reduced metal. The oxides of bismuth and antimony, when reduced on charcoal in the inner flame, also give white incrustations, which may be confounded with tellurous oxide. Antimonious oxide, however, when heated in the inner flame, gives a bluish tinge, whereas tellurous oxide gives a fine green colour to the outer flame. Moreover tellurous oxide, when heated in a tube open at both ends, volatilises entirely, forming, on the cool part of the tube, a white sublimate, which, by careful heating, may be fused to colourless drops. Antimonious oxide, on the other hand, is only partially volatilised, being partly converted into the non-volatile oxide, SbO^2; the sublimate may be driven from one part of the tube to another by heat, but does not fuse into drops. Bismuth-oxide similarly treated gives scarcely any sublimate, but melts to a dark-brown liquid, which becomes pale-yellow on cooling, and corrodes the glass. From selenium, which it resembles more closely than any other element, tellurium is distinguished by the odours emitted when the compounds of the two elements are heated on charcoal before the blowpipe, pure tellurium emitting only a slightly acid odour, whereas selenium emits a powerful odour of decayed horse-radish: traces of selenium existing in tellurium-compounds are easily detected in this manner (p. 224).

2. *Reactions in Solution.*—All native tellurium-compounds are insoluble in water, but soluble in nitric acid. Among the artificially prepared compounds, the tellurites of the alkali-metals, and also the tellurates (in the hydrated state) are easily soluble in water; the tellurites and tellurates of the other metals are insoluble or sparingly soluble in water, but for the most part soluble in hydrochloric acid. The tellurides of the alkali-metals are also soluble in water, and their solutions, when exposed to the air, decompose quickly, with separation of metallic tellurium. Tellurous acid (hydrated tellurous oxide) dissolves easily in acids; the solution in nitric acid gradually deposits anhydrous telluric oxide. In solutions not containing too great an excess of acid, especially in the hydrochloric acid solution, water throws down a precipitate of tellurous acid. The hydrochloric acid solution of tellurous oxide is yellow. Telluric acid is distinguished from tellurous acid by its greater solubility in water. The salts of the two acids are distinguished from one another by the fact that the tellurates, when heated with hydrochloric acid, give off chlorine, which is not the case with the tellurites. Moreover, the solutions of tellurates in hydrochloric acid are colourless, and are not precipitated by water like those of the tellurites, even when there is but little free hydrochloric acid present.

Sulphydric acid produces immediately, in acid solutions of tellurous oxide, a brown precipitate of tellurium-sulphide, easily soluble in sulphide of ammonium; in acid solutions of telluric oxide, the same precipitate is formed after the liquid has stood for some time in a closed vessel, and in a warm place. The colour of this precipitate distinguishes it from all other metallic sulphides which are soluble in sulphide of ammonium (that of selenium is reddish-yellow) except stannous sulphide; but solutions of stannous salts are easily distinguished from those of tellurium-salts by their reaction with chloride of gold, tellurium-solutions not forming with this reagent any precipitate resembling the purple of Cassius; moreover, solutions of tellurous oxide yield, with ammonia and alkaline carbonates, a white precipitate easily soluble in excess of the alkaline reagent, whereas the precipitates formed in like manner with stannous salts are insoluble in excess. Solutions of telluric oxide give no precipitate with alkalis.

Sulphurous acid and *alkaline sulphites* produce, in acid solutions of tellurous or telluric oxides, after some time in the cold, or immediately on heating, a black precipitate of metallic tellurium. A similar precipitate is formed by solution of *stannous chloride* and by metallic *zinc*. The precipitate of selenium formed by the same reagents in a solution of selenious acid is red. The precipitated tellurium may also be distinguished from selenium by its reaction with solution of *potassium-cyanide*, which dissolves selenium but not tellurium; further by its behaviour before the blowpipe (p. 711); and lastly, by dissolving the precipitate in nitric acid, nitromuriatic acid, or a mixture of hydrochloric acid and potassium-chlorate, neutralising the solution, after complete oxidation, with carbonate of sodium, evaporating to dryness, fusing the residue at a moderate heat with nitre, dissolving the product in water, acidulating with nitric acid, and adding chloride of barium. Selenate of barium is then precipitated, whereas tellurate of barium remains in solution.

3. *Estimation and Separation.*—Tellurium is mostly estimated in the metallic state. If it is present in solution in the form of tellurous acid, as is always the case when tellurium-ores are treated with nitric acid, it is best precipitated by *sulphurous acid* or an *alkaline sulphite.* The tellurium thereby separated is collected on a weighed filter, carefully dried at a gentle heat, and weighed. If the tellurous acid is combined with bases in such proportion that the solution does not exhibit an acid reaction, it must be mixed with hydrochloric acid in sufficient quantity to redissolve the precipitate of tellurous acid formed at first. It is best also to concentrate the liquid as much as possible before adding the reducing agent, as the tellurium is then separated more quickly and completely than from a more dilute solution. The solution thus prepared is to be heated in a flask, but not to the boiling-point, and the solution of alkaline sulphite gradually added: the tellurium is then precipitated as a black bulky powder. Nitric acid, if present, may vitiate the result by reoxidising part of the reduced tellurium: it should therefore be previously removed by warming the liquid with hydrochloric acid. If the tellurium is present as telluric acid, the latter must first be reduced to tellurious acid by heating the solution with hydrochloric acid as long as chlorine continues to escape.

The method of reduction by sulphurous acid or alkaline sulphites, serves to separate tellurium from the tellurites and tellurates of the alkali-metals, and of other metals which are not precipitated by sulphydric acid. If the quantity of alkali-metal is to be likewise estimated, the reduction must of course be effected by sulphite of ammonium or free sulphurous acid; in the latter case, the solution must be digested for some days with excess of aqueous sulphurous acid, in a closed vessel placed in a warm situation. The separation of tellurium from the tellurites and tellurates of these metals may also be effected by precipitation with *sulphydric acid.* As the precipitated tellurium-sulphide is generally mixed with free sulphur, it must be digested, while still moist, with nitromuriatic acid, or better, with hydrochloric acid and potassium-chlorate, and the tellurium precipitated from the filtered solution by an alkaline sulphite, as above. Telluric acid must first be reduced to tellurous acid by heating with hydrochloric acid.

From the tellurites and tellurates of metals which are precipitated by sulphydric acid, and form sulphides insoluble in sulphide of ammonium, tellurium may be separated by supersaturating the solution with ammonia, and digesting it at a very gentle heat with excess of *ammonium-sulphide.* The sulphide of tellurium then remains dissolved, and may be precipitated from the filtered solution by acetic or very dilute hydrochloric acid, oxidised as above with nitromuriatic acid, &c., and the tellurium precipitated by an alkaline sulphite. The same method may be used for separating tellurium from iron, cobalt, nickel, zinc, and manganese. It is, however, not so advantageous in any case as the precipitation with alkaline sulphites, because it is difficult to ensure the complete solution of the tellurium-sulphide in sulphide of ammonium.

From all metals which form non-volatile chlorides, tellurium may be separated by igniting the compound in a stream of *chlorine*, whereby it is volatilised as dichloride or tetrachloride, according to the rapidity of the stream of gas. The volatilised chloride is passed into water acidulated with hydrochloric acid, in which the tetrachloride of tellurium dissolves completely, the dichloride with separation of tellurium. The tellurium is then reduced from the solution by an alkaline sulphite.

Another method of separation, applicable in most cases, is to fuse the compound with 3 pts. dry sodium-carbonate and 3 pts. sulphur in a covered crucible, and digest the mass when cold with water. The metals combined with the tellurium then remain as insoluble sulphides, while the tellurium dissolves as sulphotellurite of sodium. From this solution the tellurium-sulphide may be precipitated by a dilute acid, and treated as above for the determination of the tellurium.

From antimony, arsenic, and tin, tellurium may be separated by precipitation with *alkaline sulphites.*

From selenium and sulphur it is separated by fusion with *potassium-cyanide*, in the manner already described under SELENIUM (p. 225).

4. *Atomic Weight of Tellurium.*—Berzelius (Pogg. Ann. xxviii. 392) determined the atomic weight of tellurium by ascertaining the increase of weight of the

metal when converted into tellurous oxide by oxidation with nitric acid. In three experiments,

	1·2725 grms.	1·5715 grms.	2·88125 grms. tellurium
yielded	1·5895 „	1·9365 „	3·6000 grms. TeO^2;
whence Te =	128·41	128·29	128·27,

or, as a mean result, 128·34. Berzelius, however, gives the preference to the second and third experiments, which give Te = 128.

Von Hauer (Wien. Akad. Ber. xxv. 135), by precipitating bromide of tellurium and potassium, $2KBr.TeBr^2$, with nitrate of silver, obtained, as a mean of five closely agreeing experiments, 69·924 per cent. bromine; whence (if Ag = 108·1, Br = 80, K = 39·2), the atomic weight of tellurium is found to be 128·06.

Dumas (Ann. Ch. Pharm. cxiii. 30), from experiments not yet published in detail, concludes that Te = 159.

TELLURIUM, FLUORIDE OF, Te^4.—Produced by dissolving tellurous oxide in hydrofluoric acid. The solution evaporated over the water-bath leaves a colourless syrup, which on cooling deposits milk-white nodules, probably an oxyfluoride.

TELLURIUM, IODIDES OF. The *di-iodide*, TeI^2, is produced by gently heating tellurium with iodine. The excess of iodine then volatilises, leaving the compound in shining black crystalline flocks. It is easily fusible, and gives off iodine when strongly heated. Water has no action upon it. (Berzelius.)

The *tetra-iodide*, TeI^4, obtained by digesting finely pulverised tellurous oxide with hydriodic acid, forms soft black granules, which stain the fingers. It is very unstable, and melts, with evolution of iodine, when heated. With boiling water it forms a dark-brown solution, while a grey-brown oxyiodide remains undissolved. The tetra-iodide dissolves in hydriodic acid, and the solution, when evaporated, deposits colourless metallic-shining prisms, probably a compound of the tetra-iodide with hydriodic acid.

By saturating the solution of the tetra-iodide in hydriodic acid with an alkali, double iodides are obtained, which separate, by spontaneous evaporation, in iron-grey metallically lustrous crystals.

The *hexiodide*, TeI^6, is perhaps contained in the brown solution of telluric oxide in hydriodic acid.

TELLURIUM, OXIDES AND OXYGEN-ACIDS OF. Tellurium forms two oxides, TeO^2 and TeO^3, which unite with bases forming salts analogous to the sulphites and sulphates.

Tellurous Oxide or **Anhydride,** TeO.—This oxide is produced when tellurium burns in the air. It may also be obtained by exposing the corresponding hydrate (tellurous acid) to a gentle heat, and separates from the aqueous solution of the hydrate when heated to 40°. The same change takes place spontaneously, though more rapidly on the application of heat, in the nitric acid solution of tellurous acid obtained by dissolving tellurium in nitrous acid: in this case the deposit of tellurous oxide is much more abundant, and, if slowly produced, is distinctly crystalline, showing here and there well-defined octahedrons. The mineral called tellurite or telluric ochre, occurring at Facebay, near Zalathna in Transylvania, in small greyish-yellow spherules, imbedded in quartz together with tellurium, exhibits, according to Petz (Pogg. Ann. lvii. 478), the reaction of tellurous oxide before the blowpipe.

Tellurous oxide is slightly soluble in water, but has no action upon litmus. It is fusible and volatile. The fused oxide is a transparent deep yellow liquid, which solidifies on cooling to a white highly crystalline mass. When fused with alkaline hydrates or carbonates, it forms tellurates.

TELLUROUS HYDRATE OR TELLUROUS ACID, $H^2TeO^3 = H^2O.TeO^2$.—This acid is best obtained by decomposing tetrachloride of tellurium with water:

$$TeCl^4 + 3H^2O = 4HCl + H^2TeO^3.$$

It may be prepared from tellurite of potassium or sodium, by adding nitric acid till a distinct acid reaction is produced; also by dissolving tellurium in dilute nitric acid of specific gravity 1·25, and pouring the solution, after the lapse of not more than a few minutes, into an excess of water. If the precipitation be delayed for a longer time, the anhydrous oxide is thrown down instead of the hydrate.

Tellurous acid, prepared by either of these processes, is a somewhat bulky precipitate, which, when dried over oil of vitriol, forms a light white earthy powder, having a bitter metallic taste. It is slightly soluble in water, especially when recently precipitated. It dissolves both in acids and in alkalis.

The solutions of tellurous hydrate in acids are all stable, with the exception of the nitric acid solution, which, as already observed, deposits telluric oxide. They do not, however, yield definite salts on evaporation, excepting the phosphoric acid solution, which deposits a white powder, and the oxalic acid solution, which deposits crystalline grains, soluble without decomposition in water.—A *sulphate of tellurium*, ($Te^{iv}S^2O^6$), is formed by gently heating finely pulverised tellurium with oil of vitriol. (See SULPHATES, p. 614.)

The solution of tellurous hydrate in hydrochloric acid is decomposed by *water*, if not very strongly acid, depositing tellurous hydrate.—*Alkalis* and *alkaline carbonates* also form a white precipitate of tellurous hydrate, soluble in excess of the alkaline reagent. —*Chloride of barium* forms a white precipitate, insoluble in ammonia.—The reactions with *sulphydric acid*, *sulphide of ammonium*, *sulphurous acid*, *alkaline sulphites*, *stannous chloride*, and *zinc*, have been already described; also the blowpipe-reactions of tellurous oxide (p. 711).

TELLURITES.—Tellurous acid forms, with the *alkali-metals*, neutral and acid salts analogous to the sulphites and selenites; also hyperacid salts; viz.:

$$\begin{array}{lll} \text{Neutral Tellurites,} & M^2TeO^3 = M^2O.TeO^3. \\ \text{Acid} \quad ,, & MHTeO^3, \text{ or } M^2O.H^2O.2TeO^2. \\ \text{Hyperacid} \quad ,, & \left.\begin{matrix} MHTeO^3 \\ H^2TeO^3 \end{matrix}\right\}, \text{ or } M^2O.3H^2O.4TeO^2. \end{array}$$

There are also anhydrous ditellurites of alkali-metal, such as $K^2O.2TeO^2$, or $K^2TeO^3.TeO^2$.—With the *alkaline earth-metals*, tellurous acid forms anhydrous mono-, di-, and tetra-tellurites, represented by the formulæ, $M''O.TeO^2$, $M''O.2TeO^2$, and $M''O.4TeO^2$.—With the *heavy metals* it appears to form only neutral salts.

The tellurites of alkali-metal are formed by direct combination, either in the dry or in the wet way; the rest either by fusing tellurous oxide with the respective bases, or by precipitation. The neutral and acid tellurites of alkali-metal are soluble in water; the tellurites of the alkaline earth-metals are slightly soluble; and those of the earth-metals and heavy metals are insoluble. Most tellurites are soluble in hydrochloric acid. The solutions are yellow, and do no not give off chlorine when heated, a character by which the tellurites are distinguised from the tellurates. If the quantity of hydrochloric acid present in these solutions is not very great, they deposit tellurous acid on dilution with water; this precipitation is, however, prevented by the presence of tartaric acid. Tellurites are mostly fusible, and solidify to a crystalline mass on cooling; the hyperacid tellurites of alkali-metal form colourless glasses after fusion. Most tellurites, when ignited with charcoal and potash, yield tellurite of potassium, which dissolves with portwine-colour in water.

Tellurite of Aluminium is a white flocculent precipitate.

Tellurite of Ammonium.—A solution of tellurous acid in ammonia gives off ammonia by evaporation, even at a very gentle heat, and yields a precipitate of tellurous acid.—According to Flückiger (Jahresb. 1862, p. 173), tellurite of ammonium is produced by heating tellurium with aqueous ammonia in sealed tubes.—The *hyperacid salt*, $(NH^4)^2O.4TeO^2.4H^2O$, or $(NH^4)HTeO^3.H^2TeO^3.3\frac{1}{2}H^2O$, is formed by dissolving tellurous acid or tetrachloride of tellurium in warm aqueous ammonia, and separates, on adding a little sal-ammoniac to the cooled solution, as a heavy white granular precipitate; a further quantity may be precipitated from the filtrate by alcohol. It is resolved by heat into ammonia, water, and tellurous oxide. (Berzelius.)

Tellurites of Barium.—The *neutral salt*, $Ba''TeO^3 = Ba''O.TeO^2$, is produced by fusing 1 at. tellurous oxide with 1 at. barium-carbonate, and solidifies, on cooling, to a colourless crystalline mass; by double decomposition it is obtained as a white, bulky, flocculent precipitate. It is sparingly soluble in water, the solution when exposed to the air depositing carbonate and tetratellurite of barium.

The *tetratellurite*, $Ba''O.4TeO^2 = Ba''TeO^3.3TeO^2$, prepared by fusing 4 at. tellurous oxide with 1 at. barium-carbonate, solidifies to a transparent colourless glass. It is also produced by mixing the aqueous solution of the neutral salt with very dilute nitric acid, and then separates in bulky flakes.

Tellurite of Cadmium is a white gelatinous precipitate, which dries up to a brittle mass, having a conchoïdal fracture. It dissolves in hydrochloric and in nitric acid. Ammonia added to these solutions, throws down cadmium-oxide; sulphydric acid and sulphide of ammonium produce in the cold a brown-red precipitate of cadmium-sulphotellurite. (Oppenheim.)

Tellurites of Calcium.—The *neutral salt*, $Ca''TeO^3$, produced by heating 1 at. tellurous oxide with 1 at. lime, forms a white mass, which remains solid at the melting-point of silver. By precipitation, it is obtained in white flocks, slightly soluble in cold, more soluble in hot water.—The *ditellurite*, $Ca''O.2TeO^2 = Ca''TeO^3.TeO^2$, melts only at a white heat, and solidifies on cooling to an opaque mass, consisting of micaceous scales.—The *tetratellurite*, $Ca''O.4TeO^2 = Ca''TeO^3.3TeO^2$, fuses more easily, giving off fumes of tellurous oxide, and likewise solidifies in micaceous scales. (Berzelius.)

Tellurite of Chromium is a grey-green precipitate, soluble in excess of the chromic salt.

Tellurite of Cobalt is a dark-purple precipitate.

Tellurite of Copper, obtained by precipitation, is a siskin-green powder, insoluble in water; when heated, it gives off water and turns black, melts easily, and solidifies to a black mass, having a conchoïdal fracture, and yielding a grey-brown powder. Before the blowpipe, it is reduced to a pale-red mass of copper-telluride. It may be fused with 1 at. cupric oxide, to a black mass having an earthy fracture. (Berzelius.)

Tellurites of Iron.—The *ferric salt* is a yellow flocculent precipitate.—The *ferrous salt* is greyish-yellow.

Tellurites of Lead.—The *neutral salt*, $Pb''TeO^3$, obtained by double decomposition with neutral acetate of lead, is a white precipitate, which when heated gives off water, turns yellow, and then melts to a translucent mass. It dissolves readily in acids, and is easily reduced before the blowpipe on charcoal to telluride of lead.—A *basic lead-salt* is produced, as a translucent bulky precipitate, on mixing tellurite of potassium with basic acetate of lead.

Tellurites of Lithium.—The *neutral salt*, $Li^2TeO^3 = Li^2O.TeO^2$, obtained by fusion, solidifies to a crystalline or tumefied mass, according to the rate of cooling.—The *ditellurite*, $Li^2O.2TeO^2$, prepared like the corresponding potassium-salt, is easily fusible, and solidifies to a crystalline mass on cooling. Cold water decomposes it into mono- and tetra-tellurite. Boiling water dissolves it, and the solution on cooling deposits the *tetratellurite*, $Li^2O.4TeO^2$, in milk-white granules. (Berzelius.)

Tellurites of Magnesium.—The *neutral salt*, $Mg''TeO^3$, obtained by precipitation, is much more soluble than the other alkaline-earthy tellurites. Its solution is decomposed by atmospheric carbonic acid into carbonate and tetratellurite of magnesium, which separates in white flocks. (Berzelius.)

Tellurite of Manganese is precipitated in white flocks having a reddish tinge.

Tellurites of Mercury.—The *mercuric salt* is a white precipitate.—The *mercurous salt* is dark-yellow, gradually turning brown, and is converted into mercuric salt on exposure to the air.

Tellurite of Nickel is a pale-green flocculent precipitate.

Tellurites of Potassium.—The *neutral* or *monotellurite*, $K^2TeO^3 = K^2O.TeO^2$, and the *ditellurite*, $K^2TeO^3.TeO^2 = K^2O.2TeO^2$, are obtained by fusing tellurous oxide with carbonate of potassium in the requisite proportions. The *monotellurite* melts at a red heat, and solidifies on cooling to a network of rather large regular crystals. It is slowly dissolved by cold, more quickly by boiling water; the solution has an alkaline taste and reaction, and is decomposed by the carbonic acid of the air.

The *ditellurite* melts, somewhat below a red heat, to yellow liquid, which solidifies on cooling to a colourless, transparent, crystalline mass. Boiling water dissolves it completely, and the solution on cooling deposits the tetratellurite as a granular precipitate.

The *tetratellurite*, or *hyperacid tellurite of potassium*, $K^2O.4TeO^2.4H^2O = 2(KHTeO^3.H^2TeO^3).H^2O$, is prepared by boiling tellurous acid for some time with carbonate of potassium, and filtering at the boiling heat. The solution, on cooling, deposits the greater part of the salt in nacreous grains, which appear under the microscope as six-sided prisms and tables. It is decomposed by cold water into mono- and di-tellurite, which dissolve, and tellurous acid, which separates as a gelatinous precipitate. The dry salt when heated gives off its water with strong intumescence, leaving the anhydrous salt, $K^2O.4TeO^2$, which melts at commencing redness, and solidifies to a colourless glass on cooling. (Berzelius.)

Tellurite of Silver, $Ag^2.TeO^3$, is a white precipitate, soluble in ammonia (Berzelius). When native telluride of silver is dissolved in nitric acid, the solution deposits, after a while, small, adamantine, acuminated, quadratic prisms, insoluble in water, and containing more than 1 at. TeO^2 to 1 at. Ag^2O. (G. Rose.)

Tellurites of Sodium.—The *neutral salt*, $Na^2TeO^3 = Na^2O.TeO^2$, obtained like the corresponding potassium-salt, forms regular crystals when slowly cooled, but swells up considerably on rapid cooling. It dissolves slowly but completely in cold water, more quickly in hot water, but does not crystallise out on cooling. Alcohol throws down from the solution a concentrated liquid, which, after a few days, yields large transparent crystals of a hydrated salt.—The *ditellurite*, $Na^2TeO^3.TeO^2 = Na^2O.2TeO^2$, obtained by fusion, like the corresponding potassium-salt, melts easily, and crystallises on cooling. It is decomposed by water, like the potassium-salt.—The *tetratellurite* or *hyperacid salt*, $Na^2O.4TeO^2.5H^2O$, or $NaHTeO^3.H^2TeO^3.H^2O$, separates from the boiling solution of the preceding salt, by slow cooling, in nacreous scales and thin six-sided tables; in other respects it resembles the hyperacid potassium-salt. (Berzelius.)

Tellurite of Strontium (neutral) is prepared like the barium-salt, which it resembles.

The *Tellurites of Thorinum, Yttrium*, and *Zirconium* are white precipitates.

Tellurite of Uranium, obtained by precipitation with a uranic salt, is a pale lemon-yellow powder.

Tellurite of Zinc is a white flocculent precipitate.

Telluric Oxide, TeO^3.—This oxide is obtained by heating the hydrate to a temperature below redness. It forms an orange-yellow mass, insoluble in water, either hot or cold, in cold hydrochloric and hot nitric acid, and in solutions of caustic alkali. When strongly heated, it gives off oxygen, and leaves tellurous oxide as a white earthy powder.

TELLURIC ACID, $H^2TeO^4 = H^2O.TeO^3$.—The potassium-salt of this acid is obtained by fusing tellurium or tellurous oxide with nitrate of potassium. The solution of this salt decomposed by a salt of barium, yields a precipitate of barium-tellurate, from which, by decomposition with sulphuric acid, telluric acid may be set free.

Telluric acid crystallises from its solution, in fine hexagonal hydrated prisms, containing $H^2TeO^4.2H^2O$, mostly forming twins. This hydrate has a metallic rather than an acid taste, and reddens litmus slightly. It dissolves slowly, but to a considerable amount in cold water, freely in boiling water. It loses its water of crystallisation at a little above 100°. The remaining acid, H^2TeO^4, is nearly insoluble in cold water, but dissolves on boiling, forming a solution from which the crystalline hydrate may be again obtained.

TELLURATES.—Telluric acid forms with the alkali-metals, neutral, acid, and hyperacid salts, represented by the formulæ, M^2TeO^4, $MHTeO^4$, and $MHTeO^4.H^2TeO^4$, respectively; also anhydrous di- and tetra-tellurites. With the other metals it forms chiefly neutral salts. The neutral and acid tellurates of alkali-metal are easily soluble in water, the anhydrous di- and tetra-tellurites sparingly soluble. Most of the other tellurates are insoluble or sparingly soluble, and are obtained by precipitation.

Most tellurates dissolve readily in cold hydrochloric acid. The solutions are not yellow, like those of the tellurites, and will bear any amount of dilution without precipitation. On boiling they give off chlorine, turn yellow, and become precipitable by water, owing to the formation of tellurous acid. The acidulated solutions of tellurates and telluric acid are decomposed, like those of the tellurites, but not very readily, by *sulphydric acid*, with precipitation of a sulphide; and by *sulphurous acid* and other reducing agents, with precipitation of tellurium, though somewhat slowly, and frequently only on the application of heat. Hence, in analysing tellurites by reduction, they should always be previously reduced to tellurites by boiling with hydrochloric acid. Tellurates when heated to redness give off oxygen, and are reduced to tellurites. Heated with charcoal and alkaline carbonate, or before the blowpipe on platinum, they behave like tellurites.

Tellurate of Aluminium is obtained by double decomposition as a white precipitate, soluble in excess of the aluminium-salt.

Tellurates of Ammonium.—The *neutral salt*, $(NH^4)^2TeO^4$, is prepared by mixing a boiling solution of the neutral potassium-salt with sal-ammoniac and a little ammonia, and separates on cooling in granular crystals, easily soluble in water, sparingly soluble in solution of ammonia or sal-ammoniac.—The *ditellurite*, $(NH^4)^2TeO^4.TeO^3 = (NH^4)^2O.2TeO^3$, is precipitated, on mixing a saturated solution of the acid sodium-salt with sal-ammoniac, as a gelatinous mass, only slightly soluble in water. When boiled with water in open vessels, it gives off ammonia; but when heated with water in sealed tubes, it partly melts to a white mass, which solidifies on cooling, and partly dissolves in the water, the solution on cooling depositing fine crystalline grains [? of the acid salt].—The *tetratellurite*, $(NH^4)^2TeO^4.3TeO^3 = (NH^4)^2O.4TeO^3$, is obtained, by decomposing the hyperacid sodium-salt with sal-ammoniac, as a white flocculent precipitate; it likewise separates from the solution of the neutral salt by evaporation at ordinary temperatures, or at a gentle heat. It dissolves with difficulty in water, and is nearly insoluble in alcohol. (Berzelius.)

Tellurates of Barium.—These salts are obtained by precipitation.—The *neutral salt*, Ba separates as a bulky precipitate, which soon sinks down, and forms a white powder when dry. It gives off water at 200°, dissolves sparingly in cold, more easily in boiling water.—The *acid salt*, $Ba''H^2(TeO^4)^2.2H^2O$, is a bulky flocculent mass, more soluble in water than the neutral salt.—The *anhydrous tetratellurate*, $Ba''O.4TeO^2$, is a bulky mass, more soluble in water than either of the preceding [is it really anhydrous?]. It turns yellow when heated, but becomes white again on cooling. (Berzelius.)

Tellurate of Cadmium, $Cd''TeO^4$, is obtained, as an amorphous white precipitate, on mixing the neutral solutions of cadmium-nitrate and a tellurate of alkali-metal. (Oppenheim.)

Tellurates of Calcium, $Ca''TeO^4$, is precipitated in white non-coherent flocks, soluble in hot water. (Berzelius.)

Tellurate of Chromium forms grey-green flocks, reddish by transmitted light; it dissolves in excess of the chromic salt, by which it is precipitated.

Tellurate of Cobalt is precipitated in bluish-red bulky flakes.

Tellurates of Copper.—The *neutral salt* is a celandine-green precipitate; the *acid salt* is somewhat lighter.

Tellurates of Iron.—The *ferric salt* separates as a pale-yellow flocculent precipitate, soluble in excess of the precipitating ferric salt.—The *ferrous salt* is a white precipitate, quickly changing colour in the air like other ferrous salts.

Tellurates of Lead.—Obtained by precipitation.—The *neutral salt*, $Pb''TeO^4 = Pb''O.TeO^3$, is a white precipitate, somewhat soluble in water.—The *ditellurate*, $Pb''O.2TeO^3$, is somewhat more soluble.—The *tetratellurate*, $Pb''O.4TeO^3$, turns yellow when heated, but becomes white again on cooling: it is moderately soluble in water.—A *basic lead-salt* separates, as a white bulky precipitate insoluble in water, on mixing the solution of a neutral tellurate of alkali-metal with basic acetate of lead (Berzelius).—A *nitrato-tellurate of lead* is formed (according to Oppenheim) on mixing a solution of lead-nitrate with free telluric acid; it is a white powder.

Tellurates of Lithium.—Prepared like the corresponding potassium-salts. The *neutral* and *acid salts* dry up to gummy masses.—The *hyperacid salt* is also a gummy mass, which is converted at 100° into a white insoluble powder; at a still higher temperature, it gives off water and turns yellow. (Berzelius.)

Tellurates of Magnesium.—These salts, being much more soluble in water than the tellurates of the other alkaline earth-metals, must be precipitated from very concentrated solutions.—The *neutral* and *acid salts* are white flocculent precipitates. (Berzelius.)

Tellurate of Manganese separates in white flocks, having a faint reddish tinge.

Tellurates of Mercury.—The *mercuric salt* is precipitated in bulky white flocks.—The *mercurous salt* is a dark yellowish-brown precipitate.—A *mercurous nitrato-tellurate* is produced (according to Oppenheim) by adding free telluric acid to a concentrated solution of mercurous nitrate. It forms at first a white curdy precipitate, but acquires a faint yellow colour on exposure to the air.

Tellurate of Nickel is precipitated in pale-greenish flocks.

Tellurates of Potassium.—These salts are prepared by dissolving the required quantities of telluric acid and potassium-carbonate in hot water.—The *neutral salt*, $K^2TeO^4.5H^2O$, may also be prepared by supersaturating crystallised telluric acid, or its concentrated aqueous solution, with caustic potash. It is very slightly soluble in water containing potash, and separates therefrom as a soft gummy coagulum. It dissolves on warming the liquid, and separates by slow cooling in needle-shaped crystals, which when heated give off water, and cake together in a white mass. According to Handl (Jahresb. 1861, p 266), it forms rhombic crystals of prismatic character, isomorphous with those of neutral potassium-sulphate, and exhibiting the combination $\infty\breve{P}2 . P . \infty\breve{P}\infty . \infty\breve{P}\infty$. Angle $\infty\breve{P}2 : \infty\breve{P}2 = 69° 11'$; $P : \infty\breve{P}\infty = 123° 42'$; $P : P$ (in the terminal edges) $= 122° 36'$ and $132° 16'$. When exposed to the air, they become moist, without deliquescing, and are converted into a mixture of acid tellurate and carbonate of potassium. On mixing the solution of the salt with a stronger acid, it deposits acid or hyperacid tellurate of potassium, according to the quantity of acid added (Berzelius).—The *acid salt*, $2KHTeO^4.3H^2O$, is sparingly soluble in cold, much more soluble in hot water, and separates from the hot solution by slow cooling, in fine woolly crystallisations. On evaporating the aqueous solution over a water-bath, it remains as a white saline mass, gummy on the edges. It has an alkaline reaction, and a metallic, somewhat alkaline taste. When heated, it gives off its water, and turns yellow even far below redness. Water decomposes the yellow mass, dissolving neutral tellurate of potassium, and leaving yellow tetratellurate (Berzelius).—The *hyperacid salt*, $2(KHTeO^4.H^2TeO^4).H^2O$, is a loose white powder, somewhat soluble in water. It gives off the greater part of its water at a gentle heat, retaining however a small quantity till it turns yellow; at a higher temperature, it is reduced to tellurite. By repeated crystallisation from its aqueous solution, it is partially decomposed, the crystals becoming mixed with those of the acid salt, while free telluric acid remains in the mother-liquor (Berzelius).—The *anhydrous tetratellurate*, $K^2O.4TeO^3$, may be obtained by heating the acid tellurate to a temperature below redness, whereupon it breaks up into water, which is evolved; neutral tellurate of potassium, which may be dissolved out; and the anhydrous tetratellurate, which remains undissolved as a yellow mass, insoluble in hydrochloric acid and in nitric acid, except after prolonged boiling. Its formation is represented by the equation:

$$6KHTeO^4 = 2K^2TO^4 + K^2TeO^4.3TeO^3 + 3H^2O.$$

Tellurates of Silver.—Telluric acid forms a neutral salt, two acid salts, and two basic salts of silver. The neutral and acid salts are obtained by double decomposition with concentrated solutions of silver-nitrate and neutral tellurate of alkali-metal.—The *neutral salt*, Ag^2TeO^4, is a dark-yellow powder, which is resolved by water, especially at the boiling heat, into a soluble acid and an insoluble basic salt. Its ammoniacal solution is colourless.—A *nitrato-tellurate of silver* separates, immediately on adding telluric acid to a concentrated solution of silver-nitrate, as a colourless crystalline precipitate, which turns slightly yellow in contact with the air, and brown when moistened with ammonia. Hydrochloric acid decomposes it, with separation of silver-chloride (Oppenheim).—The *ditellurate* and *tetratellurate of silver* are reddish-yellow flocculent precipitates.

The *tribasic salt*, $3Ag^2O.TeO^3 = 2Ag^2O.Ag^2TeO^4$, is produced on mixing the ammoniacal solutions of the neutral salt and silver-nitrate, and remains on evaporation as a black-brown saline mass.—The same compound separates as a reddish-yellow precipitate, quickly turning brown, on mixing a very dilute solution of silver-nitrate with acid tellurate of potassium.—The *sesquibasic salt*, $3Ag^2O.2TeO^3$, remains as an anhydrous liver-coloured powder, on boiling the neutral salt with water. (Berzelius.)

Tellurates of Sodium.—These salts resemble the corresponding potassium-salts, and are prepared in like manner.

Tellurate of Strontium is prepared like the calcium-salt, which it resembles.

Tellurate of Thorinum is a white pulverulent precipitate, insoluble in excess of the thorinum-salt.

Uranic tellurate is a pale-yellow powder.

Tellurates of Yttrium.—The *neutral tellurates* and *ditellurates* are obtained by precipitating the neutral and acid tellurates of potassium with an yttrium-salt.

Tellurate of Zirconium, obtained by double decomposition, is a white powder.

TELLURIUM, SELENIDE OF. Tellurium and selenium may be fused together in all proportions, the combination being attended with evolution of heat. The product is an iron-grey brittle mass, which has a crystalline fracture, melts below a red heat, boils at a higher temperature, and may be volatilised without decomposition if excluded from the air. When heated in contact with the air, it yields colourless drops, possibly consisting of a selenate of tellurium. (Berzelius.)

TELLURIUM, SULPHIDES OF. Tellurium forms two sulphides corresponding to the oxides.

Tellurous Sulphide, TeS^2, is formed by the action of sulphydric acid on a tellurous salt, or on the acidified solution of a tellurite (p. 711); also by exposing the solution of a sulphotellurite of alkali-metal to the air. It is a dark-brown or black substance, which softens at a moderate heat, and acquires a semi-metallic lustre on cooling. When strongly heated it evolves sulphur.

Tellurous sulphide combines with the sulphides of basylous metals, forming the sulphotellurites, all of which appear to contain 3 at. basylous sulphide to 1 at. tellurous sulphide, being represented by the general formula $3M^2S.TeS^2 = 2M^2S.M^2TeS^3$.

The sulphotellurites of the *alkali-metals* and of *magnesium* are most readily prepared by saturating the aqueous solutions of the corresponding tellurites with sulphydric acid gas. The solid anhydrous sulphotellurites of alkali-metal have a brownish-yellow colour; those which contain water of crystallisation are pale-yellow; they dissolve easily and with pale-yellow colour in water; less easily in alcohol, with separation of tellurous sulphide. Acids added to the solutions throw down tellurous sulphide. In the dry state these salts may be ignited in close vessels without decomposition, and at ordinary temperatures they remain unaltered for a considerable time in contact with the air; but their solutions decompose quickly in contact with the air, with formation of alkaline hyposulphite, and separation of tellurous sulphide.—The *ammonium-salt*, $3(NH^4)^2S.TeS^2$, crystallises by evaporation in a vacuum over potash, in pale-yellow four-sided prisms, which give off sulphide of ammonium in contact with the air.—The *potassium-salt*, $3K^2S.TeS^2$, separates by evaporation in a vacuum, in pale-yellow prisms, easily melting to a black liquid, which solidifies to a brown-yellow mass still soluble in water. In contact with the air, the salt decomposes and turns black.—The *sodium-salt* forms an amorphous pale-yellow mass, which decomposes quickly in contact with the air.—The *lithium-salt* exhibits similar characters.—The *magnesium-salt*, which may be prepared as above, or by precipitating the barium-salt with magnesium-sulphate, and evaporating the filtrate in a vacuum, forms a pale-yellow crystalline mass, soluble in water and in alcohol.

The sulphotellurites of the *alkaline earth-metals* are prepared by boiling the corresponding metallic sulphides with tellurous sulphide and water.—The *barium-salt* separates, on evaporating the filtrate in a vacuum, in large, transparent, pale-yellow, obliquely truncated, four-sided prisms. It is tolerably permanent in the air, and dissolves very slowly in water.—The *strontium-salt* forms a pale-yellow mass, tolerably permanent in the air, and soluble in water.—The *calcium-salt* is a yellow amorphous mass, somewhat soluble in water.

The sulphotellurites of the *heavy metals* are insoluble in water, and are obtained by precipitation.—The *cadmium-* and *cerium-salts* are brown-yellow precipitates, which gradually become darker in colour.—The *ferric salt* forms dark-brown, easily fusible flocks; the *ferrous salt* is a black precipitate.—The *gold-salt* (auric), $AuS^3.TeS^2$, is deposited, after some days, in black flocks, from a mixture of auric chloride and potassium-sulphotellurite.—The *lead-salt* is a brown precipitate, which turns black on drying.—The *mercurous salt*, $3Hg^2S.TeS^2$, is a dark-brown precipitate, which when heated gives off mercury, and is converted into a yellow-brown mass of the *mercuric salt*, $3HgS.TeS^2$.—The *platinic salt*, $3PtS^2.2TeS^2$, separates after some days, from a mixture of platinic chloride and potassium-sulphotellurite, in translucent dark-blue flocks, which appear black when dry.—The *silver-salt*, $3Ag^2S.TeS^2$, is a bulky black precipitate, which when dry acquires metallic lustre by trituration.—The *zinc-salt*, $3ZnS.TeS^2$, is a light-yellow precipitate which gradually turns brown.

Telluric Sulphide, TeS^3.—This compound is produced by saturating a solution of telluric acid with sulphydric acid gas, and gradually separates on leaving the liquid to itself in a closed vessel placed in a warm situation, covering the sides of the vessel with a blackish-grey, metallically lustrous coating, which may be rubbed off in spangles. It unites with basylous metallic sulphides, forming the sulphotellurates, which, however, have been but little investigated. (Berzelius.)

Sulphotellurate of Potassium is obtained by saturating a solution of potassium-tellurate with sulphydric acid gas. After the liquid has been filtered from the resulting black precipitate of telluric sulphide, which does not redissolve on adding potash and again passing sulphydric acid gas into the liquid, the filtrate may be concentrated by boiling without decomposition. The liquid then acquires a red colour, and deposits sulphotellurate of potassium as a light-yellow granulo-crystalline mass. (Oppenheim, J. pr. Chem. lxxi. 279.)

Sulphotellurate of Sodium is prepared like the potassium-salt. On adding soda-ley after the precipitate of telluric sulphide has settled down, and again passing sulphydric acid gas into the liquid, the precipitate quickly redissolves; and on evaporating the solution nearly to dryness, the sulphotellurate of sodium separates, in needle-shaped crystals of a sulphur-yellow colour. (Oppenheim.)

TELLUROMETHYL. See METHYL, TELLURIDE OF, iii. 992.

TELLUROUS SALTS. Salts formed by dissolving tellurous hydrate in acids (p. 713).

TEMPERATURE. See HEAT (iii. 18).

TEMPERING. The softening of steel, cast-iron, and other metals by ignition and slow cooling.

TEMPLIN-OIL. *Oil of Pine-cones. Tannenzapfenöl.*—An oil isomeric with, and very similar to, oil of turpentine, obtained by distillation of the cones of *Pinus Pumilio*, Hnk. (*P. Mughus*, Scop.), and in some parts of Switzerland from the cones of the silver-fir (*Abies Picea*, *Pinus Picea* L. *Abies pectinata*, Dec.). When recently prepared by distillation with water, it is colourless, but becomes greenish-yellow on exposure to the air. It has a balsamic odour, like that of lemon-oil; a specific gravity of 0·862 at 12°; begins to boil at 155°; but the greater part distils over between 173° and 177°, the boiling-point ultimately rising to 200°. By repeated rectification a camphene, $C^{10}H^{16}$, is obtained, having a specific gravity of 0·856 at 6°, and boiling constantly at 172°. (Flückiger, Jahresb. 1856, p. 642.)

Templin-oil agrees with oil of turpentine in solubility and refracting power. I column 100 millimetres long, it turns the plane of polarisation 85° to the left for the transition-tint, and 66° for the red ray: the oil obtained from it by rectification below 173° turns the plane of polarisation 92° to the left for the transition-tint. (Berthelot, J. Pharm. [3], xxix. 38.)

Templin-oil resinises quickly on exposure to the air, and turns acid, with formation of ozone. When mixed with ¼ vol. nitric acid and ⅛ vol. alcohol, it forms terpin or hydrate of turpentine, more quickly on addition of 1¼ vol. water. It absorbs hydrochloric acid gas, but without forming a crystallisable camphor. When the oil, saturated with hydrochloric acid gas, is treated with fuming nitric acid, a crystalline compound, $C^{10}H^{16}.HCl$, is formed, having a rotatory power of $-23°$. When templin-oil is mixed with one-third of its weight of absolute alcohol, and then saturated with hydrochloric acid gas, the liquid solidifies to a magma of the camphoroïdal compound, $C^{10}H^{16}.2HCl$, insoluble in water and in cold alcohol, but easily soluble in hot alcohol, from which solution it crystallises in laminæ. It dissolves in volatile and fixed oils in nitric acid and in sulphuric acid, melts at 55°, and solidifies to a radio-crystalline mass on cooling, but is not volatile without decomposition.

The oil obtained from the young branches and needles of *Pinus Pumilio* (iv. 649) is probably identical with templin-oil.

TENNANTITE. An arsenical fahl-ore from the Cornish mines, particularly near Redruth and St. Day, occurring in well-defined, monometric, tetrahedral crystals, isomorphous with tetrahedrite, and exhibiting imperfect dodecahedral cleavage. Hardness = 3·5 to 4. Specific gravity = 4·4 to 4·9. Lustre metallic. Colour, blackish lead-grey to iron-black; streak, dark reddish-grey. Fracture uneven. Before the blowpipe it emits copious arsenical fumes, and finally melts to a black scoria, which acts upon the magnet.

Analyses: *a* by Wackernagel; *b* by Rammelsberg (*Mineralchemie*, p. 88):

	S.	As.	Cu.	Fe.		
a.	26·88	20·53	48·68	3·09	=	99·18
b.	26·61	19·03	51·62	1·95	=	99·21

These analyses may be represented by the formula $(Cu^2; Fe'')S.2As^2S^3$, different from that of arsenical tetrahedrite—namely, $4M''S.As^2S^3$.

TENORITE. Native cupric oxide, occurring, according to Semmola (Bull. géol. xiii. 206), in the cracks and pores of Vesuvian lava, above Torre del Greco, forming very thin hexagonal plates, scales, and earthy particles, having a dark steel-grey colour, and metallic to dull lustre. Thin laminæ exhibit a brown translucence.

TEPHROITE. Orthosilicate of manganese, $Mn''SiO^4$, from Sparta, New Jersey. (See SILICATES, p. 254.)

TEPHROSIA. The leaves of *Tephrosia apollinea* (Dec.), a leguminous plant indigenous in Upper Egypt, are very much like those of *Cassia obtusa*, and are said to occur in commerce as *Folia sennæ halipensia*. (Nees v. Esenbeck, J. Pharm. [3], vi. 185.)

TERACRYLIC ACID. Syn. with PYROTEREBIC ACID (iv. 776).

TERATOLITE. Ferruginous lithomarge, from the coal-beds near Zwickau, in Saxony.

TERATONATRITE. Syn. with Glauber's salt.

TERBIUM and **ERBIUM.** Metals supposed to exist, together with yttrium, in the gadolinite of Ytterby, in Sweden. Mosander in 1843 (Ann. Ch. Pharm. xlviii. 220) examined the crude yttria obtained from gadolinite, by the process of Berzelius (see YTTRIUM), and concluded that it was a mixture of three earths of different basic power. The most basic of these—which was first precipitated from solution of the earth in hydrochloric acid by ammonia—he designated as erbia, the next as terbia, retaining the name of yttria for the least basic. A more complete separation is effected by fractional precipitation with an acid oxalate. For this purpose, the crude yttria is dissolved in excess of hydrochloric acid, and the liquid is added by drops to a solution of acid potassium-oxalate, as long as the resulting precipitate redissolves on agitation. The crystalline precipitate, chiefly consisting of erbium-oxalate, which then separates after some hours, is collected on a filter; and the filtrate is gradually mixed with more potassium-oxalate, which throws down a fresh precipitate containing a larger proportion of terbium, while the last precipitates contain scarcely anything but yttrium. The first precipitates are almost always reddish; the last are colourless. On the other hand, when a mixture of the oxalates of erbium, terbium, and yttrium is digested with dilute sulphuric acid, the yttrium-salt is chiefly dissolved at first, then the terbium, and lastly the erbium-salt. (Mosander).

The metals erbium and terbium have not been isolated. The characters of erbium-oxide or erbia, and of one or two erbium-salts, as determined by Mosander, have been already described (ii. 497); erbia is especially distinguished by being yellow after ignition in the air, and becoming colourless by ignition in hydrogen.

The characters of terbium-oxide or terbia are not described by Mosander; but its salts are described as having a saccharine and astringent taste. In the solid state, they exhibit an amethyst-colour, but not of constant tint or intensity.—The *nitrate* is a rose-red, crystalline, deliquescent mass, and its solution becomes coloured during evaporation, even before any separation of crystals takes place.—The *sulphate* forms crystals, which are larger than those of yttrium-sulphate, and effloresce at about 50°, crumbling to a white powder. (Mosander.)

Subsequent investigations by different chemists have, however, thrown considerable doubt on the existence of terbium. Berlin in 1860,[*] in applying the preceding method of separation on a larger scale, obtained only erbia and yttria, the intermediate precipitates being always resolvable, by repeated fractional precipitation, into the oxalates of erbium and yttrium. He was also unable to obtain the sulphate efflorescing at 50°, which Mosander describes as distinguishing terbium from erbium.

Similar results have been obtained by Popp (Ann. Ch. Pharm. cxxxi. 179), who moreover finds that the absorption-spectrum of an erbium-solution exhibits certain bands, identical with those of didymium (ii. 322); and that on passing chlorine through the solution of an erbium-salt mixed with sodium-acetate, and heated to the boiling-point, the peculiar yellow precipitate characteristic of cerium (i. 831) is obtained. Hence Popp concludes that the supposed earths, erbia and terbia, are nothing but yttria contaminated with the oxides of the cerium-metals. His experiments cannot, however, be considered as disproving the existence of erbium, inasmuch as mixtures of erbium-salts with those of cerium and didymium might exhibit the characters above mentioned; but Popp's results agree with those of Berlin, in tending to show that Mosander's terbia is really a mixture of erbia and yttria; and this conclusion is further corroborated by the recent experiments of Bahr and Bunsen (Ann. Ch. Pharm. cxxxvii. 1). These chemists separate erbia and yttria as follows.

The precipitate formed by oxalic acid, in the solution obtained by heating gadolinite with hydrochloric acid, contains the oxalates of erbium and yttrium, besides those of calcium, cerium, lanthanum, and didymium, with traces of manganous oxalate and silica. These oxalates are converted into nitrates; the solution is treated with sulphate of potassium, with the usual precautions (i. 831), to separate the cerium-metals; the erbium and yttrium, which still remain in solution, are again precipitated by oxalic acid; the oxalates are ignited; and the residual oxides, after being carefully freed from admixed potassium-carbonate by boiling with water, are dissolved in nitric acid, and again precipitated from the acid solution by oxalic acid, this series of operations being repeated till the solution of the mixed earths in nitric acid, when examined in the spectral apparatus, no longer exhibits the absorption-bands characteristic of didymium. The last portions of calcium and magnesium are separated by precipitating the acid solution of the mixed earths with ammonia, the calcium and magnesium then remaining in solution; the precipitate is dissolved in nitric acid; and the solution, now containing nothing but erbia and yttria, is precipitated by oxalic acid.

To separate the erbia and yttria, the oxalates are converted into nitrates; the solution is evaporated in a platinum-dish, till the first bubbles of nitrous acid make their appearance; and the dish is quickly cooled by placing it in cold water, whereupon the viscid mass solidifies to an extremely brittle glass. On dissolving the mass in a quantity of warm water just sufficient to prevent the solution from becoming turbid on boiling, nitrate of erbium, still containing yttrium, separates on slow cooling in needles, which must be separated from the mother-liquor by decantation, and quickly rinsed with water containing about 3 per cent. of nitric acid. This mother-liquor, treated in a similar manner, yields a second crop of crystals of erbium-nitrate containing yttrium; the mother-liquor of these yields a third crop, and so on, the proportion of yttrium-nitrate in the successive crops of crystals continually increasing. By mixing a certain number of the earlier and comparatively pure crops of crystals, and treating them in a similar manner, products are obtained of still greater purity; and by repeating this mode of treatment several times, nitrate of erbium is ultimately obtained containing no appreciable quantity of yttrium.

Pure erbia, obtained by ignition of the nitrate or oxalate, has a faint rose-red colour (not yellow, as stated by Mosander). It does not melt at the strongest white heat, but aggregates to a spongy mass, glowing with an intense *green* light, which, when examined by the spectroscope, exhibits a *continuous* spectrum intersected by a number of bright bands. Solutions of erbium-salts, on the other hand, give an absorption-spectrum exhibiting dark bands, and *the points of maximum intensity of the light bands in the emission-spectrum of glowing erbia coincide exactly in position with the points of greatest darkness in the absorption-spectrum.* The position of these bands is totally different from those in the emission- and absorption-spectra of didymium; in fact, there is not a single line of the erbium-spectrum which corresponds with that of didymium. (Bahr and Bunsen.)*

---

[*] Forhandlinger ved de Skandinaviske Naturforskeres attende Möde i Kjöbenhaven, 1860, p. 448.

Erbia is a protoxide, $Eb''O$, containing 87·6 per cent. erbium and 12·4 oxygen; it does not unite directly with water. It dissolves slowly but completely in warm hydrochloric, nitric, and sulphuric acids. The erbium-salts have a rose-red colour, deeper in the hydrated than in the anhydrous state; they have an acid reaction and sweet astringent taste.—*Nitrate of Erbium*, obtained as above described, is a basic salt, $Eb''(NO^3)^2.Eb''O.3H^2O$, crystallising in small imperfectly-defined needles, having a light rose-colour, permanent in the air, giving off their crystallisation-water at a moderate heat, and being converted into erbia at a red heat without change of form. It dissolves with difficulty in nitric acid, and is decomposed by water into nitric acid and a gelatinous hyperbasic salt.—The *sulphate*, $3Eb''SO^4.8H^2O$, isomorphous with the sulphates of yttrium and didymium, forms light rose-coloured crystals, which give off their water of crystallisation when heated, and recover it with great rise of temperature when moistened with water. The hydrated salt dissolves very slowly in water, the anhydrous salt very quickly, a character exhibited also by the sulphates of the cerium-metals. It is partially decomposed by ignition.—The *oxalate*, $C^2Eb''O^4.H^2O$, is precipitated from boiling acid solutions of erbium-salts as a light rose-coloured, heavy, sandy powder, which may be easily washed by decantation, and does not give off its water till heated nearly to the temperature at which it decomposes.

The mother-liquors from the several crystallisations of erbium-nitrate contain nitrate of yttrium, together with a certain quantity of the erbium-salt and the nitrates of the cerium-metals, which have not gone down with the nitrate of erbium in the successive crystallisations, but have accumulated in the mother-liquors. To obtain a pure yttrium-salt, therefore, the cerium-metals must, in the first place, be removed by repeated treatment with sulphate of potassium, till the remaining solution, when examined by the spectroscope, shows no trace of the didymium-lines. The sulphate of yttrium thus far purified, but still containing erbium, is next reconverted into nitrate; the solution of this salt is evaporated; the residue heated nearly to redness; and the resulting mixture of the oxides and hyperbasic nitrates of yttrium and erbium is treated with cold water, whereby a solution is obtained, containing nitrate of yttrium with less erbium-salt than before, and a residue rich in erbium; and by repeating this treatment several times, a nitrate of yttrium is at length obtained, which exhibits no trace of an absorption-spectrum, and when ignited leaves pure colourless yttria. (See YTTRIUM.)

The result of the whole series of operations is, therefore, to separate the crude yttria obtained from gadolinite into two earths, yttria and erbia, without any indication of an earth (the so-called terbia) of intermediate basicity.

On the other hand, Delafontaine (Ann. Ch. Pharm. cxxxiv. 99; Jahresb. 1864, p. 196; Bull. Soc. Chim. [1866] i. 168) still maintains the separate existence of erbia and terbia. He finds that the first precipitates thrown down by acid potassic oxalate (as in Mosander's method), from a solution of crude yttria, yield, on ignition, a yellow residue; and if this be redissolved, and subjected several times to the same treatment, an earth is obtained of continually deeper yellow colour, and consisting mainly of erbia, with comparatively small quantities of terbia and yttria; from which it may be further purified by dissolving it in nitric acid, evaporating to dryness, redissolving in water, saturating the neutral solution in the cold with pulverised potassic sulphate, and washing the resulting precipitate (consisting of erbio-potassic sulphate) with a saturated solution of potassic sulphate, which dissolves the double sulphates of the other two metals. The erbio-potassic salt dissolves easily in hot water, and the solution, treated with potash, yields erbium-hydrate, which may be redissolved, and completely purified from terbium and yttrium by repetition of the same treatment.

Anhydrous erbia, thus obtained, has a yellow colour of various depths, but becomes white by ignition in hydrogen. The hydrate is white, absorbs carbonic acid from the air, and when heated to redness, leaves the anhydrous oxide in dense hard lumps of a deep orange-yellow colour. Its solutions are colourless, or sometimes have a faint rose-colour, and do not exhibit any absorption-spectrum.

Terbia, the separation of which from yttria is not specially described, is (according to Delafontaine) an earth of a pale rose-colour, and does not become colourless by ignition in hydrogen. It dissolves easily in acids, forming rose-coloured solutions, which yield an absorption-spectrum. Delafontaine is of opinion that the earth described by Bahr and Bunsen as erbia, is really terbia, the true erbia, which is first precipitated by oxalic acid from the solution of the mixed earths, having, as above mentioned, a yellow (not a rose) colour, and not producing an absorption-spectrum. Bahr and Bunsen, on the contrary, are of opinion that the yellow colour and other peculiarities of Delafontaine's erbia are to be attributed to imperfect separation of the cerium-metals.

---

* The paper above referred to is accompanied by exact diagrams of the erbium- and didymium-spectra.

Further experiments are perhaps required, to afford a perfectly satisfactory answer to the question whether crude yttria is a mixture of three earths or of only two; but, for the present, the very carefully conducted experiments of Bahr and Bunsen must be regarded as throwing great doubt on the existence of the third of these earths—the so-called terbia. The fact which tells most strongly in favour of the opposite view, is that Delafontaine's terbia exhibits an absorption-spectrum, whereas his erbia does not; but the descriptions hitherto given of his methods of separation are not sufficiently precise to enable us to judge of their efficiency.

According to Delafontaine, the atomic weight of yttrium is 74·4 (yttria = $Y''O$); that of erbium is higher, and that of terbium higher still. He further regards it as probable that gadolinite contains a fourth metal, whose salts have an absorption-spectrum partly corresponding with that of didymium.

According to Bahr and Bunsen, the atomic weight of yttrium is 61·7, and that of erbium 112·6.

TEREBAMIC ACID. $C^7H^{11}NO^3 = \left.\begin{matrix}H^2\\(C^7H^8O^2)''\\H\end{matrix}\right\}\begin{matrix}N\\O\end{matrix}$. *Terebamide.*—This compound is produced, by heating terebic acid in ammonia-gas to 140°–160°, as a sublimate, which dissolves slightly in cold, easily in hot water and alcohol. The solutions are neutral to litmus, and do not decompose carbonates. Terebamic acid dissolves easily in caustic alkalis, and is separated from the solution by acids in its original state. —The *barium-salt*, $C^{14}H^{20}Ba''N^2O^6.2H^2O$, is easily soluble in water, and dries up on evaporation to a gum: it is precipitated in the crystalline state by alcohol, and forms, after drying, a loose web of microscopic needles having a silky lustre. (Handw. d. Chem. viii. 575.)

TEREBAMIDE. See the preceding article.

TEREBENE. An optically inactive isomer of turpentine-oil (*q. v.*).

TEREBENES. Syn. with CAMPHENES (i. 724).

TEREBENIC ACID. Syn. with TEREBIC ACID.

TEREBENTHENE. One of the isomers of turpentine-oil obtained by the decomposition of the hydrochlorate, $C^{10}H^{16}.HCl$, or the hydrobromate, $C^{10}H^{16}.HBr$. It also forms the chief portion of the turpentine of *Pinus maritima*. (See TURPENTINE OIL.)

TEREBENTILIC ACID. $C^8H^{10}O^2$. (J. Personne, Ann. Ch. Pharm. c. 253.)—This acid is obtained by passing the vapour of fused turpentine-hydrate over soda-lime heated to 400°, and treating the resulting mass with hydrochloric acid; the reaction is attended with the evolution of large quantities of marsh-gas and hydrogen:

$$C^{10}H^{20}O^2 = C^8H^{10}O^2 + 2CH^4 + H^2.$$

This acid is white, has a faint odour resembling that of the goat, is heavier than water, melts at 90°, and distils with partial decomposition at 250°. It is insoluble in cold, but soluble in boiling water, and separates, on cooling, as a powder consisting of small needle-shaped crystals; it is very soluble in alcohol and in ether. By sublimation, it crystallises in small spangles, apparently having the form of oblique prisms. Its vapour is acrid, and attacks the nose strongly.

Terebentilic acid is monobasic.—Its *calcium-salt*, formed by treating the acid with lime, crystallises in small silky needles, resembling sulphate of quinine.—The *lead-salt* is uncrystallisable, and resembles gum-arabic.—The *silver-salt*, $C^8H^9AgO^2$, is slightly soluble in boiling water, and crystallises on cooling.

With alcohol, terebentilic acid easily forms an ether having the odour of pears and pine-apples.

TEREBENZIC ACID. An acid produced, according to Cailliot (Ann. Ch. Phys. [3], xxi. 31), together with terephthalic acid, by the action of nitric acid on turpentine-oil. It is separated from the terephthalic acid by boiling water or cold alcohol, and crystallises from the aqueous solution, on cooling, in small shining needles said to have the composition $C^{14}H^7O^4$. It volatilises easily with the vapour of boiling water, melts at 169°, boils at a much higher temperature, but sublimes at 100° when heated in open vessels. Its ether has an agreeable odour of anise, and boils at 130°. The metallic terebenzates are about as soluble in water as the benzoates.

TEREBIC ACID. $C^7H^{10}O^4 = \left.\begin{matrix}(C^7H^8O^2)''\\H^2\end{matrix}\right\}O^2$.—A product of the action of nitric acid upon turpentine-oil, discovered by **Bromeis** (Ann. Ch. Pharm. xxxvii. 297), who called it *turpentinic acid*; further examined by **Rabourdin** (J. Pharm. [3], vi. 185), who designated it as *terebilic* or *terebenic acid*; by **Cailliot** (L. Institut. 1849, p. 353), and lastly by **Svanberg** and **Eckmann** (J. pr. Chem. lxvi. 220).

To prepare it, oil of turpentine is heated with four or five times its weight of nitric acid diluted with an equal bulk of water, as long as red fumes are evolved, whereby a reddish-yellow brittle resin and a yellow acid liquid are obtained. This liquid, evaporated to a syrup, and diluted with a large quantity of water, deposits a whitish-yellow precipitate, having the consistence of pitch; and the watery liquid separated therefrom yields crystalline terebic acid. (**Svanberg** and **Eckmann**.)

Terebic acid crystallises (according to **Bromeis**) in tolerably regular forms, appearing under the microscope as four-sided prisms with oblique terminal faces, and exhibiting an extraordinary lustre on their lateral faces. It has a purely acid taste, dissolves slightly in cold, more readily in boiling water, easily in alcohol and ether. It is not decomposed by nitric acid at the boiling heat, but sulphuric acid chars it. The acid melts at 200° without loss of weight; but at a higher temperature it begins to boil, and is resolved into carbonic anhydride and pyroterebic acid: $C^7H^{10}O^4 = CO^2 + C^6H^{10}O^2$.

Terebates.—Terebic acid is dibasic. It decomposes carbonates, forming acid salts, $C^7H^9MO^4$ and $C^{14}H^{18}M''O^8$, which have an acid reaction, but do not exert any further action upon carbonates. In contact with metallic oxides and hydrates, however, the acid forms neutral salts, $C^7H^8M^2O^4$ and $C^7H^8M''O^4$. It resembles salicylic acid in forming acid more readily than neutral salts. It also forms acid ethers, which act with bases like a monobasic acid.

The neutral terebates all contain water of crystallisation, and retain at least one atom of it until heated to a temperature at which they decompose. When dehydrated as far as possible without decomposition, they have the composition $C^7H^8M''O^4.H^2O$. Hence they are regarded by Cailliot as salts of a peculiar acid, $C^7H^{12}O^5$, which he calls **diaterebic acid**. But, as they yield terebic acid when decomposed by acids, this supposition does not appear to rest on very good grounds.

Terebates of Ammonium.—The *neutral salt* is deliquescent and uncrystallisable. —The *acid salt*, $C^7H^9(NH^4)O^4$, forms very soluble prisms; which give off their ammonia, slowly at ordinary temperatures, quickly at 100°.

Terebates of Barium.—The *neutral salt*, $2C^7H^8Ba''O^4.5H^2O$, obtained by adding baryta-water to a solution of the acid salt, and precipitating the excess of baryta with carbonic acid, dries up to a gummy mass, which gives off 2 at. water at 140°, leaving the salt $2C^7H^8Ba''O^4.3H^2O$. This hydrate, which appears also to be precipitated by alcohol from the aqueous solution, deliquesces on exposure to the air, and then yields crystals of another hydrate, $C^7H^8Ba''O^4.3H^2O$ (**Cailliot**).—The *acid barium-salt*, $C^{14}H^{18}Ba''O^8.2H^2O$, or $C^7H^8Ca''O^4.C^7H^{10}O^4.2H^2O$, obtained by treating the aqueous acid with carbonate of barium, is precipitated from its syrupy solution by alcohol in needles (**Cailliot**); according to **Svanberg** and **Eckmann**, it is uncrystallisable. A more dilute solution mixed with alcohol slowly deposits nodules of the neutral salt, while free terebic acid remains in solution.

The *neutral calcium-salt* separates, by spontaneous evaporation of its solution, in microscopic tables, containing $2C^7H^8Ca''O^4.5H^2O$; but on boiling the solution, it is deposited in small crystals containing $C^7H^8Ca''O^4.H^2O$.

Terebates of Lead.—The *neutral salt*, $3C^7H^8Pb''O^4.2H^2O$, forms crystalline nodules, which are insoluble in cold water, and are decomposed by boiling water, with formation of a basic salt.—A *basic lead-salt*, $2C^7H^8Pb''O^4.Pb''H^2O^2.3H^2O$, is also precipitated on evaporating a solution of 1 at. lead-oxide in 1 at. terebic acid.—**Cailliot** likewise describes a salt containing $2C^7H^8Pb''O^4.5H^2O$, which he calls *metaterebate of lead*, representing it as $2PbO.C^{14}H^{18}O^{11}$.—The *acid lead-salt*, $C^{14}H^{18}Pb''O^8.H^2O = C^7H^8Pb''O^4.C^7H^{10}O^4.H^2O$, is obtained by saturating the aqueous acid with litharge, taking care that the latter is not added in excess, and crystallises from the liquid, evaporated to a syrup, in small white groups of crystals resembling cauliflower-heads.

The *acid potassium-salt*, $2C^7H^9KO^4.H^2O$, obtained by dissolving carbonate of potassium in an equivalent quantity of the acid, and evaporating to a syrup, forms very soluble crystals, which give off their water at 100°.—The *acid sodium-salt*, $2C^7H^9NaO^4.H^2O$, prepared like the preceding, also gives off its water at 100°.

Silver-salts.—The *neutral salt*, $C^7H^8Ag^2O^4.H^2O$, obtained by precipitating a solution of the neutral barium-salt with nitrate of silver, is uncrystallisable (**Svanberg** and **Eckmann**). According to **Cailliot**, it dissolves very slightly in boiling water, and separates therefrom in needles.—The *acid silver-salt*, $C^7H^9AgO^4$, obtained by precipitating the acid ammonium- or barium-salt with nitrate of silver, then evaporating, and leaving the solution to cool slowly, forms beautiful shining prisms.

TEREBIC ETHERS. Terebic acid, as already observed, forms acid ethers, which react like monobasic acids; they are prepared by the direct action of terebic acid on the several alcohols.—*Ethyl-terebic acid*, $C^7H^9(C^2H^5)O^4 = \left.\begin{matrix}C^7H^8O^2\\C^2H^5\\H\end{matrix}\right\}O^2$, is an oil, having a burning but not acid taste, sparingly soluble in water, and not capable of being distilled without decomposition. Its salts have but little stability, and are resolved by the slightest heat into metallic terebate, ethyl-terebic acid, and alcohol, *e.g.*:

$$C^{14}H^{16}Ba''(C^2H^5)^2O^8 + H^2O = C^7H^8Ba''O^4 + C^2H^6O + [C^7H^9(C^2H^5)O^4].$$

The *methylic* and *amylic ethers* resemble the ethylic ether in composition and in properties. (Cailliot, *loc. cit.*)

TEREBILIC ACID. Syn. with TEREBIC ACID.

TERECAMPHENE. An isomer of turpentine-oil (*q.v.*).

TERECHRYSIC or **TERECRYLIC ACID.** $C^6H^8O^5$. An acid said by Cailliot to be contained, together with oxalic, terephthalic, terebenzic, and turpentinic acids, in the watery liquid obtained by oxidising turpentine-oil with nitric acid diluted with an equal bulk of water.

TERENITE. A mineral from Antwerp, in New York, of specific gravity 2·53, regarded by Dana (ii. 203) as an altered form of scapolite.

TEREPHTHALAMIDE. See TEREPHTHALIC AMIDES (p. 726).

TEREPHTHALIC ACID. $C^8H^6O^4 = \left.\begin{matrix}(C^8H^4O^2)''\\H^2\end{matrix}\right\}O^2$. *Insolinic Acid.*—A product of the oxidation of turpentine-oil and other hydrocarbons and of certain aldehydes. It was discovered by Cailliot (Ann. Ch. Phys. [3], xxi. 28), who obtained it by the action of nitric acid on turpentine-oil, and more completely examined by De la Rue and Hugo Müller (Ann. Ch. Pharm. cxxi. 86). Hofmann (*ibid.* xcvii. 197), by oxidising cuminic acid, cuminic aldehyde, and cymene with chromic acid, obtained a dibasic acid, which he called insolinic acid, and represented by the formula $C^9H^8O^4$, but, according to De la Rue and Müller, this acid is identical with terephthalic acid. According to Schwanert (*ibid.* cxxxii. 257), terephthalic acid is produced by the action of nitric acid upon several volatile oils: cymene, turpentine-oil, lemon-oil, thymene, and cajeput-oil, oxidised with nitric acid, yield terephthalic and camphretic acids; cumin-oil yields terephthalic but no camphretic acid; camphor, wormwood-oil, borneol, and peppermint-oil yield camphretic but no terephthalic acid; thymol does not yield either of these acids; thyme-oil or thymene yields, together with terephthalic acid, an oil having the composition of Hofmann's insolinic acid. De la Rue and Müller (*ibid.* cxx. 339; cxxi. 86) have obtained terephthalic acid, together with other acids, by the action of dilute nitric acid on rectified coal-tar oil (a mixture of toluene, xylene, and pseudocumene), and on the liquid hydrocarbons of Burmese naphtha; they find also that it is always produced in the preparation of toluylic acid from cymene, and in the treatment of that hydrocarbon with fuming nitric acid for the production of nitrotoluylic acid, the result being the same whether the cymene has been obtained from Roman cumin-oil or from camphor. According to Beilstein (*ibid.* cxxxiii. 32; cxxxvii. 301), xylene oxidised with dilute nitric acid yields only toluylic acid: $C^8H^{10} + O^3 = C^8H^8O^2 + H^2O$; but when treated with sulphuric acid and potassic dichromate, it yields, by further oxidation, terephthalic acid, which indeed is likewise produced by the direct treatment of toluylic acid with the same oxidising mixture.

Preparation.—1. From *Turpentine-oil.*—The oil is treated, in a retort, with a large excess of nitric acid diluted with an equal bulk of water, as long as red fumes continue to escape. The acid mother-liquor thus obtained is separated from the resin, and the residue is treated with cold water, which again leaves an orange-yellow resin, containing terephthalic and terebenzic acids. The latter may be removed by solution in cold alcohol and boiling water; the terephthalic acid is then dissolved in ammonia; and the resulting ammonium-salt, after being purified by repeated crystallisation, and boiling with animal charcoal, is decomposed by a mineral acid.

2. From *Cuminic Acid, Cuminic Aldehyde, Xylene*, &c.—One part of cuminic acid is cohobated for about twelve hours with 1 pt. of dichromate of potassium, 8 pts. of strong sulphuric acid, and 12 pts. of water. Terephthalic acid is then found floating on the green liquid, after cooling, as a white flour-like powder, and the liquid retains in suspension a greenish half-fused mass, consisting of chromic terephthalate. The liquid is now to be filtered, the insoluble matter washed with water to remove the soluble chromium-salt, and the residue boiled with ammonia, which dissolves terephthalic acid, leaving chromic oxide undissolved. The ammoniacal solution saturated with hydrochloric acid yields a white powder,

which, when repeatedly boiled with water, or heated with boiling alcohol (to remove adhering cuminic acid), constitutes pure terephthalic acid (Hofmann). In a similar manner terephthalic acid may be prepared from Roman cumin-oil, which is a mixture of cuminic aldehyde and cymene. Beilstein prepares it by boiling 100 grms. xylene for several days with 400 grms. potassium-dichromate and 550 grms. oil of vitriol diluted with twice its weight of water,—then filtering, dissolving the residue in carbonate of sodium, diluting with a large quantity of water, and precipitating with hydrochloric acid.

Properties.—Terephthalic acid is a white, tasteless, crystalline powder, not perceptibly soluble in water, alcohol, ether, chloroform, or acetic acid. When warmed with strong sulphuric acid, it dissolves in considerable quantity, without formation of a sulphoterephthalic acid, and is separated in its original state on addition of water. When heated, it sublimes without previous fusion, forming an indistinctly crystalline sublimate, which has the same composition and properties as the original acid; terephthalic acid is not therefore, like its isomer, phthalic acid, resolved by heat into water and the anhydride. When heated with potash, it is resolved, like phthalic acid, into benzene and carbonic anhydride (De la Rue and Müller). Hofmann's insolinic acid melts at a very high temperature, its melting- and boiling-points nearly coinciding. When distilled, it partly sublimes unaltered, while the rest is decomposed, with formation of benzoic acid and benzene, carbonic anhydride being evolved, and a carbonaceous residue remaining in the retort.*

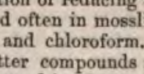
Terephthalates.—Terephthalic acid dissolves in alkalis, neutralising them completely, and is precipitated from its salts by phthalic acid. Although dibasic, it does not form any double salts, and shows but little tendency to form acid salts. Nearly all the terephthalates are soluble and crystallisable, and so inflammable that they may be set on fire by a spark from flint and steel, and burn away slowly like tinder, emitting the characteristic odour of benzene. Terephthalic acid forms acid and neutral ethers (p. 727).

Terephthalate of Ammonium, $C^8H^4(NH^4)^2O^4$, crystallises, by slow evaporation, in small crystals having a strong lustre (Beilstein).—The *barium-salt*, $C^8H^4Ba''O^4.4H^2O$, obtained by mixing the concentrated solution of the ammonium-salt with chloride of barium, crystallises from water in concentrically-grouped tablets, which become anhydrous at 150°, and dissolve in 355 pts. water at 5°.—The *calcium-salt*, $C^8H^4Ca''O^4.3H^2O$, prepared in like manner, dissolves in 1213 pts. water at 6° (Beilstein).—The *silver-salt*, $C^8H^4Ag^2O^4$, separates as a curdy precipitate on mixing the solution of the ammonium-salt with nitrate of silver. (De la Rue and Müller.)

Nitroterephthalic Acid, $C^8H^5(NO^2)O^4$, is formed by the action of a mixture of fuming sulphuric and nitric acids on terephthalic acid, and separates from water in cauliflower-like aggregates. It dissolves easily in hot alcohol, forms well-crystallised metallic salts, and crystallisable ethers, which dissolve easily in alcohol and melt at low temperatures. By reducing agents it is converted into oxyterephthalamic or amidoterephthalic acid (*infra*). (De la Rue and Müller.)

OXYTEREPHTHALIC ACID, $C^8H^6O^5$, is produced by the action of nitrous acid on oxyterephthalamic acid. It forms well-crystallised salts, less soluble than the corresponding terephthalates. (De la Rue and Müller.)

TEREPHTHALIC AMIDES. 1. *Terephthalamide*, $C^8H^8N^2O^2 = N^2.H^4.(C^8H^4O^2)''$, produced by the action of ammonia on terephthalic chloride, is a white amorphous body, not dissolved by any solution.—2. *Nitroterephthalamide*, $C^8H^7(NO^2)N^2O^2$, formed by the action of fuming nitric acid on terephthalamide, crystallises in fine prisms.—3. *Terephthalyl-nitrile*, $C^8H^4N^2$, is obtained by treating terephthalamide with phosphoric anhydride, distilling over as a liquid, which solidifies in the neck of the retort. It forms fine prismatic crystals, colourless and scentless, insoluble in water and in benzene, easily soluble in cold alcohol. When boiled with caustic alkalis, it is gradually converted into ammonia and terephthalic acid.



4. *Oxyterephthalamic Acid*, $C^8H^7NO^4 = \left.\begin{matrix}H^3\\(C^8H^3O^2)'''\\H\end{matrix}\right\}\begin{matrix}N\\O^2\end{matrix}$, or *Amidoterephthalic Acid*, $C^8H^5(NH^2)O^4$, is produced by the action of reducing agents on nitroterephthalic acid. It crystallises in thin prisms, and often in mosslike groups of crystals, sparingly soluble in cold water, ether, alcohol, and chloroform. It unites both with acids and with bases; the solutions of the latter compounds are highly fluorescent.

The ethers of oxyterephthalamic acid are formed by the action of reducing agents on those of nitroterephthalic acid.—The *ethylic ether* forms large crystals resembling uranic nitrate; its solutions are strongly fluorescent. Oxyterephthalamic acid is converted by nitrous acid into oxyterephthalic acid.

---

* The physical characters of insolinic acid are the same as those of terephthalic acid; but the analyses of the acid and of its salts agree very nearly with the numbers required by Hofmann's formula $C^9H^8O^4$, and differ considerably from those required by the formula of terephthalic acid.

TEREPHTHALIC CHLORIDE, $C^8H^4O^2Cl^2$, is produced, together with phosphoric oxychloride, by the action of phosphoric pentachloride on terephthalic acid at 40°. It forms beautiful crystals, inodorous at ordinary temperatures, but smelling when heated like benzoic chloride, which it resembles in its reactions. (De la Rue and Müller.)

TEREPHTHALIC ETHERS. Terephthalic acid forms both neutral and acid ethers. The neutral ethers are formed by the action of terephthalic chloride upon alcohols, or by that of alcoholic iodides on the silver- or potassium-salt of terephthalic acid.—The acid ethers are usually formed in small quantity, together with the neutral ethers, by the action of alcoholic iodides on terephthalate of silver. They are well-marked monobasic acids, and form salts insoluble in alcohol.

Neutral Amylic Terephthalate, $C^8H^4(C^5H^{11})^2O^4$, forms pearly scales, which melt at the heat of the hand.—The *neutral ethylic ether*, $C^8H^4(C^2H^5)^2O^4$, forms long prismatic crystals resembling urea, and easily soluble in alcohol (De la Rue and Müller). It melts at 44°, solidifies at 29°, is insoluble in water, but dissolves easily in alcohol and ether (Beilstein).—The *neutral methylic ether*, $C^8H^4(CH^3)^2O^4$, forms beautiful flat prismatic crystals, several inches long, which melt at a temperature above 100°, and sublime without decomposition. It dissolves easily in warm, less easily in cold alcohol (De la Rue and Müller). According to Beilstein, it melts at 140°, and solidifies again at 130°.—The *neutral phenylic ether*, $C^8H^4(C^6H^5)^2O^4$, is white, crystalline, and melts at a temperature above 100°. (De la Rue and Müller.)

TEREPHTHALYL-NITRILE. See Terephthalic Amides (p. 726).

TEROPIAMMONE. Syn. with Triopianylamide. (See Opianic Acid, Amides of, iv. 206.)

TERPILENE. See Turpentine-oil, Hydrates of.

TERPIN. }
TERPINOL. } Hydrates of turpentine-oil (*q. v.*).

TERRA CATECHU. Syn. with Catechu (i. 816).

TERRA DI SIENA. A ferruginous clay, occurring near Siena, in Italy, in thick brownish-yellow masses, often light-yellow in the middle, and yielding a greenish-yellow powder. It has a specific gravity of 3·46, a conchoïdal fracture, and adheres strongly to the tongue. According to Rowney, it contains 75·3 per cent. ferric oxide, 9·5 alumina, 11·1 silica, and 13·0 water, besides small quantities of lime and magnesia. When burnt, it becomes brown-red, and yields a dark-red powder. It is used as a pigment, both in its natural state, as *raw siena*, and, after ignition, as *burnt siena*.

TERRA FOLIATA TARTARI. A name of potassium-acetate. Sodium-acetate is sometimes called *Terra fol. tart. crystallisabilis.*

TERRA JAPONICA. Syn. with Catechu.

TERRA LEMNIA. Lemnian earth (iii. 570).

TERRA MIRACULOSA. Obsolete name of bole.

TERRA MURIATICA. Obsolete name of magnesia.

TERRA NOBILIS. A name applied by Bergemann to the diamond, at a time when its real nature was not known.

TERRA PONDEROSA. An old name of baryta. *Terra ponderosa salita*, old name of barium-chloride.

TERRA UMBRA. See Umber.

TERRA VITRESCIBILIS. One of the three elementary earths assumed by Becher, and supposed to be especially abundant in siliceous minerals.

TESSELITE. Syn. with Apophyllite (i. 351).

TESSERAL PYRITES. A name applied to the native arsenides of cobalt, smaltine and skutterudite, both of which crystallise in the monometric or tesseral system (i. 1041).

TETARTINE. Syn. with Albite. (See Felspar, ii. 621.)

TETARTOHEDRY. See Crystallography (ii. 121, 144).

TETRA. A prefix applied to compounds containing 4 at. of a chlorous element to 1 at. of a basylous element: *e.g.*, tetrachloride of tin, $SnCl^4$; also to substitution-compounds, in which 4 at. hydrogen are replaced by a radicle, simple or compound: *e.g.*, tetrachloroquinone, tetramethylammonium, &c.

TETRACLASITE. Syn. with SCAPOLITE (p. 203).

TETRADECYL, or **TETRADECATYL.** $C^{14}H^{29}$; also called *Myristyl.*—The fourteenth term of the series of alcohol-radicles, $C^{n}H^{2n+1}$.—*Tetradecylic hydride,* $C^{14}H^{30}$, is one of the constituents of American petroleum: it boils between 236° and 240°, and is converted by chlorine into the corresponding chloride, $C^{14}H^{29}Cl$.—*Tetradecylic* or *Myristic Alcohol*, or *Methal*, $C^{14}H^{30}O$, is one of the constituents of spermaceti (iii. 1072).

TETRADYMITE. Native telluride of bismuth (p. 707).

TETRAHEDRITE. *Fahl-ore, Grey Copper, Fahlerz, Kupferfahlerz, Panabase.* —Varieties: *Polytelite, Weissgiltigerz* or *Silberfahlerz*; *Schwarzgiltigerz* and *Graugiltigerz*; *Spaniolite* or *Quecksilberfahlerz.*

The name tetrahedrite, or fahl-ore, is applied to a group of isomorphous minerals, crystallising in hemihedral forms of the monometric or regular system, and consisting of mixtures of sulphur-salts (sulphantimonites and sulpharsenites), in which the sulphur of the base is to that of the acid, for the most part, as 4 : 3. The general formula of the group is, therefore, $\left.\begin{matrix} 4(M^2\,;\,N'')S \\ (Sb^2\,;\,As^2)S^3 \end{matrix}\right\}$ or $\left.\begin{matrix} (M^2\,;\,N'')^4 \\ Sb^2\,;\,As^2 \end{matrix}\right\}S^7$, the symbol M denoting Cu (*cuprosum*) and Ag, and N″ denoting Fe, Sn, and Hg (= 200).

The forms of most frequent occurrence are the regular tetrahedron, $\frac{O}{2}$ (*fig.* 190, ii. 230), the triakis-tetrahedron $\frac{2O2}{2}$ (*fig.* 796), and the combinations $+\frac{O}{2} \cdot \infty O\infty$ (*fig.* 197, ii. 231), $+\frac{O}{2} \cdot \infty O$ (*fig.* 203, ii. 232), $+\frac{O}{2} \cdot +\frac{2O2}{2}$ (*fig.* 797), $+\frac{O}{2} \cdot +\frac{2O2}{2} \cdot \infty O$ (*fig.* 798), $+\frac{2O2}{2} \cdot \infty O \cdot \frac{\frac{3}{2}O}{2}$, and others.

Fig. 796.

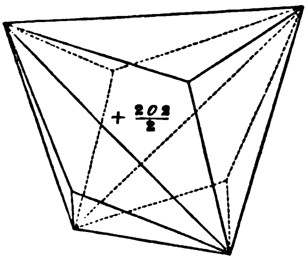


Fig. 797.

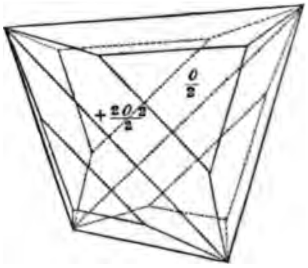
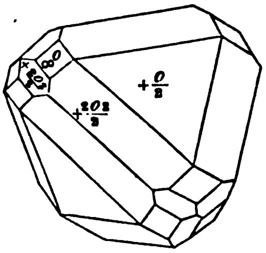


Twin-crystals occur, with octahedral composition-face. Cleavage octahedral in traces. The mineral also occurs granular to impalpable, and compact. Hardness = 3 to 4·5. Specific gravity = 4·5 to 5·11. Lustre metallic. Colour between steel-grey and iron-black. Streak generally the same as the colour. Opaque, or subtranslucent in very thin splinters, with cherry-red transmitted colour. Fracture subconchoïdal, uneven. Rather brittle.

Fig. 798.



Before the blowpipe, it gives off fumes of antimony and sometimes of arsenic, then melts, and after roasting leaves a globule of copper. When pulverised, it dissolves with little residue in nitric acid, forming a brownish-green solution.

The best mode of analysing tetrahedrite is that of H. Rose, which consists in heating the mineral in a stream of chlorine; the metals are thereby converted into chlorides, some of which are volatile, while others are fixed, a division which greatly facilitates the further separation (p. 537).

Analyses:—1, 2. H. Rose (Pogg. Ann. xv. 576).—3. Svanberg (Kongl. Vetensk. Acad. Förhl. iv. 85).—4. Rammelsberg (*Mineralchemie*, p. 87).—5, 6, 7. H. Rose, (*loc. cit.*)—8. Genth (Sill. Am. J. xvi. 83).—9. Scheidhauer (Pogg. Ann. lviii. 161).—10. Von Hauer (Jahrb. Geolog. Reichs. 1852, p. 98):—

	S.	Sb.	As.	Cu.	Fe.	Zn.	Ag.	Hg.

Most of these analyses agree nearly with the general formula above given.

When the mineral contains much silver, it is called *Polytelite*, *Silberfahl-ore*, or *Weissgiltigerz*. A variety of this mineral, which occurs massive and fine-granular, of specific gravity 5·438 and 5·465, at the "Hoffnung Gottes" mine, near Freiberg, contains 36 to 38 per cent. lead, together with 22·53 S, 22·39 Sb, 5·92—5·73 Ag, 3·72—3·83 Fe, 3·15—6·7 Zn, 0·19—0·32 Cu = 100. In this mineral the sulphur-ratio for the bases and acids is 3 : 2; but it may be regarded as tetrahedrite, if some of the bases are reckoned as impurities.

An ore from mine Altar, near Coquimbo, was found by Field (Chem. Soc. Qu. J. iv. 332) to contain 30·35 per cent. S, 3·91 As, 20·28 Sb, 36·72 Cu, 7·26 Zn, 1·23 Fe, 0·075 Ag, and 0·008 Au. It is soft, of greasy appearance, greenish-grey, slightly reddish, and yields a bright-red powder. Domeyko considers it impure, containing blende, pyrites, and galena. Ettling observes that it is analogous in constitution rather to enargite than to tetrahedrite, corresponding to the formula $4M^2S.(Sb^2; As^2)S^3$.

Aphthonite, or *Aftonite*, from Wermland, Sweden, has a steel-grey colour, and black streak; hardness = 3; specific gravity = 4·87. It gives the formula $7M^2S.(Sb^2; As^2)S^3$.

Annivite is a massive ore from the Anniviersthal in the Valais, containing (after deduction of 9·4 per cent. of quartz) 26·22 per cent. S, 12·10 As, 9·71 Sb, 5·45 Bi, 39·26 Cu, 4·15 Fe, 2·22 Zn = 99·21, which agrees nearly with the formula $3M^2S.(Sb^2; As^2; Bi^2)S^3$; but the mineral does not appear to have been completely examined. Kenngott (*Uebersicht*, 1855, p. 120) regards it as an impure tetrahedrite.

Tennantite, which is a sulpharsenite of copper and iron, isomorphous with tetrahedrite, is by some mineralogists regarded as a variety of the latter; but its composition does not agree with the formula $4M^2S.As^2S^3$, but rather with $7M^2S.2As^2S^3$. (See TENNANTITE, p. 720.)

For a full discussion of the formula of tetrahedrite, see *Rammelsberg's Mineralchemie* (pp. 90—99).

Large tetrahedral crystals of tetrahedrite, having mostly a rough dull surface, are found in the Cornish mines near St. Austel. More brilliant and highly modified crystals occur at Andreasberg in the Harz, Kremnitz in Hungary, Freiberg in Saxony, Kapnik in Transylvania, and Dillenberg in Nassau. (Dana, ii. 82.)

TETRAMERCURAMMONIUM. See MERCURY-BASES, AMMONIACAL (iii. 917).

TETRAMETHYLAMMONIUM. $N(CH^3)^4$.—Most of the compounds of this base have been already described (iii. 999). Stahlschmidt (Pogg. Ann. cxix. 421; Jahresb. 1863, p. 403), by treating tri-iodide of nitrogen, or tri-iodamide, NI^3,[*] with an excess of methylic iodide, has obtained penta-iodide of tetramethylammonium, together with iodoform:

$$2NI^3 + 9CH^3I = 2N(CH^3)^4I^5 + CHI^3 + 2HI.$$

The brown liquid resulting from the reaction, is almost wholly soluble in boiling absolute alcohol; the solution, on cooling, deposits green crystals of the pentaiodide; and the mother-liquor, on further evaporation, yields iodoform.—If the liquid contains free ammonia, protoiodide of tetramethylammonium is likewise formed, and unites with the iodoform, producing the crystalline compound, $C^6H^{14}NI^7 = N(CH^3)^4I.2CHI^3$.

The pentaiodide of tetramethylammonium easily gives up 4 at. of its iodine to alkalis and reducing agents. With aqueous potash, it forms a yellow solution, which contains the protoiodide, together with iodide and iodate of potassium, and, when treated with acids, again yields the pentaiodide.

---

[*] Stahlschmidt finds that when a solution of iodine in absolute alcohol, saturated at ordinary temperatures, is mixed with 3 or 4 vols. of strong aqueous ammonia, the resulting precipitate, after thorough washing with cold water, has the composition of tri-iodamide, NI^3; but if the iodine-solution be mixed with 2 or 3 vols. of a saturated solution of ammonia in absolute alcohol, the precipitate, after being well washed with absolute alcohol, consists of di-iodamide, NHI^2.

On mixing a warm, saturated, alcoholic solution of the pentaiodide with aqueous ammonia, or heating the pulverised compound with strong aqueous ammonia, or mixing an alcoholic solution of iodine with iodide of tetramethylammonium and ammonia, a brown-black or dark-green explosive compound is formed, consisting of a compound of tri-iodide of tetramethylammonium with di-iodamide: $C^4H^{13}N^2I^5 = N(CH^3)^4I^3.NHI^2$, or less probably of di-iodide of tetramethylammonium and tri-iodamide, $N(CH^3)^4I^2.NI^3$. This compound may be dried without decomposition, if the drying be carefully conducted; but it explodes easily when touched with a feather, or with oil of vitriol, or when heated above 100°. It is insoluble in water and in dilute alcohol; but hot absolute alcohol dissolves it, apparently with decomposition, and formation of tetramethylammonium-pentaiodide.—*Nitrate of silver* removes all the iodine in the form of silver-iodide. The compound is decomposed by boiling *potash-ley*, with formation of a small quantity of iodoform. With *sulphydric acid* it decomposes in the manner shown by the equation:

$$C^4H^{13}N^2I^5 + 3H^2S = N(CH^3)^4I + NH^4I + 3HI + S^3.$$

Hydrochloric acid also decomposes it, with separation of iodine. (Stahlschmidt.)

TETRAMETHYL-ETHYLENE. When 1 vol. ethylenic bromide is heated with 2 vols. methylic sulphide to 100°, the two bodies gradually unite into a crystalline mass, consisting of tetramethyl-ethylene-sulphobromide, $C^6H^{16}Br^2S^2 = \left.\begin{matrix}(CH^3)^4\\(C^2H^4)''\end{matrix}\right\}\begin{matrix}S^2\\Br^2\end{matrix}$, which dissolves easily in water, and separates therefrom, by evaporation in a vacuum, in well-defined crystals. This compound dissolves in all proportions of hot water, less freely in alcohol, not at all in ether, and is precipitated by ether from the alcoholic solution, in white prisms. When treated with a silver-salt, it forms, together with bromide of silver, a crystallisable very deliquescent compound. With recently precipitated silver-oxide, it yields a caustic alkaline solution, containing the oxide $(CH^3)^4(C^2H^4)S^2O$. The deliquescent hydrochlorate forms, with platinic chloride, the double salt $(CH^3)^4(C^2H^4)S^2Cl^2.PtCl^4$. (Cahours, Compt. rend. lx. 620, 1147; Jahresb. 1865, p. 477.)

TETRANITRONAPHTHALENE. $C^{10}H^4(NO^2)^4$.—Trinitronaphthalene (iv. 15), treated with fuming nitric acid in sealed tubes, is converted into tetranitronaphthalene; and both nitro-compounds, when acted upon by iodide of phosphorus, yield iodides of polyatomic bases, analogous to iodide of picrammonium (iv. 640). (Lautemann and D'Ajuiar, Bull. Soc. Chim. 1864, i. 431.)

TETRAPHOSPHAMIC ACIDS. (Gladstone, Proc. Roy. Soc. xv. 515.)—These are amic acids derived from tetraphosphoric acid, $P^4H^6O^{13}$ (the acid of Fleitmann and Henneberg's phosphates, iv. 537), and produced by the action of water on the compounds of phosphoric oxychloride with ammonia.*—*Tetraphosphotetramic acid*, $P^4(NH^2)^4H^2O^9$, or $\left.\begin{matrix}P^4\\H^{10}\end{matrix}\right\}\begin{matrix}N^4\\O^9\end{matrix}$, is a solid stable body, insoluble in alcohol, but soluble in water, and combining readily with bases, the amount of replaceable hydrogen appearing to vary from 1 to 6 atoms.

Triammoniated Tetraphosphodiamic Acid, $P^4(NH^2)^2(NH^4)^3HO^{11} = \left.\begin{matrix}P^4\\H^5\\(NH^4)^3\end{matrix}\right\}\begin{matrix}N^2\\O^{11}\end{matrix}$, is a viscid liquid, insoluble in alcohol, but very soluble in water. It forms a liquid compound with ammonia, but metallic salts appear to break it up into a variety of bodies. By the action of heat, boiling water, strong acids, or alkaline carbonates, it may be converted into tetraphosphotetramic acid. Among the bodies formed from it when heated alone, is a white substance, insoluble or nearly so in cold water, and having the same composition as ammonium-metaphosphate, PNH^4O^3; this substance is at once transformed, by hot water or dilute acids, into pyrophosphodiamic acid.

Tetraphosphopentazotic Acid, $P^4N^5H^9O^7$, is formed when oxychloride of phosphorus is fully saturated with ammonia, and the resulting mass is heated to about 230°, and washed with cold water. It is an insoluble body capable of decomposing metallic salts, and contains 1 at. of hydrogen replaceable by potassium or ammonium. When treated with slightly acidulated nitrate of silver, it yields a tetrazotic salt, $P^4N^4H^4Ag^2O^7$; which, when decomposed by mineral acids, yields tetraphosphotetramic acid and other compounds. [For the discussion of the rational formulæ of all these compounds, see the original paper above cited.]

TETRAPHOSPHATES. This name may be applied to one of the classes of phosphates discovered by Fleitmann and Henneberg, namely $M^6P^4O^{13}$ (iv. 537).

---

* Phosphoric oxychloride absorbs either 2 or 4 molecules of ammonia, forming white solids, probably consisting of sal-ammoniac, mixed, in the one case, with $P(NH^2)Cl^2O$, and in the other with $P(NH^2)^2ClO$. (Gladstone.)

TETRASULPHODIPHENYLENIC ACID. $C^{12}H^6.4H^2SO^4$.—An acid formed, together with trisulphodiphenylenic acid, $C^{12}H^6.3H^2SO^4$, by heating sulphate of diazobenzidine (tetrazodiphenyl) with strong sulphuric acid (iv. 413).

TETRATHIONIC ACID. See SULPHUR, OXYGEN-ACIDS OF (p. 641).

TETRAZODIPHENYL. $C^{12}H^6N^4$. Syn. with DIAZOBENZIDINE (iv. 412).

TETRAZODIPHENYL-AMIDOBENZOL. $C^{24}H^{20}N^8$. Syn. with DIAZOBENZIDINE-ANILINE (iv. 413).

TETRAZODIPHENYLIMIDE. $N^2H^2(C^{12}H^6N^4)^{iv}$.—A compound produced by the action of aqueous ammonia on perbromide of diazobenzidine (iv. 412).

TETRAPHYLINE. Syn. with triphyline. (See PHOSPHATES, iv. 572.)

TETRENE. Syn. with TETRYLENE.

TETRETHYLAMMONIUM. $N(C^2H^5)^4$. Most of the compounds of this base have been already described (ii. 561).—A *chloriodide*, $N(C^2H^5)^4Cl^2I$, is produced by adding aqueous protochloride of iodine to a solution of chloride of tetrethylammonium in dilute hydrochloric acid. On gently heating the liquid, and leaving it to stand, the chloriodide is deposited in large fern-leaf crystals, belonging to the regular system. It is more soluble in dilute hydrochloric acid than in water, which latter causes decomposition. The solution reacts like protochloride of iodine. (W. A. Tilden, Chem. Soc. J. xix. 145.)

The following compounds of tetrethylammonium with metallic acids have been examined by Al. Classen (J. pr. Chem. xciii. 446; Jahresb. 1864, p. 420):

Tungstate, $(C^8H^{20}N)^2O.2WO^3$	deliquescent.
Molybdate, $(C^8H^{20}N)^2O.2MoO^3.3H^2O$	deliquescent.
Stannates, $\begin{cases}(C^8H^{20}N)^2O.6SnO^2.H^2O\\(C^8H^{20}N)^2O.7SnO^2.H^2O\end{cases}$	insoluble quadratic octahedrons.
Neutral chromate, $(C^8H^{20}N)^2O.CrO^3$	not crystallisable.
Dichromate, $(C^8H^{20}N)^2O.2CrO^3$	prismatic crystals.
Arsenate, $(C^8H^{20}N)^2O.As^2O^5$	crystalline.
Antimonate, $2(C^8H^{20}N)^2O.Sb^2O^5$	deliquescent.

Most of these salts are obtained by treating the metallic acid with a solution of the base; the chromate by decomposing chromate of silver with hydrate of tetrethylammonium. When heated, they yield offensive-smelling products, the dichromate decomposing explosively.

TETRYL, or **BUTYL.** C^4H^9.—The fourth alcohol-radicle of the series C^nH^{2n+1}. In the free state, its molecule contains C^8H^{18}, so that it is isomeric, or perhaps identical (iii. 182), with octylic hydride, $C^8H^{17}.H$. It was first isolated by Kolbe (Chem. Soc. Mem. iii. 278; Chem. Soc. Qu. J. ii. 157), who obtained it by the electrolysis of valerianic acid, and named it *Valyl*; Wurtz (Ann. Ch. Pharm. xciii. 112; xcvi. 364) afterwards obtained it by the decomposition of tetrylic iodide, and examined its properties more fully.

Preparation.—1. *By the action of Potassium or Sodium on Tetrylic Iodide.*—100 pts. of tetrylic iodide and 13 or 14 pts. of sodium, are introduced into a flask, provided with an upright condensing-tube kept cool by ice-water. The action begins at ordinary temperatures, with evolution of heat, the sodium swelling up, and gradually becoming covered with a blue crust. As the action slackens it must be accelerated by external heat, and the liquid kept boiling till the blue colour of the sodium has disappeared, and the flask contains a white mass of sodium-iodide saturated with tetryl. The tetryl is then distilled from the flask, and the distillate rectified over sodium, till the metal completely retains its lustre in the boiling liquid, and is no longer attacked. The portion which, in the last rectification, distils over between 105° and 108° is pure tetryl. When potassium is used, a considerable quantity of the tetryl is resolved into tetrylic hydride and tetrylene: $C^8H^{18} = C^4H^{10} + C^4H^8$. (Wurtz.)

2. *By the Electrolysis of Valerianic Acid:*

$$2C^5H^{10}O^2 = C^8H^{18} + 2CO^2 + H^2.$$

—When an electric current of four Bunsen's cells is passed through a cold saturated solution of potassic valerate,—hydrogen, carbonic anhydride, and tetrylene gases are evolved, and an oily liquid rises to the surface, consisting of tetryl and tetrylic valerate. On boiling this liquid with an alcoholic solution of potash, valerate of potassium gradually separates, while the tetryl remains dissolved in the alcoholic liquid, and may be purified by washing with water, drying over chloride of calcium, and rectification. (Kolbe.)

Properties.—Tetryl is a colourless oily liquid, having a faint but agreeable odour, and a slight taste, with burning aftertaste. Specific gravity = 0·694 at 16°

(Kolbe); 0·7135 at 0° (Kopp); 0·7057 at 0° (Wurtz). Its expansion-coefficient (between 11° and 88°), is, according to Kopp:

$$0{\cdot}0012125t + 0{\cdot}00000027933t^2 + 0{\cdot}000000016297t^3.$$

It boils at 108° (Kolbe); at 108·5° (Wurtz); at 106° under a barometric pressure of 745mm. (Kopp), and distils completely without decomposition. Vapour-density = 4·053 (Kolbe); 4·070 (Wurtz); 4·07 and 3·88 (Gr. Williams); the calculated value (C^8H^{18} = 2 vols.) is 3·95.

Tetryl is insoluble in water, but mixes in all proportions with alcohol and ether. None of the tetryl-compounds can be directly prepared from it.—*Chlorine* and *bromine* act upon it, but form substitution-products.—With *pentachloride of antimony* it yields hydrochloric acid and chlorinated products not yet examined.—*Pentachloride of phosphorus* is decomposed by it only after long boiling, with formation of trichloride of phosphorus, chlorinated tetryl, and hydrochloric acid. When the vapours of iodine and tetryl are passed together over *spongy platinum* heated in a tube to 300°, a large quantity of hydriodic acid is formed, together with a small quantity of an iodised organic substance, probably a substitution-product.—*Hydrochloric acid* has no action upon tetryl, either at ordinary temperatures, or at a temperature near that of boiling oil. (Wurtz.)

Tetryl forms compounds with other alcohol-radicles.

Tetryl-ethyl, $C^6H^{14} = C^4H^9.C^2H^5$, obtained by the action of sodium on a mixture of tetrylic and ethylic iodides, has been already described (ii. 525).

Tetryl-amyl, $C^9H^{20} = C^4H^9.C^5H^{11}$, is prepared by decomposing a mixture of tetrylic and amylic iodides with sodium, in the manner described for the preparation of tetryl. The greater part of the resulting liquid distils over between 130° and 140°, and, by repeated fractional distillation, pure tetryl-amyl is obtained as a colourless liquid, boiling at 132°, having a specific gravity of 0·724 at 0°. Vapour-density = 4·46 (calc. = 4·42). (Wurtz.)

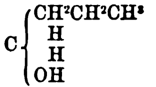
Tetryl-hexyl, $C^{10}H^{22} = C^4H^9.C^6H^{13}$, is obtained by the electrolysis of a mixture of œnanthylate and valerate of potassium. The oily liquid, which collects on the surface of the aqueous solution, is a mixture of several hydrocarbons; and when subjected to fractional distillation, yields, between 100° and 140°, a liquid containing tetryl-hexyl, which, when further rectified, boils between 155° and 160°, and exhibits a vapour-density of 4·917 (calc. = 4·907); but it has not been obtained pure.

TETRYL, ACETATES OF. $C^6H^{12}O^2$.—There are two ethers having this composition, the one corresponding with normal tetrylic alcohol, the other with isotetrylic alcohol (*infra*).

Normal Tetrylic Acetate, $C^4H^9.C^2H^3O^2 = \left.\begin{matrix}C^2H^3O\\C^4H^9\end{matrix}\right\}O$, is produced by distilling equivalent quantities of dry acetate and tetrylsulphate of potassium, or by heating normal tetrylic iodide with a slight excess of silver-acetate in a glass tube, and distilling off the resulting liquid. The distillate is purified by washing with a dilute solution of sodic carbonate, then dried over chloride of calcium, and rectified. It is a colourless liquid, of agreeable odour, specific gravity = 0·844 at 16°, and boiling at 114°. Vapour-density = 4·073; calc. = 4·017. By prolonged boiling with potash, it is resolved into acetic acid and normal tetrylic alcohol. (Wurtz, Ann. Ch. Pharm. xciii. 121.)

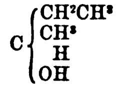
Isotetrylic Acetate, perhaps $C^4H^8\left\{\begin{matrix}H\\C^2H^3O^2\end{matrix}\right.$, is produced, together with tetrylene, by heating isotetrylic iodide (obtained from erythromannite, p. 736), with acetate of silver in sealed tubes. On distilling off the tetrylene, the isotetrylic iodide remains, and may be purified like the normal ether. It is a colourless liquid, boiling at 111° to 113°, and having a strong, agreeable, aromatic odour, but not fruity, like the normal acetate. (De Luynes, Jahresb. 1864, p. 501.)

TETRYL ALCOHOLS. $C^4H^{10}O$.—In the article "SECONDARY AND TERTIARY ALCOHOLS" (p. 216), it is observed that there are three possible tetryl or butyl alcohols, represented by the following formulæ:—



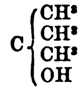
$$C\left\{\begin{matrix}CH^2CH^2CH^3\\H\\H\\OH\end{matrix}\right.$$

Primary.



$$C\left\{\begin{matrix}CH^2CH^3\\CH^3\\H\\OH\end{matrix}\right.$$

Secondary.



$$C\left\{\begin{matrix}CH^3\\CH^3\\CH^3\\OH\end{matrix}\right.$$

Tertiary.

An alcohol having the composition $C^4H^{10}O$, is produced, together with ethylic and amylic alcohols, in the fermentation of sugar, and is found in the fusel-oil obtained from mangold-wurzel, and sometimes in that obtained from potatoes. This, which was discovered by Wurtz in 1852 (Compt. rend. xxxv. 210; Ann. Ch. Pharm. xciii. 107), and is distinguished as normal tetrylic or butylic alcohol, is supposed to be the primary alcohol. An alcohol, most probably identical with it, has been obtained by Schöyen (Ann. Ch. Pharm. cxxx. 233), by heating chloride of tetryl prepared from ethyl (p. 734) with acetate of potassium and glacial acetic acid, whereby it is converted into tetrylic acetate, and distilling this compound ether with baryta-water.

An abnormal tetrylic alcohol (whether secondary or tertiary has not yet been ascertained) is produced by distilling the iodide or the acetate of tetryl, obtained from erythromannite, with potash.

a. *Normal Tetrylic Alcohol*, $C^4H^{10}O = \left.\begin{matrix}C^4H^9\\H\end{matrix}\right\}O$. *Hydrate of Tetryl. Tetrylic Hydrate.* (Wurtz, *loc. cit.*)—This alcohol was first obtained from potato-fusel-oil, in which, however, it is not always present. It is best prepared by subjecting the fusel-oil obtained in the rectification of mangold-wurzel molasses to fractional distillation, the portions which distil over between 80° and 105°, 105° and 115°, 115° and 125°, being collected apart. The first portion is washed with water, and the separated oily layer repeatedly rectified, the portion which passes over at 104° being each time collected apart. The latter is mixed with the portion which distilled over between 105° and 115°, and with that part of the last fraction (between 115° and 125°) which, when the latter was repeatedly rectified, passed over below 115°. The whole of the distillates obtained between 105° and 115° are then mixed together, and boiled for forty-eight hours with a concentrated solution of caustic potash, in such a manner that the vapours may be condensed and allowed to run back again. The impure tetrylic alcohol is then distilled over; separated from the water which passed over with it; afterwards mixed with half its weight of quicklime, to dehydrate it more completely, and distilled off after standing for twenty-four hours; this distillate is repeatedly rectified and the portion which passes over between 108° and 110° is collected apart: if the boiling-point remains within these limits during the distillation, the tetrylic alcohol thus obtained is very nearly pure. The process of rectification may be considerably abridged by interposing between the flask and the condensing apparatus an upright tube with two bulbs, and having a thermometer inserted into its upper part; the less volatile portions then condense on the sides of the tube, and run back into the flask, whereby the separation of the more volatile portions is greatly facilitated. (Wurtz.)

For complete purification, the tetrylic alcohol is converted into iodide of tetryl, which boils at 121°, and is easily separated, by fractional distillation, from iodide of ethyl boiling at 74°, and iodide of amyl at 146°; the iodide of tetryl is converted into acetate by treating it with acetate of silver; the acetate of tetryl decomposed by continued boiling with strong solution of potash, the vapours being condensed and made to run back; and the tetrylic alcohol thereby separated, is deecanted and rectified over caustic baryta.

Properties.—Tetrylic alcohol is a transparent colourless liquid, more mobile than amylic alcohol, and having an odour similar to that of the latter, but less pungent and more vinous. It does not turn the plane of polarisation of light. Specific gravity = 0·8032 at 18·5°. Boiling-point = 10°. Vapour-density, obs. = 2·589; calc. = 2·565.

Tetrylic alcohol dissolves in 1½ times its weight of *water* at 18°, and is precipitated therefrom, as an oily layer, on addition of chloride of calcium, chloride of sodium, or any other easily soluble salt. It dissolves *chloride of calcium*, forming a crystallisable compound; also recently fused *chloride of zinc*, forming a syrupy liquid.

Decompositions.—1. Tetrylic alcohol takes fire on the approach of a burning body, and burns with a bright flame.—2. *Potassium* decomposes it, with evolution of hydrogen, forming tetrylate of potassium, C^4H^9KO.—3. *Caustic potash*, in a state of fusion, converts it into butyric acid, with evolution of hydrogen, and formation of a butyrate, When dropt upon *soda-lime* heated to 250°, it is likewise decomposed, with evolution of hydrogen, and formation of a butyrate.—4. *Hydrochloric acid* heated in a sealed tube with tetrylic alcohol, converts it into chloride of tetryl (p. 734).—5. *Pentachloride* and *oxychloride of phosphorus* likewise convert it into chloride of tetryl.—6. *Bromine* and *phosphorus*, added alternately in small portions, convert tetrylic alcohol into bromide of tetryl, with evolution of hydrobromic acid (p. 734).—7. Similarly, *iodine* and *phosphorus* give rise to the formation of iodide of tetryl (p. 735).—8. *Oil of vitriol* acts violently on tetrylic alcohol, the mixture becoming very hot and strongly coloured, while sulphurous acid is evolved, and an oily layer separates out, consisting chiefly of hydrocarbons polymeric with tetrylene. When the alcohol is rapidly mixed with excess of oil of vitriol, great heat is produced, and gas is given off in small quantity, which may, however, be increased by external heating; it consists chiefly of tetrylene, together with sulphurous and carbonic anhydrides. When tetrylic alcohol is gradually mixed with an equal volume of oil of vitriol, and the vessel kept cool, tetryl-sulphuric acid is produced.—9. Tetrylic alcohol heated with excess of *zinc-chloride* is decomposed, with formation of tetrylene, hydride of tetryl, and other less volatile hydrocarbons.—10. With *chloride of cyanogen*, tetrylic alcohol forms chloride of tetryl and tetrylic urethane:

$$2C^4H^{10}O + CNCl = C^4H^9Cl + C^5H^{11}NO^2. .$$

If the tetrylic alcohol, as is generally the case, contains a little water, carbonate of tetryl and sal-ammoniac are formed at the same time:

$$2C^4H^{10}O + CNCl + H^2O = (C^4H^9)^2CO^3 + NH^4Cl$$

(E. Humann, Ann. Ch. Pharm. xcv. 256).—11. Tetrylic alcohol obtained by fermentation yields, by distillation with *sulphuric acid* and *potassic dichromate*, a mixture of butyric and propionic acids with the corresponding aldehydes (Michaelson, Jahresb. 1864, p. 336). The alcohol obtained by Schöyen from tetrylic chloride, as above mentioned, also yields butyric acid when subjected to the same treatment.

Isotetrylic Alcohol. (De Luynes, Ann. Ch. Pharm. cxxviii. 330, cxxxii. 274; Jahresb. 1863, p. 503; 1864, p. 501.)—This alcohol is produced by the action of moist silver-oxide on isotetrylic iodide (obtained by the action of hydriodic acid on erythromannite, ii. 505), or, better, by heating isotetrylic acetate (obtained by decomposing the iodide with acetate of silver) to 100° for thirty hours. The alcohol then separates as an oily layer on the surface of the liquid, and may be purified by drying with carbonate of potassium, and rectification, finally over lumps of sodium. It is a colourless liquid, having a strong odour and burning taste, a specific gravity of 0·85 at 0°, and boiling at 95°—98° (about 10° lower than the normal alcohol). It mixes in all proportions with *alcohol* and *ether*; dissolves also in *water*, and is precipitated from the solution by carbonate of potassium; it dissolves *chloride of calcium*. It absorbs *hydriodic acid*, forming isotetrylic iodide, identical with that produced by the action of hydriodic acid on erythromannite.—With *bromine* it forms a heavy liquid, which strongly attacks the eyes, and varies in boiling-point from 110° to 158°.

Isotetrylic alcohol, when heated for some hours to 250°, is for the most part resolved into water and tetrylene. The corresponding iodide gives off tetrylene when distilled with alcoholic potash. These isotetryl-compounds, therefore, like the β-hexyl-compounds (iii. 152), with which they are homologous, show a great tendency to give up their olefine. In this respect they appear to react more like compounds of tetrylene than of tetryl, and as such they are, in fact, regarded by De Luynes,—the alcohol as $C^4H^8.H^2O$ or $C^4H^8\left\{\begin{matrix}H\\HO\end{matrix}\right.$; the iodide as $C^4H^8.HI$. But the property of readily giving up the olefine does not afford a decisive argument in favour of this view, inasmuch as the same property is possessed, though in a less marked degree, by the normal alcohols $C^nH^{2n+2}O$, all of which, when treated with oil of vitriol or other strong dehydrating agents, are resolved into water and the olefine.

TETRYL, BROMIDE OF. C^4H^9Br. (Wurtz, Ann. Ch. Pharm. xciii. 114.)—This compound is prepared by the action of bromine and phosphorus on tetrylic alcohol. A few drops of bromine are added to tetrylic alcohol; a small piece of phosphorus thrown in, the liquid being kept cool and shaken till the colour of the bromine is destroyed; the addition of bromide and phosphorus then repeated, and so on continually, till vapours of hydrobromic acid are abundantly evolved, and a quantity of bromine has been added at least equal to that of the tetrylic alcohol. The liquid is then distilled at a temperature not exceeding 100°, and the resulting vapours are passed into a flask containing water, which dissolves the hydrobromic acid, while the impure bromide of tetryl collects at the bottom. The latter is washed with water, dried with a little chloride of calcium, and rectified; that which passes over at 89° is pure bromide of tetryl.

It is an oily liquid, having an ethereal odour, and boiling at 89°. Specific gravity = 1·274 at 16°. Vapour-density, obs. = 4·720; calc. = 4·749.

Potassium decomposes bromide of tetryl, slowly at ordinary temperatures, but violently when heated. When the two substances are heated together in a sealed tube, decomposition begins as soon as the potassium melts, a large quantity of gas (probably tetrylene and tetrylic hydride) being evolved, and the tube exploding with violence.—*Ammonia* acts slowly on bromide of tetryl at ordinary temperatures, forming hydrobromate of tetrylamine. (Wurtz.)

TETRYL, CARBONATE OF. See CARBONIC ETHERS (i. 801).

TETRYL, CHLORIDE OF. C^4H^9Cl. (Wurtz, Ann. Ch. Pharm. xciii. 113.)

Prepared: 1. By the action of hydrochloric acid on tetrylic alcohol. When the alcohol is saturated with hydrochloric acid gas, and the liquid sealed up in a glass tube is heated in the water-bath, a large quantity of chloride of tetryl is produced, and may be obtained pure by washing the product with water, distilling, and separating the portion which goes over between 70° and 75°.—2. By the action of pentachloride or oxychloride of phosphorus on tetrylic alcohol. The alcohol is placed in a flask with a long neck, which must be kept very cool, and the chloride of phosphorus added by small portions. Violent action takes place, attended with great evolution of heat, and the pentachloride is converted into oxychloride, which then acts on the last portions of tetrylic alcohol. The oxychloride may also be used from the beginning instead of the pentachloride, in which case the action is less violent. In either case, the contents of the flask must be left to stand for 24 hours, and then distilled, the portion which passes over below 100° being collected apart; this portion is then washed with water, dried over chloride of calcium, and rectified, collecting separately the portion which distils over at 70°.—3. By the action of chlorine on tetrylic hydride. (Pelouze and Cahours.)

4. By distilling amylic alcohol with calcic hypochlorite (120 grms. amylic alcohol with 1,500 grms. bleaching powder, and 2,500 grms. water). The oily distillate yields, after fractionation, about 20 grms. of a liquid boiling between 62° and 64°; and on treating this with oil of vitriol, and afterwards with potash (to remove chloroform), pure tetrylic chloride is obtained. (F. Gerhard, Ann. Ch. Pharm. cxxii. 363; Jahresb. 1862, p. 409.)

Chloride of tetryl is a liquid lighter than water, and having an ethereal odour, recalling also that of chlorine: specific gravity = 0·88 (Gerhard). Boiling-point about 70°. It is rapidly decomposed by potassium, with rise of temperature and evolution of gas (Wurtz). Chlorine converts it into trichloride of carbon. (Gerhard.)

TETRYL, CYANIDE OF. See Cyanides (ii. 272).

TETRYL, FORMATE OF. See Formic Ethers (ii. 695).

TETRYL, HYDRATE OF. Normal tetrylic alcohol, $C^4H^9.H.O$ (p. 732).

TETRYL, HYDRIDE OF. $C^4H^{10} = C^4H^9.H$.—This compound, discovered by Wurtz (Ann. Ch. Pharm. xciii. 112), is produced, together with tetrylene, by heating tetrylic alcohol with excess of zinc-chloride. When the gaseous mixture thus evolved is passed, first through a tube surrounded with ice and inclined upwards, to condense the less volatile hydrocarbons formed at the same time, and allow them to flow back again —then through a tube surrounded with a freezing mixture, a very volatile, mobile, colourless liquid condenses in this tube, and on being removed from the freezing mixture, quickly evaporates, yielding a mixture of about equal volumes of tetrylene and tetrylic hydride. The tetrylene may be absorbed by a coke-ball saturated with sulphuric anhydride, and tetrylic hydride then remains nearly pure.

Tetrylic hydride is one of the constituents of American petroleum, being found, according to Pelouze and Cahours (Ann. Ch. Phys. [4], i. 5), in the most volatile portion of the oil, boiling between 5° and 10°. Ronalds (Chem. Soc. J. xviii. 54), by subjecting the portion which distilled between 0° and 4° (containing tetrylic hydride with smaller quantities of tritylic and ethylic hydrides), to fractional distillation, and collecting the distillate in a well-cooled receiver, obtained the tetrylic hydride in a state of purity. It is a very mobile liquid, having a sweetish odour, a specific gravity of 0·60 at 0°, and vapour-density = 2·11 (calc. = 2·006). It burns with a yellow, faintly luminous flame, is insoluble in water, but dissolves in alcohol and in ether. Alcohol of 98 per cent. absorbs 11 or 12 times its volume of the vapour. When 1 vol. of the vapour is mixed with 2 vols. chlorine-gas, chloride of tetryl condenses, and 2 vols. hydrochloric acid gas are produced.—The portion of American petroleum distilling between 6° and 8° is a mixture of tetrylic and amylic hydrides. (Ronalds.)

TETRYL, IODIDES OF. *a. Normal tetrylic iodide*, C^4H^9I, is produced by the action of phosphorus and iodine on tetrylic alcohol. 1·5 pt. iodine is added to 1 pt. tetrylic alcohol in a vessel surrounded with cold water, and a quantity of phosphorus equal to about $\frac{1}{10}$ of the iodine, added in successive small portions, the mixture being heated towards the end of the process, to render the action complete. The dark colour of the liquid then gradually changes to brownish-yellow, whilst hydriodic acid is abundantly evolved, which, together with a small quantity of tetrylic iodide that passes over with it, is received in a small quantity of cold water. As soon as the colouring produced by the iodine has disappeared, and the liquid is in full ebullition, it is left to cool, and that which remains in the distillation-vessel is washed, first with the aqueous hydriodic acid previously collected—whereby a small quantity of undecomposed tetrylic alcohol is dissolved—and then with pure water; it is then dehydrated with chloride of calcium, and freed from the still remaining portion of tetrylic alcohol, by treating it while warm with pulverised iodide of phosphorus, till the latter crystallises out on cooling. The liquid is then distilled, and the distillate is washed with water, dehydrated over chloride of calcium, and rectified, the portion which passes over between 118° and 122° being collected.

Tetrylic iodide is colourless when recently prepared, but soon turns brown by exposure to light. It refracts light strongly; boils at 121°; but when a mixture of water and iodide of tetryl is distilled, the thermometer, at the beginning of the distillation, when the tetrylic iodide chiefly passes over, indicates only 88° to 89°. Specific gravity = 1·604 at 19°. Vapour-density = 6·217 (calc. = 6·344).

Tetrylic iodide *burns* with difficulty, and only in contact with a burning body; the combustion is attended with evolution of iodine-vapours. It is but slowly attacked by *aqueous potash*, even when boiled therewith for some time; but *alcoholic potash* decomposes it, with formation of tetrylic alcohol and iodide of potassium.—*Potassium* decomposes iodide of tetryl, yielding tetryl and iodide of potassium.—With *tetrylate of potassium*, C^4H^9KO, it forms tetrylic ether and iodide of potassium (p. 736).—With *oxide of silver*, it forms tetrylic ether and iodide of silver.—With *silver-salts* (*e.g.* the carbonate, sulphate, acetate, &c.) it forms iodide of silver and a compound ether (*e.g.* carbonate, sulphate, acetate, &c.) of tetryl. A solution of nitrate of silver is immediately precipitated by iodide of tetryl. (Wurtz.)

β. *Isotetrylic iodide*, perhaps $(C^4H^8)''\left\{\begin{matrix}H\\I\end{matrix}\right.$. (De Luynes, Jahresb. 1862, p. 479; 1863, p. 503; 1864, p. 500).—This compound is produced by the action of hydriodic acid on erythromannite (ii. 505):

$$C^4H^{10}O^4 + 7HI = C^4H^9I + 4H^2O + 3I^2.$$

Thirty grms. of perfectly dry (fused) erythromannite are slowly distilled with 350 to 400 grms. of fuming hydriodic acid, of specific gravity 1·99. As soon as the liquid boils, isotetrylic iodide distils over, together with undecomposed hydriodic acid. It is purified by washing with potash-ley, then with water, dried over chloride of calcium, and rectified. With weaker acid (of specific gravity 1·70, for example), a greenish product is obtained, which decomposes partially during rectification, and is best purified by a second distillation with hydriodic acid.—2. By the action of hydriodic acid gas on isotetrylic alcohol, &c.

Isotetrylic iodide, when recently prepared, is colourless, and has an agreeable ethereal odour. Its specific gravity is 1·632 at 0°, 1·600 at 20°, and 1·584 at 30°. It boils at about 118°. Vapour-density = 6·597 at 20°; = 6·517 at 24°. It is insoluble in water, but soluble in alcohol and ether. When exposed to light at a somewhat high temperature, it becomes coloured.—*Chlorine* decomposes it, separating iodine, and forming an aromatic liquid, which boils at 120° (probably $C^4H^8Cl^2$).—With *bromine* it gives off iodine, and yields bromide of tetrylene, $C^4H^8Br^2$.

TETRYL, NITRATE OF. $C^4H^9NO^3$. (Wurtz, Ann. Ch. Pharm. xciii. 120.)—Prepared by mixing tetrylic iodide with a small quantity of fused urea, and a slight excess of fused silver-nitrate. The reaction takes place immediately, accompanied by so much heat that part of the product distils over; the rest must be afterwards volatilised, by heating the mixture to 140°—150°. The distillate is purified by washing with slightly alkaline water, drying with chloride of calcium, and rectification.

TETRYL, OXIDE OF. $C^8H^{18}O = (C^4H^9)^2O$. (Wurtz, Ann. Ch. Pharm. xciii. 117.)—Produced: 1. By the action of tetrylic iodide on tetrylate of potassium. The product thus obtained is, however, difficult to purify from tetrylic alcohol, as the boiling-points of the two liquids differ but little from each other.—2. A purer product is obtained by the action of tetrylic iodide on oxide of silver.

Ethyl-tetrylic ether, $(C^2H^5)(C^4H^9)O$, is produced by the action of ethylic iodide on tetrylate of potassium. It is a colourless fragrant liquid, having a specific gravity of 0·7507.

TETRYL, SULPHATE OF. See SULPHURIC ETHERS (p. 629).

TETRYL, SULPHYDRATE OF. $C^4H^{10}S = C^4H^9.H.S$. *Tetrylic* or *Butylic Mercaptan*. (E. Hermann, Ann. Ch. Pharm. xcv. 256; Chem. Soc. Qu. J. viii. 274.)—Produced by distilling, at the heat of the water-bath, a mixture of aqueous sulphydrate of potassium and concentrated aqueous tetrylsulphate of potassium, the product being received in a well-cooled flask:

$$C^4H^9KSO^4 + KHS = C^4H^{10}S + K^2SO^4.$$

The oily liquid which condenses is decanted, placed in contact with chloride of calcium, and distilled, the portion which passes over between 85° and 90° being collected apart.

Tetrylic mercaptan is a colourless very mobile liquid, having the peculiar disagreeable odour which characterises the mercaptans. Specific gravity = 0·848 at 11·5°. Vapour-density = 3·10. Boils at 88°. It has no action on vegetable colours, is very sparingly soluble in *water*, but freely in *alcohol* and *ether*; it dissolves *sulphur* and *iodine*. It is very inflammable, and burns with a pale-blue flame.—Dilute *nitric acid* acts very strongly upon it, forming an oily liquid which floats on the surface.

Potassium decomposes tetrylic mercaptan, with evolution of hydrogen, and formation of a white granular tetrylmercaptide of potassium, C^4H^9KS. Tetrylic mercaptan is also decomposed by several metallic oxides, or by the solutions of their salts, forming tetrylmercaptides: *e.g.* with *mercuric oxide*:

$$2C^4H^{10}S + Hg''O = C^8H^{18}Hg''S^2 + H^2O.$$

The mercury-compound thus obtained forms white nacreous scales, which are unctuous to the touch, and very fusible. It is decomposed by sulphydric acid, with formation of mercuric sulphide and tetrylic alcohol.—The *lead-compound*, $C^8H^{18}Pb''S^2$, is a yellow crystalline precipitate, formed on evaporating an alcoholic solution of tetrylic mercaptan into acetate of lead.—The *cupric* and *auric salts* are white precipitates.

TETRYLAMINE. $C^4H^{11}N = N.H^2.C^4H^9$. *Butylamine.* (Wurtz, Ann. Ch. Pharm. xciii. 124.)—This base, produced by the action of potash on cyanate or cyanurate of tetryl, is metameric with diethylamine, $N.H.(C^2H^5)^2$, ethyl-dimethylamine, $N.C^2H^5.(CH^3)^2$, and methyl-tritylamine, $N.H.CH^3.C^3H^7$. Petinine, a volatile base obtained by Anderson from the most volatile portion of bone-oil, is also isomeric, or perhaps identical, with tetrylamine.

To prepare tetrylamine, 2 pts. of potassic tetrylsulphate are distilled with 1 pt. of recently prepared and perfectly dry potassic cyanate; the pasty mixture of tetrylic cyanate and cyanurate, which distils over, is dissolved in alcohol; and the solution is boiled with fragments of caustic potash. Carbonate of potassium is then formed, and tetrylamine distils over, and is condensed in a small quantity of cold water acidulated with hydrochloric acid. The boiling is continued till the residue fuses completely, and no longer gives off alkaline vapours. The resulting solution of hydrochlorate of tetrylamine is evaporated to dryness; and the residual salt, freed by fusion from the water which it retains, is pulverised when cold, and rapidly mixed with an equal weight of quicklime. This mixture is then introduced into a tube of hard glass, which must be filled with it to about four-fifths; the upper part of the tube is filled with fragments of caustic baryta; a gas-delivery tube, bent at right-angles, is adapted to the larger tube, and made to pass into a small flask surrounded with ice; and the tube is carefully heated in a combustion-furnace, from the closed end onwards. The evolved tetrylamine is then completely dehydrated by the caustic baryta, and condenses in a cooled flask.

Tetrylamine is a transparent colourless liquid, having a strongly ammoniacal and somewhat aromatic odour, and producing dense white fumes with hydrochloric acid. It boils at 69°—70° (petinine at about 70·5°). It dissolves in all proportions of water, alcohol, and ether; the aqueous solution smells like the pure base, and is very caustic; when concentrated it is somewhat viscid.

Salts of Tetrylamine.—Most metallic solutions are precipitated by tetrylamine in the same manner as by ammonia.—The *zinc*, *cadmium*, and *copper* precipitates dissolve in excess of the reagent; gelatinous *alumina* likewise dissolves in excess of tetrylamine; the precipitates formed in solutions of *chromium*, *nickel*, and *cobalt*, are insoluble in excess of tetrylamine.—With *nitrate of silver*, tetrylamine forms a tawny yellow precipitate, easily soluble in excess. Gelatinous *silica* dissolves in tetrylamine, and remains in the pulverulent and amorphous state when the solution is evaporated.

Hydrochlorate of Tetrylamine, $C^4H^{11}N.HCl$, crystallises in deliquescent needles, which melt below 100°; when exposed to the air, it gives off thick white fumes, and volatilises without residue.—The *chloroaurate*, $(2C^4H^{11}N.HCl).AuCl^3$, crystallises on evaporation in rectangular plates of a pale-yellow colour, melting and changing to orange-yellow at 100°.—The *chloroplatinate*, $2(C^4H^{11}N.HCl).PtCl^4$, crystallises by evaporation in beautiful orange-yellow laminæ, soluble in water and in alcohol.

TETRYLENE. C^4H^8. *Butylene, Butyrene, Butene, Valylene, Ditetryl*.—This hydrocarbon was discovered, in 1825, by Faraday (Phil. Trans. 1825, p. 440), who obtained it by compressing the illuminating gas produced by the destructive distillation of fixed oils. Some years later, Kolbe (Ann. Ch. Pharm. lxix. 269) obtained it by the electrolysis of valerianic acid; and Wurtz (Ann. Ch. Pharm. xciii. 107) has shown that it is a frequent product of the decomposition of tetryl-compounds, being formed especially in the dehydration of tetrylic alcohol by strong sulphuric acid or chloride of zinc, and as a secondary product of the action of potassium or silver-oxide on tetrylic iodide, part of the tetryl thereby set free being resolved into tetrylene and tetrylic hydride (p. 735); it is formed also, in small quantity, in the decomposition of amylic alcohol at a red heat. Lastly, De Luynes (Compt. rend. lvi. 1175; Ann. Ch. Phys. [4], ii. 355; Jahresb. 1863, p. 504; 1864, p. 500) has shown that it is produced by decomposing isotetrylic iodide (p. 736) with alcoholic potash or acetate of silver, isotetrylic acetate being also produced in the latter case.

Preparation.—1. From *Oil-gas.*—Faraday obtained tetrylene by subjecting the illuminating gas, which was prepared in London some years ago by decomposing fixed oils at a moderate red heat, to a pressure of 30 atmospheres. 1,000 cubic feet of the gas thus treated yielded about 4 litres of so-called empyreumatic oils, consisting chiefly of tetrylene and benzene. As the former of these hydrocarbons boils below 0°, it may be separated, in great part, by gradually warming the mixture to 38° in a suitable distillatory apparatus connected with a receiver cooled to $-18°$; and by subjecting the distillate several times to the same treatment, but each time at a lower temperature, the tetrylene may be obtained nearly pure.

Tetrylene is also formed by subjecting acetate of sodium or oleate of calcium, mixed with soda-lime, or butyrate of barium, or by itself, to destructive distillation; also by heating glucose with soda-lime; in each case, however, the tetrylene is accompanied by a large quantity of tritylene, amylene, and other hydrocarbons. The gases thus evolved are fixed by passing them through bromine, whereby they are all converted into bromides; and from the mixture thus obtained, the bromide of tetrylene may be separated by fractional distillation. (Berthelot, Ann. Ch. Pharm. cviii. 200.)

2. From *Valerianic Acid.*—A concentrated solution of potassic valerate is subjected to the action of an electric current with platinum electrodes. Tetrylene is then evolved at the positive pole, together with tetryl and carbonic anhydride, while the gas evolved at the negative pole consists wholly of hydrogen; and if a porous diaphragm be interposed between the two electrodes, the tetrylene will pass off, mixed only with tetryl and carbonic anhydride. To separate it, the gaseous mixture is passed, first through a tube surrounded with a frigorific mixture, and through alcohol, to condense and absorb the tetryl; then through water, to take up the alcohol; and lastly through strong potash-ley and over solid potash, to absorb the carbonic acid and water. The tetrylene obtained by this process is merely a secondary product, probably formed by oxidation of a portion of the tetryl, which is the immediate product of the electrolytic action (p. 731):

$$\underset{\text{Tetryl.}}{C^8H^{18}} + O = \underset{\text{Tetrylene.}}{2C^4H^8} + H^2O.$$

3. From *Tetrylic Alcohol.*—When this alcohol is quickly mixed with excess of sulphuric acid, the mixture gently heated, and the evolved gas freed from sulphurous and carbonic acids by absorption with potash, tetrylene is obtained nearly pure, being contaminated only with a small quantity of a hydrocarbon of higher atomic weight.—When tetrylic alcohol is heated with excess of zinc-chloride, nearly pure tetrylene is evolved at first, afterwards a mixture of tetrylene and tetrylic hydride.

4. From *Erythromannite.*—This substance is distilled with hydriodic acid, as already described (p. 736), and the resulting isotetrylic iodide (or tetrylenic hydriodate) is treated with alcoholic potash, or, better, with acetate of silver. The isotetrylic iodide is poured upon an equal weight of silver-acetate, contained in strong glass tubes, which can be quickly sealed; and after the violent reaction which immediately takes place is over, the tubes are cooled in a mixture of ice and salt. On opening them, and exposing them to a gentle heat, gradually raised to 40° or 50°, the whole of the tetrylene is given off, and may either be collected as gas, or condensed in a U-tube cooled to a low temperature. Isotetrylic acetate (p. 734) remains behind in the tubes. (De Luynes.)

Properties.—Tetrylene at $-18°$ is a colourless mobile oil, having an ethereal but peculiar and penetrating odour. At the temperature of a mixture of ether and solid carbonic anhydride, it solidifies to a white crystalline mass, which liquefies again as soon as it is taken out of the freezing mixture (De Luynes). The liquid boils below 0° (Faraday); at $+3°$ (De Luynes). The tension of its vapour at $+15°$ is equal to 4 atmospheres (Faraday). Vapour-density = 1·933 (Kolbe); calc. = 1·940. The gas burns with a red, blue-edged, very smoky flame. It is sparingly absorbed by *water*, easily by *alcohol*, and still more by *ether*: the alcoholic solution gives up the gas, with effervescence, on dilution with water; so likewise does the ethereal solution when diluted, first with alcohol, then with water. It dissolves easily in *glacial acetic acid*, and completely in strong *sulphuric acid*, without formation of sulphurous acid, producing a yellow liquid, from which water separates a light fragrant oil (De Luynes); according to Faraday, the product of this reaction is a conjugated acid [? homologous with ethionic or isethionic acid], which forms peculiar salts. The gas is likewise absorbed by *oils*, both fixed and volatile, *olive-oil* taking up about six times its own volume. It unites with *chlorine* (Faraday; Kolbe), and *bromine* (Hofmann), forming oily products.—Aqueous *hydriodic acid*, saturated at 0°, quickly absorbs tetrylene-gas, forming isotetrylic iodide or tetrylenic hydriodate, C^4H^9I, identical with that produced by the action of hydriodic acid on erythromannite. (De Luynes.)

TETRYLENE-DIAMINE. $C^4H^{12}N^2 = N^2\left\{\begin{matrix}(C^4H^8)'' \\ H^4\end{matrix}\right.$.—A base produced by the action of nascent hydrogen (evolved from tin and hydrochloric acid) upon cyanide of ethylene: $C^2H^4C^2N^2 + H^8 = C^4H^{12}N^2$. It boils above 140°, and its chloroplatinate contains 39·45 per cent. platinum, agreeing with the formula $C^4H^{12}N^2.H^2Cl^2.PtCl^4$. (T. Fairley, Chem. Soc. J. xvii. 362.)

TETRYLENIC ACETATE. $C^8H^{14}O^4 = \left.\begin{matrix}(C^4H^8)'' \\ (C^2H^3O)^2\end{matrix}\right\}O^2$.—Prepared by distilling bromide of tetrylene with acetate of silver. The distillate is purified by repeatedly rectifying the portion which distils above 140°, over dry acetate of silver, and finally by itself, the portion which passes over above 190° being collected apart. Acetate of tetrylene is a colourless oily liquid, inodorous in the cold, but smelling slightly of acetic acid when warmed. It boils at about 200°, is insoluble in water, but dissolves readily in alcohol and in ether. It is easily decomposed by alkalis, with separation of tetrylenic alcohol. (Wurtz.)

TETRYLENIC ALCOHOL. $C^4H^{10}O^2 = \left.\begin{matrix}(C^4H^8)'' \\ H^2\end{matrix}\right\}O^2$. *Tetryl-* or *Butyl-glycol.* (Wurtz, Ann. Ch. Phys. [3], lvi. 412.)—A diatomic alcohol, homologous with ordinary glycol, and produced in like manner, by heating tetrylenic acetate with potash. It is a colourless, viscid, inodorous liquid, having a mild aromatic taste. Specific gravity = 1·048 at 0°. Boiling-point = 183°—184°. Vapour density, obs. = 3·19; calc. = 3·12. It dissolves in all proportions of *water*, *alcohol*, and *ether*.

Tetrylenic alcohol is easily oxidised by *nitric acid*; when heated with dilute nitric acid, it yields oxalic acid. When dilute nitric acid is cautiously poured upon the aqueous solution of the alcohol, so that the two liquids may mix and react slowly, butylactic acid, or oxybutyric acid, $C^4H^8O^3$ (i. 688), is formed, together with another acid, whose calcium-salt is insoluble in water (the silver-salt of the latter yielded 9·2 per cent. carbon and 1·1 hydrogen).—Tetrylenic alcohol, heated with *hydrate of potassium* or *sodium*, is decomposed, with evolution of hydrogen, but not so readily as ordinary glycol. Oxalic acid appears to be formed in this reaction. Succinic acid is not found among the products of oxidation, either by nitric acid or by hydrate of potassium.

Tetrylenic alcohol heated with *hydriodic acid*, is converted into tetrylic iodide, the glycol being first reduced to tetrylic alcohol, according to the equation:

$$C^4H^{10}O^2 + 2HI = C^4H^{10}O + H^2O + I^2,$$

and the tetrylic alcohol converted into tetrylic iodide by the further action of the hydriodic acid. (Wurtz, Ann. Ch. Phys. [3], lxiii. 124.)

TETRYLENIC BROMIDE, $C^4H^8Br^2$, is formed on mixing tetrylene-gas with bromine-vapour, also (according to De Luynes) by the action of bromine on isotetrylic iodide, C^4H^9I, the reaction being attended with evolution of iodine and hydrobromic acid. It is an oily liquid, boiling at 158° (Wurtz; De Luynes), and, according to Cahours (Compt. rend. xlvi. 244), is resolved, by heating with alcoholic ammonia, into bromide of ammonium and bromotetrylene, C^4H^7Br.

TETRYLENIC CHLORIDE. $C^4H^8Cl^2$.—Produced by the direct combination of chlorine and tetrylene gases in diffused daylight, the tetrylene being kept in excess.

The oily product, after being freed from hydrochloric acid, by washing it, first with very weak potash, then with pure water, is dried over chloride of calcium, and distilled, the portion which passes over below 130° being collected apart; and this portion is subjected several times to fractional distillation, till an oil is obtained, boiling constantly at 125° (Faraday; Kolbe). The same compound is probably formed by the action of chlorine on isotetrylic iodide (p. 736), the liquid thus obtained boiling at 120°. (De Luynes.)

Chloride of tetrylene is a colourless oil, having an agreeable sweetish odour, like that of Dutch liquid, and a burning taste. Specific gravity = 1·112 at 28°. Boiling-point = 123°. Vapour-density = 4·426 (Kolbe); by calculation, 4·39. It is insoluble in water, but mixes with alcohol and ether. It burns brightly in the flame of a spirit-lamp emitting smoke mixed with vapours of hydrochloric acid. It is decomposed by heating with alcoholic potash, yielding chloride of potassium and a volatile oily liquid, probably consisting of chlorotetrylene, C^4H^7Cl.

The less volatile portions of liquid, boiling above 130°, which remain behind in the rectification of tetrylenic chloride, are probably also substitution-products, formed simultaneously with the tetrylenic chloride. The same bodies are obtained when chloride of tetrylene is exposed to sunshine in contact with excess of chlorine. A viscid mass is then formed, which still contains hydrogenated products, and does not yield any crystals of trichloride of carbon. (Faraday.)

Tetrylene-gas is likewise absorbed in large quantity by pentachloride of antimony; and on distilling the product, a chlorinated oil is obtained, having the composition $C^4H^7Cl^3$, or $C^4H^7Cl.Cl^2$.

TETRYL-GLYCOL. Syn. with Tetrylenic Alcohol.

TETRYLIN-TRIAMINE. $C^4H^{13}N^3 = N^3\left\}\begin{matrix}(C^4H^7)''' \\ H^6\end{matrix}\right.$.—A triatomic base produced by the action of nascent hydrogen (evolved by the action of tin on hydrochloric acid) upon cyanoform:

$$CH.C^3N^3 + H^{12} = C^4H^{13}N^3.$$

It boils at a temperature above 150°, and forms a platinum-salt containing $2(C^4H^{13}N^3.3HCl).3PtCl^4$. (Fairlie, Chem. Soc. J. xvi. 362.)

TETRYL-ŒNANTHYL. $C^4H^9.C^7H^{13}O$. *Tetryl-œnanthol. Butyl-œnanthyl. Butyl-butyrone.* (See Butyrone, i. 698.)

TETRYLSULPHURIC ACID. $C^4H^9.H.SO^4$. See Sulphuric Ethers (p. 629).

TETRYLSULPHYDRIC ACID. $C^4H^9.H.S$. *Tetrylmercaptan* (p. 736).

TEUCRIUM. The herb of several species belonging to this genus, formerly used in medicine, contains a peculiar, resinous, bitter principle. *T. Polium* is said to be used in Greece as a remedy against the bites of serpents. (Landerer, Buchn. Repert. xcii. 246).

TEUTLOSE (from τεῦτλον, beet).—A kind of sugar, resembling glucose, said to exist, under certain circumstances, in the juice of beet. According to Michaelis (J. pr. Chem. lxxiv. 397), the sugar, sometimes optically inactive, sometimes lævorotatory, produced from the cane-sugar of beet, especially when the juice is acid, is different from ordinary inverted sugar (p. 465).

TEXALITE. A name applied by R. Hermann (J. pr. Chem. lxxxii. 368) to native magnesium-hydrate, $Mg''H^2O^2$, occurring at Woods Mine, Texas, Lancaster County, Pennsylvania, in monoclinic forms homœomorphous with epidote, whereas the ordinary form of magnesium-hydrate (brucite), is rhombohedral; but, according to Auerbach's observations of the polarising properties of the so-called texalite crystals, they also belong to the hexagonal system. (Jahresb. 1861, p. 979.)

TEXASITE. $Ni''CO^3.2Ni''H^6O^4$. Syn. with Emerald-nickel. (See Carbonates, i. 789.)

THIACETONE. One of the compounds, or rather mixtures, obtained, according to Zeise, by the action of ammonia and sulphur on acetone (i. 28).

THALITE. A name applied by D. Owen (Sill. Am. J. xiii. 420), to an altered soapstone from the north shore of Lake Superior, which he supposed to contain a peculiar earth, *thalia*; this however, according to Smith (*ibid.* xvi. 95), and Genth (*ibid.* xvii. 130), was merely impure magnesia.

THALLEIOCHIN, or **DALLEIOCHIN.** A product of the action of chlorine-water on sulphate of quinine (p. 18).

THALLITE. Syn. with Epidote.

THALLIUM. *Atomic weight*, 204; *Symbol*, Tl.—An element discovered by Crookes, in 1861, in a seleniferous deposit from the sulphuric acid manufactory in Tilkerode, in the Harz. In the distillation of some impure selenium prepared from this deposit, a considerable residue was left, which was at first supposed to contain tellurium, till spectrum-analysis showed that a new element was present, whose spectrum consisted of a single sharp and brilliant green line (hence the name thallium, from θαλλός, a green bud). This element was at first suspected to be a metalloïd, but further examination proved it to be a true metal. It was first obtained, in a distinct metallic form, by Crookes, towards the end of the year 1861, and soon afterwards by Lamy, whose experiments appear to have been made without previous knowledge of Crookes's results.* It has since been made the subject of numerous researches, and a great number of its compounds have been prepared and carefully examined. A full account of the results obtained down to January 1864, together with a list of memoirs, is given by Crookes, in the *Journal of the Chemical Society*, vol. xvii. p. 112. The most important papers on thallium and its compounds, published since that date, are the following:—

On the Extraction of Thallium.—Schrötter, Wien. Akad. Ber. xlviii. [2], 734.—

---

* Respecting the controversy about the priority of the discovery of the metallic nature of thallium, see Jahresb. f. Chem. 1862, p. 177.

G. Werther, J. pr. Chem. xci. 385.—Streng, Zeitschr. f. Chem. 1865, p. 106.—Bunsen, Ann. Ch. Pharm. cxxxiii. 108.—Willm, Ann. Ch. Phys. [4], v. 5.

Solubility of Thallium-salts.—Crookes, Chem. News. x. 27.

Chlorides of Thallium.—Werther, J. pr. Chem. xci. 385.—Nicklès, Compt. rend. lviii. 537.—Hebberling, Ann. Ch. Pharm. cxxxiv. 11.—Willm, *loc. cit.*

Bromides and Iodides of Thallium.—Werther, *loc. cit.*—Willm, *loc. cit.*—*On the Bromides* also, Willm, Bull. Soc. Chim. 1864. ii. 89.—Nicklès, *loc. cit.*

Fluorides of Thallium.—Kuhlmann, Compt. rend. lviii. 1037.—Buchner, J. pr. Chem. xcvi. 404.

Oxides and Oxygen-salts of Thallium.—(Schönbein, J. pr. Chem. xciii. 35.—Werther, *loc. cit.*—Kuhlmann, *loc. cit.*—Strecker, Ann. Ch. Pharm. cxxxv. 207.—Willm, *loc. cit.*: also, Bull. Soc. Chim. 1866, ii. 165.—*On the Phosphates of Thallium*, Lamy, Ann. Ch. Phys. [4], v. 410.

The memoir of Willm, above referred to, contains a summary of the results relating to thallium and its compounds down to 1865. (See also Jahresb. f. Chemie, 1864, pp. 245—257; 1865, pp. 242—255.)

Sources.—As sulphide, thallium is very widely distributed as a constituent of iron- and copper-pyrites. Amongst those ores in which it occurs most abundantly (although in these cases it does not constitute more than from the 100,000th to the 4,000th bulk of the ore), may be mentioned iron-pyrites from Theux near Spa in Belgium, from Namur, Philipville, Alais, the South of Spain, France, Ireland, Cornwall, Cumberland, and different parts of North and South America; in copper-pyrites from Spain, as well as in crude sulphur prepared from this ore; in blende and calamine from Theux; in blende, calamine, metallic zinc, sulphide of cadmium, metallic cadmium, and cake-sulphur from Nouvelle-Montagne; in native sulphur from Lipari and Spain; in bismuth, mercury, and antimony ores, as well as in the manufactured products from these minerals (frequently in so-called pure medicinal preparations of these metals); in commercial selenium and tellurium (probably as selenide and telluride).

Thallium is likewise frequently present in copper and in commercial salts of that metal. In Spain a very impure copper is prepared by allowing copper-pyrites to oxidise in the air, washing out the resulting sulphate of copper, and placing scrap-iron in the liquid, which causes the copper to precipitate in the powdery state. The metal is then collected together, dried, strongly compressed, and heated to the melting-point. It is brought over to this country in the form of rectangular cakes, weighing about 20 lbs. each. The sulphide of thallium, oxidising to sulphate along with the sulphide of copper, is washed out by the water, and precipitated with the copper by the iron. The two metals readily alloy together.

Thallium is also present in tolerable quantity in lepidolite from Moravia, and in mica from Zinnwald (Schrötter). It has likewise been found in the deliquescent "Sel-a-Glace" from the mother-liquors of the saltworks at Nauheim. This consists of a mixture of the chlorides of magnesium, potassium, and sodium, with relatively considerable quantities of rubidium- and cæsium-chlorides, and sensible traces of thallium-chloride. (Böttger.)

Many samples of commercial sulphuric acid and yellow hydrochloric acid contain thallium. The source in these cases is evidently the pyrites used in the sulphuric acid works.

Preparation.—*a. From Iron Pyrites.*—The pyrites from the Société Anonyme de Rocheux et d'Oneux, Theux, contains about 1 pt. of thallium in 4,000. Two tons of this ore were worked in the following manner:—

The pyrites, broken up into pieces of the size of a walnut, is distilled in hexagonal cast-iron pipes, closed at one end, and arranged in a reverberatory furnace. Conical sheet-iron tubes are luted on to the open ends, and the retorts are kept at a bright-red heat for about four hours. At the end of the operation, the receivers are found to contain from 14 lbs. to 17 lbs. of dark-green or grey-coloured sulphur for every 100 lbs. of ore used. The whole of the thallium originally in the pyrites is found in this sulphur. The sulphur may be dissolved out by means of carbonic disulphide, which leaves the sulphide of thallium behind; or it may be extracted by boiling with caustic soda. The former plan occasions less loss of thallium, but, owing to the inconvenience of working with large bulks of of carbonic disulphide the soda process is preferable. 12 lbs. of caustic soda, 18 lbs. of the thalliferous sulphur, and 1½ gallon of water, are boiled together till the sulphur has disappeared; 6 gallons of water are added; and the clear liquid, when cool, is decanted from a voluminous black precipitate, which has been separated from the sulphur. The precipitate is then collected on a calico filter and washed. It contains the greater portion of the thallium in the form of sulphide, together with iron, copper, mercury, zinc, &c. Some thallium, however, is dissolved in the alkaline liquid and lost. The black precipitate is then dissolved in hot dilute sulphuric acid, to which a little nitric acid is added, and the liquid is diluted with water and filtered. Hydrochloric acid and sulphite of sodium will now throw down the nearly insoluble white protochloride of thallium, which is to be filtered off and washed. (Crookes.)

β. *From Sulphur or Pyrites in the Wet Way.*—The material is dissolved in nitromuriatic acid, until nothing but bright-yellow sulphur is left; water is then added, and the filtrate is evaporated with sulphuric acid, until it is nearly dry, and sulphuric vapours are copiously evolved. The residue is dissolved in a large excess of hot water, and carbonate of sodium is added to alkaline reaction, and then cyanide of potassium (free from sulphide of potassium). The liquid is then heated gently for some time, and filtered. The precipitate contains the whole of the lead (and bismuth) which may be present, as carbonates, whilst the thallium remains in solution. A current of sulphuretted hydrogen being now passed through the liquid, precipitates all the thallium, whilst the copper, antimony, tin, and arsenic remain dissolved. The precipitated sulphide is filtered off, washed, and dissolved in dilute sulphuric acid, and the thallium is precipitated as chloride, by means of hydrochloric acid. (Crookes.)

γ. *From the Flue-dust of Pyrites-burners.*—This is by far the most economical source of thallium at present known. In burning thalliferous pyrites for the purpose of manufacturing sulphuric acid, the thallium oxidises together with the sulphur, and is driven off by the heat. If the passage leading from the burners to the leaden chambers is only a few feet long, the greater portion of the thallium escapes condensation, and volatilises into the leaden chambers; it there meets with aqueous vapour, sulphurous and sulphuric acids, and becomes converted into thallious sulphate. This being readily soluble, both in water and dilute sulphuric acid, and not being reduced by contact with the leaden sides, remains in solution, and accompanies the sulphuric acid in its subsequent stages of concentration, &c. If, on the other hand, the passage connecting the burners and chambers is 10 or 15 (or more) feet in length, nearly the whole of the thallium is condensed, together with a considerable number of other bodies which constitute "flue-dust,"—namely mercury, copper, arsenic, antimony, iron, zinc, cadmium, bismuth, lime, and selenium, together with ammonia, sulphuric, nitric, and hydrochloric acids. The amount of thallium in these flue-deposits is very various, seldom amounting to as much as ¼ per cent., although in some as much as 8 per cent. has been found.

The following is the plan adopted by Crookes for extracting the metal from this dust on the large scale:—The dust is first mixed in wooden tubs with an equal weight of boiling water, and is well stirred; during this operation a considerable quantity of nitrous acid is evolved; after which the mixture is allowed to rest for 24 hours for the undissolved residue to deposit. The liquid is then syphoned off, and the residue is washed, and afterwards treated with a fresh quantity of boiling water. The collected liquors, which have been syphoned off from the deposit, are allowed to cool, precipitated by the addition of a considerable excess of strong hydrochloric acid, and the precipitate, consisting of very impure chloride of thallium, is allowed to subside. The chloride obtained in this way is then well washed on a calico filter, and afterwards squeezed dry. Three tons of the dust yielded 68 pounds of this rough chloride (Crookes). For the further treatment see below.

Werther boils the flue-dust repeatedly with carbonate of sodium; precipitates the filtrate with excess of ammonium-sulphide; converts the precipitate into sulphate by boiling it with sulphuric acid, with addition of a little nitric acid; precipitates the ammoniacal solution of the latter with iodide of potassium; and reduces the iodide of thallium by fusion with cyanide of potassium.

δ. *From Commercial Hydrochloric Acid.*—Many samples of yellow hydrochloric acid contain thallium. It may be separated by neutralising with ammonia, and adding sulphide of ammonium. The black precipitate contains the thallium, together with iron and some other metallic impurities of the acid. It is to be dissolved in sulphuric acid, and the thallium precipitated by hydrochloric acid as protochloride.

The crude protochloride of thallium obtained by either of the above methods is added, by small portions at a time to half its weight of hot oil of vitriol in a porcelain or platinum dish, the mixture being constantly stirred, and the heat continued till the whole of the hydrochloric acid and the greater portion of the excess of sulphuric acid are driven off. The fused acid sulphate is now to be dissolved in an excess of water, and an abundant stream of sulphuretted hydrogen passed through the solution. The precipitate, which may contain arsenic, antimony, bismuth, lead, mercury, and silver, is separated by filtration, and the filtrate is boiled till all free sulphydric acid is removed. The liquid is now to be rendered alkaline with ammonia, and boiled; the precipitate of iron and alumina, which generally appears in this place, is filtered off;

and the clear solution evaporated to a small bulk. Sulphate of thallium then separates out on cooling, in long, clear, prismatic crystals. As sulphate of ammonium is much more soluble than sulphate of thallium, the latter can readily be separated from the small quantity of the former salt present. The two salts do not crystallise together.

In order to avoid the inconvenience of driving off the excess of oil of vitriol in the decomposition of chloride of thallium, it may in some cases be preferable to proceed as follows:—Boil the chloride of thallium in solution of sulphide of ammonium for five minutes: decomposition takes place readily. Filter, and wash with hot sulphuretted water till no more chlorine can be detected in the filtrate; then dissolve the sulphide on the filter in dilute sulphuric acid, and treat the solution with ammonia, &c., as above directed. (Crookes.)

ε. *From the Saline Residues of the Saltworks at Nauheim.*—The strong solution is mixed with a quantity of platinic chloride not sufficient for complete precipitation, and the precipitate is boiled five or six times with three times its weight of water; the insoluble residue, consisting of the platinum-salts of cæsium, rubidium, and thallium, is boiled with a weak solution of potash and a little hyposulphite of sodium, till a clear solution is obtained; and this solution is treated with cyanide of potassium and sulphydric acid, whereby the thallium is precipitated as sulphide. The liquid is then to be filtered, and the residue washed and dissolved in sulphuric acid. (Böttger.)

ζ. *From Lepidolite and Mica.*—The residue obtained by reduction of the platinum-salts of rubidium, cæsium, and thallium, as described under RUBIDIUM (p. 128), is carefully washed with water, to dissolve the chlorides of cæsium and rubidium; the washed platinum-black is dissolved in nitromuriatic acid, and evaporated to drive off the excess of acid; and the dry mass is digested with water, which leaves the whole of the thallium-chloroplatinate (still containing a little rubidium) undissolved. This residue, after addition of a few drops of hydrochloric acid, is boiled with finely granulated zinc; the excess of zinc is dissolved out of the precipitated metals by hydrochloric acid (which does not take up any thallium); and the washed residue is heated with nitric acid, which dissolves the thallium, and leaves the platinum. (Schrötter.)

η. *From the Mother-liquors of Zinc-sulphate.*—The mother-liquor of zinc-vitriol, obtained at Goslar, in the Harz, by working pyrites from the Rammelsberg, is (according to Bunsen) a very convenient source of thallium. When boiled down to a specific gravity of 1·441 at 24°, it contains (according to an analysis by Neuhoff) 0·05 per cent. chloride of thallium, together with the sulphates of zinc, cadmium, manganese, copper, and many other salts. When mixed with an equal volume of hydrochloric acid, it yields a precipitate of thallium-chloride; and with iodide of potassium, in presence of a sufficient quantity of sodic hyposulphite, a precipitate of thallium-iodide free from copper. The simplest method of obtaining the thallium is to precipitate it, together with copper and cadmium, by immersing plates of zinc in the *cold* liquor. The metallic powder thereby precipitated, after being quickly rinsed, is digested with water containing sulphuric acid; and the resulting solution, containing thallium (together with cadmium), is precipitated with iodide of potassium. A cubic metre of the liquor thus treated yielded 0·6 kilogrm. thallium. (Bunsen.)

θ. To recover the thallium remaining in the mother-liquor of any of the preparations above described, Willm precipitates the solution (reduced, if necessary, by sulphurous acid) with iodide of potassium, decomposes the precipitated iodide of thallium with nitric acid (in a distillatory apparatus, arranged so as to condense the volatilised iodine), and evaporates the resulting solution of thallium-nitrate to the crystallising point. Insoluble residues are treated with nitromuriatic acid, the neutralised solution is precipitated with sulphide of ammonium; and the precipitated sulphide of thallium is converted into sulphate by treatment with sulphuric acid.

Preparation of Metallic Thallium.—The metal is reduced from its solution, generally from the sulphate, either by electrolysis, or by the action of zinc.—1. When an electric current from two or three Grove's cells, with platinum terminals, is passed through an acidulated solution of thallium-sulphate in its own weight of water, the metal is deposited on the negative pole, in brilliant plates and long needle-shaped crystals, stretching out towards the positive pole, and presenting an appearance like that known as the tin-tree. The reduction is complete when hydrogen begins to escape at the negative pole. The crystalline metallic sponge may then be squeezed into a compact mass round the platinum terminal, well rinsed with water, removed from the platinum, and kneaded by the fingers into a solid lump. (Crookes.)

2. For reducing considerable quantities of thallium, it is best to employ metallic zinc. Plates of pure zinc (which should leave no residue whatever when dissolved in sulphuric acid) are arranged vertically round the sides of a deep porcelain dish holding a gallon. Crystallised sulphate of thallium, in quantities of about seven

pounds at a time, is then placed in the dish, and water poured over to cover the salt. Heat is applied, and, in the course of a few hours, the whole of the thallium will be reduced to the state of a metallic sponge, which readily separates from the plates of zinc on slight agitation. The liquid is poured off, the zinc removed, and the spongy thallium washed several times. It is then strongly compressed between the fingers, and preserved under water until it is ready for fusion. In this manner upwards of a hundredweight of metallic thallium may be reduced in the course of twenty-four hours. (Crookes.)

The metal is readily obtained in the coherent form by fusing the sponge. This is most conveniently performed under cyanide of potassium on the small scale, and under coal-gas when working with large quantities. In the former case, the sponge, strongly compressed and quite dry, is broken into small pieces, which are dropt one by one into cyanide of potassium fused in a porcelain crucible. They instantly melt, forming a brilliant metallic button at the bottom. When cold, the cyanide of potassium may be dissolved in water, when the thallium will be left in the form of an irregular lump, owing to its remaining liquid and contracting after the cyanide has solidified.

On the large scale, the fusion is best effected in an iron crucible. This is placed over a gas-burner, and a tube is arranged so that a constant stream of coal-gas may flow into the upper part of the crucible. Lumps of the compressed sponge are then introduced, one after the other as they melt, until the crucible is full of metal. It is then stirred up with an iron rod, and the thallium may either be poured into water and obtained in a granulated form, or cast into an ingot. Thirty or forty fusions have been performed in the same crucible without the iron being acted upon in the least by the melted thallium. (Crookes.)

According to Willm, pure thallium is best obtained by heating the oxalate in a glass tube, the metal then remaining in the fused state.

Properties.—Thallium is a perfect metal, with high metallic lustre. In colour it most resembles cadmium, not being so brilliantly white as silver, but free from the blue tinge of lead. The true colour can scarcely be seen by cutting or scraping the surface, as it tarnishes too quickly. It is best observed by scraping the metal under water, or by fusing it in hydrogen, and allowing the melted globule to flow away from the dross. When fused under coal-gas, the liquid metal in the crucible can hardly be distinguished from mercury. It takes a very high polish by friction with appropriate materials, under water. Thallium tarnishes at ordinary temperatures, quickly becoming coated with a film, which almost entirely protects it from further action of the air. The specific gravity of thallium varies according to the treatment it has undergone. A lump melted and slowly cooled under cyanide of potassium was found to have a density of 11·81, increasing by strong pressure to 11·88. When *squeezed* into wire, a portion was found to have a density as high as 11·91. Lamy gives it as 11·86. De la Rive states it to be 11·85 after fusion, and 11·80 after being *drawn* into wire. Thallium is the softest known metal admitting of free exposure to the air. The finger-nail, and even a piece of lead, scratch it readily. It marks paper like plumbago, forming a streak, blue at first, then turning yellow, and in a day or two fading nearly out. Sulphide of ammonium or sulphuretted hydrogen will at any time temporarily restore the dark streak. Thallium has less tenacity than lead, and does not become brittle at any temperature between − 18° C. (0° F.) and its melting-point. It is very malleable, and can be hammered into foil as thin as tissue-paper; its hardness is not sensibly increased by hammering. It can be drawn into wire only with difficulty, but it is squeezed into wire very readily, by the process technically known as "squirting." Thallium-wire is almost devoid of elasticity, retaining any form into which it is bent, with scarcely a tendency to spring to its original position. When first prepared, the wire appears amorphous, and will remain so if kept at the ordinary temperature in carbonic anhydride, or in petroleum free from air. In water it gradually becomes crystalline, resembling the *moiré* of tinplate; this effect is immediately produced when thallium in wire, ingot, or plate, tarnished or clean, is boiled in water.

Thallium is a very crystalline metal, and crackles almost as much as tin when bent. When several pounds of it are fused, and allowed to cool slowly, and the interior liquid portion poured off from that which has solidified, well-defined crystals, in octahedrons and fernlike forms, are produced. The melting-point of thallium is 290°, according to Lamy; 293·9° according to Crookes, who determined it by fusing about two pounds of the pure metal. Thallium does not become pasty before melting; it expands considerably before complete fusion, and contracts strongly on cooling. Two pieces of the metal weld together under strong pressure at the ordinary temperature, and after filling the steel die with scraps and cuttings, they may be readily squeezed into a solid rod, apparently as tenacious as when obtained by fusion.

The most characteristic property of thallium is the intense green colour which the metal or any of its compounds communicates to a colourless flame. This colour, when examined in the spectroscope, is seen to be absolutely monochromatic, appearing as one intensely brilliant and sharp green line, coinciding with the number 1442·6 on Kirchhoff's spectrum-chart. The thallium-spectrum is simpler than that of any other element yet examined. An amplifying power as great as has ever been applied to the spectrum (16 heavy glass prisms), does not affect the integrity of the line, and the high temperature of the hydrogen- or oxyhydrogen-flame shows no new lines; thallium has therefore a simpler spectrum than sodium or lithium, which stand next to it in this respect. The spectral reaction of thallium is very delicate, the 5-millionth part of a grain of thallium-sulphate being sufficient to produce it.

The length of the wave of the green thallium-line is 0·0005348 millimetre. (J. Müller, Pogg. Ann. cxviii. 641.)

When sparks from an induction-coil are passed between two pieces of thallium-wire, the light ceases to be purely monochromatic. On viewing it by the spectroscope, several new lines make their appearance; besides the usual intense line in the green, five others are particularly observable: first, a very faint one in the orange; next, two of nearly equal intensity in the green, more refrangible than Tl α, with a third much fainter, these three lines in the green being nearly equidistant; and, lastly, a bright well-defined line in the blue. The photographic spectrum contains several very characteristic groups of lines, recalling the features of the spectra of cadmium and zinc, and less strongly that of lead (W. A. Miller, Proc. Roy. Soc. xii. 407). The thallium-line has no counterpart in the black lines of the solar spectrum.

Thallium is strongly repelled by both poles of an electromagnet, being nearly equal to bismuth in diamagnetic character. In respect of electric conductivity, it lies between tin and lead. Taking the conducting power of silver at 100, that of thallium is 9·16 according to Matthiessen, 8·64 according to De la Rive. Matthiessen and Vogt find that the conducting power of thallium decreases, between 0° and 100°, by 31·420 per cent., which is a larger percentage decrement than that obtained for many other pure metals—namely, 25·307 per cent. The specific heat of thallium is given by Lamy at 0·0325, and by Regnault at 0·03349 and 0·03361.

Thallium, when heated in the air, begins to volatilise at a red heat, evolving brown vapours of oxide; it boils below a white heat, and may be distilled in a current of hydrogen. The hydrogen takes up mechanically a litle thallium, which is not deposited upon traversing five feet of cold glass tubing, as the emergent gas, when ignited, burns with a bright-green flame.

When heated to redness and plunged into oxygen, thallium burns brilliantly (Lamy). Before the blowpipe, on charcoal, it melts instantly, evolving copious brown fumes. The bead, if heated to redness, glows for some time after the source of heat is removed, continually evolving vapours which appear to be a mixture of metal and oxide. On cooling, the adjacent parts of the charcoal are found to be coated with small globules of volatilised metal, surrounded with a reddish amorphous sublimate of mixed protoxide and sesquioxide. The principal globule of metal is also coated with a fused layer of protoxide, resembling lead in this respect. When thallium is heated in an open glass tube, it melts, and becomes rapidly converted into the more fusible protoxide, which strongly attacks the glass. This oxide is of a dark-red colour when hot, solidifying to a brown crystalline mass.

Some of the compounds of thallium are very volatile, the chloride, for instance, distilling with the vapour of water, and volatilising when heated to a temperature below redness. Other compounds, such as the sulphate and phosphate, will bear a full red heat without loss.

Thallium is easily reduced to the metallic state. In aqueous solution, the metal is readily obtained by the electric current, or by the reducing action of metallic zinc. In the dry state, its salts may be reduced at a high temperature by charcoal and carbonate of sodium, or by cyanide of potassium, or from the chloride by an alkali-metal. The pure metal is scarcely attacked by hydrochloric acid, even when boiling. It is dissolved somewhat more readily by sulphuric acid, especially if it be in contact with a piece of platinum; nitric acid attacks it violently.

In electro-chemical position, thallium is very near cadmium, being precipitated from the sulphate by zinc and iron, but not by cadmium, tin, or copper.

Several thallium-salts are sensitive to light; the protochloride darkens readily, though by no means so rapidly as chloride of silver.

Thallium-salts are highly poisonous, producing symptoms like those of lead-poisoning. (Lamy, Compt. rend. lvii. 442; Jahresb. 1863, p. 265.)

Thallium forms two classes of compounds—namely, the thallious compounds, in which it is uni-equivalent; and the thallic compounds, in which it is tri-equivalent. Thus it forms two oxides, Tl^2O and Tl^2O^3, with corresponding chlorides, bromides, iodides, and oxygen-salts. In some of its chemical relations it resembles the alkali-metals, forming a readily soluble and highly alkaline protoxide, a soluble and alkaline carbonate, an insoluble chloroplatinate, and a thallio-aluminic sulphate, similar in form and composition to common potash-alum. In most respects, however, it is more nearly allied to the heavy metals, especially to lead, which it resembles closely in appearance, density, melting-point, specific heat, and electric conductivity. Its relationship to the heavy metals is further shown by its high atomic weight; the complexity of its photographic spectrum, which contrasts strongly with the simplicity of those of the alkali-metals (Miller); the highly poisonous character of its compounds; its easy reduction from solution by zinc; the production of a brown insoluble peroxide by electrolytic action (p. 753); the complete or nearly complete insolubility of its sulphide, phosphide, iodide, bromide, chloride, chromate, and phosphate. Thallium differs also essentially from the alkali-metals in the slight affinity of its protoxide for water, this oxide not only being non-deliquescent, but remaining in the anhydrous state when its aqueous solution is evaporated at ordinary temperatures in a vacuum over oil of vitriol. The argument in favour of its relationship to the alkali-metals, derived from the formation of a thallium-alum, can no longer be considered valid, now that a silver-alum of similar form and composition has been shown to exist (p. 580).

THALLIUM, ALLOYS OF. These compounds have not been much studied. When thallium is projected into a crucible containing melted copper, it boils, and in great part volatilises, some however uniting with the copper. By repeated additions of thallium, a hard, brittle, white alloy may be formed. With a still smaller quantity of thallium, the mixture is gold-coloured; and with 95 per cent. of copper, it forms a hard button, flattening somewhat under the hammer, but soon cracking at the edges. In small quantities, thallium appears to diminish the malleability and ductility of copper. Copper prepared in Spain, by the cementation-process already described, frequently contains considerable quantities of thallium, which may perhaps account for its pre-eminently bad quality.—With lead, thallium melts readily, forming a malleable alloy.—With mercury it unites easily, forming a solid crystalline amalgam.—Platinum and thallium unite, with incandescence. When a piece of metallic thallium is placed on a platinum-wire loop, and held in the flame of a spirit-lamp, the two metals rapidly melt together, becoming nearly white hot, and evolving abundant fumes of thallium; the resulting alloy is highly crystalline, very hard, and almost as brittle as glass. The most convenient way of obtaining the green light of thallium is to alloy a platinum-wire loop in this manner. When this loop is introduced into a spirit-lamp, or heated before the blowpipe, a green tint of extraordinary splendour is communicated to the flame.—An alloy of thallium and tin is easily obtained by fusion under cyanide of potassium, or coal-gas. With 5 per cent. of thallium, the alloy is perfectly malleable.

THALLIUM, BROMIDES OF. The *protobromide*, or *Thallious bromide*, $TlBr$, is formed by adding thallium to bromine, or by double decomposition. It forms a very pale-yellow precipitate, fusible below redness, and is intermediate in solubility between the chloride and iodide (Lamy). According to Willm (Bull. Soc. Chim. 1864, ii. 89), it is nearly insoluble in cold, and very slightly soluble in boiling water. In contact with bromine and a small quantity of water, it gradually dissolves, with rise of temperature, to a liquid, which, when evaporated in a vacuum, solidifies to a pungent, yellow, deliquescent, crystalline mass of impure *tribromide*, or *thallic bromide*, $TlBr^3$ (containing rather less bromine than that required by the formula). On mixing the aqueous solution of the tribromide with the protobromide, or subjecting it to partial reduction, the hot liquid yields long, siskin-yellow, shining needles, appearing under the microscope as quadratic prisms, and consisting of the *dibromide*, $Tl^2Br^4 = TlBr.TlBr^3$. They are decomposed by water into a protobromide which separates, a tribromide which remains dissolved, and a *sesquibromide*, $Tl^4Br^6 = TlBr^3.3TlBr$, which crystallises in translucent, orange-red, six-sided laminæ. This last compound is likewise decomposed by treatment with water, with separation of protobromide. (Willm.)

The tribromide forms, with *bromide of ammonium*, a double salt, $NH^4Br.TlBr^3.5H^2O$, crystallising in long, yellow, transparent needles, which easily give off their water in a vacuum. A concentrated alcoholic solution of the tribromide mixed with *ammonia*, yields a white precipitate of the compound $TlBr^3.3NH^3$, which quickly turns yellow, and is easily decomposed by water, with separation of black sesquioxide of thallium. (Willm.)

A compound of thallic bromide with ethylic oxide, $2TlBr^3.3(C^2H^5)^2O$, is produced by adding bromine to anhydrous ether in which metallic thallium or the protobromide is suspended. This compound dissolves in bromide of ammonium, yielding the double salt $NH^4Br^3.TlBr^3$, with 2 at. and 3 at. water, the former hydrate crystallising in rhomboïdal or six-sided tables, the second in needles; both melt in their water of crystallisation below 100°. (Nicklès, Compt. rend. lviii. 537.)

THALLIUM, CHLORIDES OF. Thallium forms four chlorides analogous to the bromides:—

Protochloride of Thallium, or *Thallious Chloride*, TlCl.—Metallic thallium is attacked at ordinary temperatures by chlorine; when heated in the gas, it burns and forms a yellow liquid, which solidifies on cooling to a pale-yellow or white crystalline mass. If excess of chlorine has been present, the product consists almost entirely of higher chlorides; but in presence of an excess of thallium, the white protochloride is the only compound formed. Boiling hydrochloric acid attacks thallium but slowly, the action soon ceasing, owing to the formation of a layer of difficultly soluble chloride of thallium. When hydrochloric acid, or a soluble chloride, is added to a solution of thallious oxide or a thallious salt, a white curdy precipitate of protochloride is thrown down, scarcely to be distinguished at first sight from chloride of silver. When boiled in water, it dissolves like chloride of lead, and separates again on cooling; the crystals, however, are much smaller and less brilliant than those of chloride of lead. Protochloride of thallium is also precipitated when sulphurous acid or an alkaline sulphite is added to one of the higher chlorides.

One part of the protochloride dissolves in 283·4 pts. of water at 15·5°, and in 52·5 pts. of boiling water. It is insoluble in alcohol, and scarcely, if at all, more soluble in aqueous ammonia, cyanide of potassium, or hydrochloric acid, than in water. When boiled in nitric or nitromuriatic acid, it is converted into a higher chloride. It may be heated to 260° without loss of weight; at a slight increase of heat, it suddenly melts to a thin brown liquid, white vapours being simultaneously evolved. On cooling, it solidifies to a white, shining, crystalline, somewhat flexible mass. The specific gravity of the fused chloride is 7·02 (Lamy). The fused lump is reduced to the metallic state by zinc and dilute acid, like fused chloride of silver. According to Lamy, chloride of thallium is unalterable by light; but according to Crookes, it undergoes a considerable darkening when exposed either to sunlight or diffused daylight.

Protochloride of thallium forms double salts with trichloride of gold and tetrachloride of platinum.—The *chloroaurate* separates from the hot aqueous solution containing a slight excess of auric chloride, in brilliant gold-coloured crystals; it is slightly soluble in water, and when ignited leaves an alloy of gold and thallium.—The *chloroplatinate*, $2TlCl.PtCl^4$, is precipitated as a pale-yellow crystalline powder, very sparingly soluble in water, much less so than the corresponding potassium-, rubidium-, or cæsium-salts (*q.v.*), 1 pt. of it requiring for solution 15,585 pts. water at 15·5°, and 1,948 pts. at 100°. (Crookes.)

Sesquichloride of Thallium, Tl^2Cl^3 or $Tl^4Cl^6 = TlCl^3.3TlCl$.—This compound is produced by dissolving thallium or the protochloride in nitromuriatic acid, and separates on cooling in yellow crystalline scales. It may also be prepared by heating the trichloride till it melts, and no longer gives off chlorine (p. 748). [Werther obtained by these processes only variable mixtures of the protochloride and trichloride; but other experimenters have obtained a definite product.] The sesquichloride, when heated, melts below redness, forming a dark-brown liquid, which solidifies to a lighter-coloured mass. It is soluble in 380·1 times its weight of water at 15·5°, and in 52·9 pts. of boiling water. Pure water produces a slight decomposition into sesquioxide and protochloride, which, however, may be prevented by the addition of a drop of nitric or hydrochloric acid. When slowly crystallised from slightly acidulated boiling water, it separates in brilliant orange-yellow hexagonal plates, considerably darker than when it is obtained by more rapid crystallisation, and presenting the closest resemblance to iodide of lead. Sesquichloride of thallium is also precipitated by the cautious addition of sulphite of sodium to one of the higher chlorides. Whenever it separates from a liquid, it shows remarkable crystalline characters, and when just precipitated, produces a magnificent satiny lustre in the liquid. Solution of ammonia, potash, or even thallious oxide, added to the sesquichloride, produces instant decomposition into sesquioxide and protochloride, according to the following equation:

$$4Tl^2Cl^3 + 3(NH^4)^2O = Tl^2O^3 + 6TlCl + 6NH^4Cl.$$

When pure dry ammoniacal gas is passed over the sesquichloride, heat being applied with a spirit-lamp, the salt first assumes a deep orange tint, without fusing, and loses its brilliant, almost metallic lustre. On increasing the heat, the chloride fuses, and at the same time sal-ammoniac vapours are abundantly evolved. The melted compound froths up, and assumes a deeper tint, ultimately becoming brown, and then gradually paler, until there finally remains perfectly white protochloride of thallium.

The reaction between ammonia-gas and sesquichloride of thallium is represented by the following equation:—

$$3Tl^2Cl^3 + 4NH^3 = 6TlCl + 3NH^4Cl + N.$$

The sesquichloride, heated in a stream of *sulphydric acid gas*, is converted into black sulphide of thallium, with evolution of hydrochloric acid and volatilisation of sulphur. Its aqueous solution yields, with sulphydric acid, a slight red precipitate, which disappears on boiling, leaving only a small quantity of sulphur.—*Sulphide of ammonium* or *potassium* produces complete precipitation. (Hebberling, Jahresb. 1865, p. 250.)

Platinic chloride added to the aqueous solution throws down thallious chloroplatinate, $2TlCl.PtCl^4$, while thallic chloride remains in solution. (**Werther**, *ibid.* p. 246.)

Dichloride of Thallium, $Tl^2Cl^4 = TlCl^3.TlCl$, is formed by carefully heating either thallium or the protochloride in a slow current of chlorine, the resulting chloride being kept liquid. The dichloride is pale-yellow, rather hygrometric, and decidedly more fusible than the sesquichloride. It is reduced to sesquichloride by heat. (Lamy.)

Trichloride of Thallium, or *Thallic Chloride*, $TlCl^3$.—This compound is formed by dissolving the trioxide in hydrochloric acid, or by acting upon thallium or a lower chloride with a large excess of chlorine at a gentle heat. According to Werther (Jahresb. 1864, p. 247), it is most easily prepared by treating thallium or the protochloride with chlorine-gas under water, till the resulting solution is no longer precipitated by platinic chloride. The solution freed from excess of chlorine by a stream of carbonic anhydride, and evaporated in a vacuum, yields a crystalline mass composed of long colourless prisms of the hydrated trichloride, $TlCl^3.H^2O$, sometimes also long deliquescent needles, containing $2TlCl^3.15H^2O$. It melts easily, and decomposes with loss of chlorine, the residue consisting, according to **Lamy**, of the sesquichloride; according to **Werther**, of mixtures of the trichloride and protochloride.

Trichloride of thallium unites with the chlorides of the alkali-metals, forming colourless crystallisable double salts, which easily decompose with separation of thallic oxide (Ficklès, J. Pharm. [4], i. 26).—The *ammonium-salt*, $3NH^4Cl.TlCl^3.2H^2O$, is produced (with simultaneous formation of chloride of nitrogen) by passing chlorine into a solution of thallious chloride containing a large quantity of sal-ammoniac; more readily by digesting the ether-compound of thallic chloride (*infra*) with sal-ammoniac; it then separates in large six-sided tables, belonging to the trimetric system, easily soluble in water and in alcohol (Nicklès).—The *potassium-salt*, $3KCl.TlCl.\frac{3}{2}H^2O$, crystallises from a mixed solution of the component chlorides in modified cubes (Willm).—The *cupric salt*, $Cu''Cl^2.2TlCl^3$, separates from the mixed solution of its constituent salts, in opaque green crystals, simultaneously with colourless transparent prisms, which have not been examined. (Willm.)

A compound of thallic chloride with *ethylic oxide*, $TlCl^3.(C^2H^5)^2O.HCl + H^2O$, is obtained, according to Nicklès (Jahresb. 1864, p. 252), by passing chlorine into anhydrous ether, in which metallic thallium or the protochloride is suspended. Two layers of liquid are then formed, the lower containing the ether-compound, which remains behind on evaporating the product at 100° in a stream of carbonic anhydride. It dissolves in ether and in water containing hydrochloric acid, decomposes alkaline carbonates, and when treated with an excess of the latter, deposits sesquioxide of thallium. With sulphurous acid it yields protochloride of thallium.

THALLIUM, CYANIDE OF. Obtained by mixing the concentrated solutions of potassic cyanide and thallious carbonate, or by neutralising thallious oxide with prussic acid (Kuhlmann); more easily by mixing strong solutions of potassic cyanide and thallious nitrate (Crookes). It separates in shining crystalline plates, not very soluble in water. When heated, it decrepitates and melts easily, and when intensely heated on platinum-foil, volatilises without reduction, or alloying with the platinum.

Ferroso-thallious Cyanide, or *Ferrocyanide of Thallium*, precipitated on mixing ferrocyanide of potassium with thallious nitrate, forms yellow crystals, slightly soluble in water.

THALLIUM, DETECTION AND ESTIMATION OF. 1. *Reactions in the Dry Way.*—The behaviour of metallic thallium before the blowpipe, and the peculiar characters of its spectrum, have been already described (p. 745). The green line Tlα is alone sufficient to distinguish thallium from all other elements. Thallium-salts, when ignited, generally fuse below redness, and then volatilise; some of them, however, as the sulphate and phosphate, will stand a bright-red heat without change; the chlorides, on the other hand, distil over with vapour of water. On charcoal before the blowpipe they volatilise, communicating an intense green colour to the flame.

2. *Reactions in Solution.*—*a.* Thallious salts are for the most part colourless,

unless the acid itself is coloured. They are mostly soluble in water, neutral to test-paper, and have a slight metallic taste. Their aqueous solution is rapidly precipitated in metallic crystals by *zinc*, and slowly by *iron*.—*Phosphoretted hydrogen* precipitates a black phosphide.—*Sulphydric acid* added to a solution of a thallious salt containing a weak acid, such as carbonic or acetic, separates the whole of the metal in the form of a deep brown sulphide; from solutions of thallium-salts of the stronger acids, such as the sulphate or nitrate, sulphydric acid precipitates nothing if the acid is in excess, and only a small portion of the metal if the solution is neutral.—*Sulphide of ammonium* precipitates thallium-salts completely, the precipitated sulphide being insoluble in sulphide of ammonium, in caustic alkalis, their carbonates and cyanides, and only slightly soluble in acetic acid.—*Hydrochloric acid* and *soluble chlorides* precipitate a difficultly soluble white chloride; *hydrobromic acid* and *bromides* precipitate a white nearly insoluble bromide; and *hydriodic acid* and *iodides* precipitate an insoluble yellow iodide.—*Alkalis, alkaline carbonates*, or *bicarbonates* produce no change in thallious salts; *phosphate of sodium* gives a white precipitate, nearly insoluble in ammonia, easily soluble in acids.—*Chromate of potassium* gives a yellow precipitate of thallious chromate, insoluble in cold nitric or sulphuric acid, but turning orange-red on boiling in the acid solution.—*Platinic chloride* precipitates a very pale-yellow insoluble double salt.

From these reactions it appears that, in examining a mixed metallic solution, according to the ordinary method of qualitative analysis (i. 217), thallium will be found in the precipitate thrown down by sulphide of ammonium, together with iron, nickel, manganese, &c. From these metals it may be easily separated by precipitation with iodide of potassium or platinic chloride, or by reduction to the metallic state with zinc. According to Hebberling, iodide of potassium is, next to the spectral reactions, the most delicate of all tests for the presence of thallium, producing a visible precipitate in a solution of thallious sulphate, containing only 0·0105 pt. of the salt in 1,000 pts. of the liquid.

β. Thallic salts are easily distinguished from thallious salts by their behaviour with alkalis, and with soluble chlorides or bromides. Their solutions give with *ammonia*, and with fixed *alkalis* and their *carbonates*, a brown gelatinous precipitate of thallic oxide, containing the whole of the thallium. *Hydrochloric acid* and soluble *chlorides* or *bromides* produce no precipitate in solutions of pure thallic salts; but if a thallious salt is likewise present, a precipitate of sesquichloride or sesquibromide is formed. Oxalic acid forms in solutions of thallic salts a white pulverulent precipitate, *phosphoric acid* a white gelatinous precipitate, and *arsenic acid* a yellow gelatinous precipitate: these three precipitates, however, are sparingly soluble only in presence of a large quantity of free acid, so that they are not always produced by the corresponding alkaline salts.—*Sulphocyanate of potassium* forms in acid solutions of thallic salts a black-grey precipitate, in very slightly acid solutions a yellow precipitate, which is dissolved by boiling water, and at the same time reduced to a thallious salt.—*Chromate of potassium* does not precipitate thallic salts (Willm, Jahresb. 1865, p. 255). According to Strecker, on the contrary (*ibid.* p. 253), chromate of potassium forms, in a solution of thallic sulphate, a yellow precipitate, which turns brown in contact with water. Thallic nitrate gives with *ferrocyanide of potassium* a siskin-green, with the *ferrocyanide* a yellow precipitate. A solution of thallic sulphate or nitrate, mixed with *tartrate of sodium*, gives, with *ammonia*, a white curdy precipitate, soluble in excess of ammonia, to a liquid which deposits the brown sesquioxide on boiling. But when the sesquioxide is boiled with tartaric acid, carbonic anhydride and formic acid are evolved, and a solution is formed, which deposits crystals of thallious tartrate. The ammoniacal solution of thallic oxide formed in presence of tartaric (or phosphoric) acid, gives with *sulphide of ammonium* or *sulphydric acid*, a brown precipitate, melting at the boiling heat to a metallically lustrous ball, which dissolves in hot dilute sulphuric acid, with evolution of sulphydric acid and deposition of sulphur.—*Iodide of potassium* added to the same ammoniacal solution, forms a black precipitate, which changes on boiling to thallious iodide mixed with a small quantity of iodoform. (Strecker.)

3. *Estimation and Separation.*—Thallium, when it occurs in solution as a thallious salt, is most conveniently estimated as protoiodide, TlI, in which state it is obtained by precipitation with iodide of potassium. The precipitate is quite permanent in the air, and at the temperature at which it is weighed. It is but very slightly soluble in water, insoluble or nearly so in saline solutions, alcohol of 92 per cent., and aqueous ammonia, but perceptibly soluble in water containing free acids or fixed alkalis. On mixing the hot ammoniacal solution of a thallious salt with iodide of potassium, the thallious iodide separates immediately as a curdy precipitate, which, after standing for several hours, may be collected on a weighed filter, and washed with

alcohol, or, if this is inadmissible, with ammonia. It is then dried at 115°, and weighed: it contains 49·40 per cent. thallium. (G. Werther, Zeitschr. Anal. Chem. iii. 1; Jahresb. 1864, p. 712.)

Thallium may also be estimated in the form of thallious sulphate, but not quite so exactly as by the method just described. The sulphate bears a dull red heat without perceptible volatilisation, but it is volatilised at a bright-red heat. Thallium is very completely precipitated from solutions of thallium-salts by *platinic chloride*; but the precipitated chloroplatinate is troublesome to manage, as it is very finely divided, and is apt to run through the filter when washed with water or with alcohol. (Werther.)

In solutions of thallic salts, the thallium may be estimated by reducing the thallic to thallious salts with an alkaline sulphite, and then precipitating with *iodide of potassium* (Crookes), or, by precipitating the thallium with *ammonia*, as sesquioxide, and collecting the precipitate on a weighed filter. The separation of thallious from thallic salts may be effected—at least in the case of the chlorides or sulphates,—by first precipitating the sesquioxide with ammonia, and then throwing down the remaining portion of thallium from the hot dilute filtrate by iodide of potassium (Werther). The separation may also be effected by platinic chloride, which precipitates only the thallious salt.

The method of precipitation with iodide of potassium serves also to separate thallium from most other metals, the solution being first mixed with an alkaline sulphite to ensure the reduction of any thallic salt that may be present to the state of thallious salt. If copper is present, the iodide of potassium will throw down cuprous as well as thallious iodide; but by treating the washed precipitate with ammonia, in contact with the air, the copper will be dissolved out, and the thallium will remain as thallious iodide. The separation of copper from thallium may also be effected, though not so exactly, by precipitating the copper with sulphuretted hydrogen in an acid solution. The same method serves also to separate thallium from lead and silver. The precipitated sulphides are apt, however, to carry down small quantities of thallium-sulphide.

Small quantities of thallium often occur in bismuth minerals and preparations made from them, especially the carbonate. To detect the thallium, the dilute solution of the substance is mixed with a slight excess of sodium-carbonate, and a small quantity of potassium-cyanide, then gently warmed and filtered. If the bismuth-compound contained only 1 pt. of thallium in 100,000, the addition of a few drops of ammonium-sulphide will produce a dark-brown precipitate of thallium-sulphide, which gradually collects together, and may be further examined by the spectroscopic method. From carbonate of bismuth, thallium may be easily dissolved out by digestion with cyanide of potassium, less completely with carbonate of sodium. (Crookes.)

Volumetric Estimation.—Thallium may be estimated volumetrically with *permanganate of potassium* in the same manner as iron. For this purpose it must be in the state of thallious chloride, or of a thallious oxygen-salt mixed with hydrochloric acid, and the solution must not contain more than 1 gramme of thallium in 500 c.c.; the permanganate-solution should also be more dilute than for the estimation of iron. The titration of the permanganate may be made with pure iron, with thallium, or with a thallious salt (the alum, for example); 2 at. iron (112 pts.), correspond to 1 at. thallium (204 pts.), inasmuch as the protochloride TlCl is converted by oxidation into the trichloride $TlCl^3$, so that 1 at. thallium takes up the same quantity of oxygen as 2 at. iron. The solution of the thallious salt, diluted as above mentioned, is mixed with a few drops of hydrochloric and a few drops of sulphurous acid, and heated to the boiling-point to expel the latter; then left to cool, and mixed with the permanganate. (Willm, Zeitschr. Ch. Pharm. 1863, p. 479; Jahresb. 1863, p. 689.)

4. *Atomic Weight of Thallium.*—Lamy, by decomposing the sulphate with nitrate of barium, and the chloride with nitrate of silver, obtained numbers varying between 203·5 and 204·6; mean, 204·2. Crookes found, as a mean of five experiments, the number 202·96. Werther also estimates it at somewhat lower than 204, namely, about 203·5 or 203·7. The number 204 is, however, generally adopted.

THALLIUM, FLUORIDES OF. Thallium forms two fluorides, TlF and TlF^3.—Metallic thallium is but slowly attacked by hydrofluoric acid. The carbonate, however, dissolves easily in the acid, and the solution deposits *thallious fluoride*, in white hydrated crystals derived from an oblique rhombic prism, with adamantine facets; they are not altered by light. On heating these crystals, the anhydrous fluoride, TlF, volatilises as a white, crystalline, anhydrous mass, which blackens like chloride of silver on exposure to light. Thallium-fluoride forms an acid solution, even after repeated crystallisation. The crystallised compound decomposes slowly on exposure to the air, giving off hydrofluoric acid (Fr. Kuhlmann, Bull. Soc. Chim. [1864],

i. 57; Jahresb. 1864, p. 253). Willm (Jahresb. 1865, p. 244), by dissolving carbonate of thallium in aqueous hydrofluoric acid, and evaporating, obtained thallious fluoride, in hydrated, very deliquescent, six-sided tables, which gave off their water at 100°, with partial decomposition. According to M. Buchner (J. pr. Chem. xlvi. 404), thallious fluoride separates from its solution, by slow evaporation, in colourless cubo-octahedrons, having a strong vitreous lustre. It dissolves, with alkaline reaction, in 1·25 pt. water at 15°, more easily in boiling water, sparingly in alcohol. When heated, it melts, volatilises, and solidifies again in the crystalline form. A solution containing excess of hydrofluoric acid deposits, by evaporation over oil of vitriol, *hydrothallious fluoride*, $HF.TlF$, in crystals having the same form as those of thallious fluoride. This compound has an acid reaction, dissolves in an equal weight of water, and decomposes above 100° into hydrofluoric acid and fluoride of thallium (Buchner). Kuhlmann, by treating carbonate of thallium with silicofluoric acid, obtained a *silicofluoride of thallium*, $2TlF.SiF^4.2H^2O$. It crystallises in cubic forms, dissolves easily in water, forming an acid solution, distils without decomposition, and attacks glass after some time only. Werther, by treating carbonate of thallium with hydrofluoric acid containing a large quantity of silica, obtained the anhydrous silicofluoride, $2TlF.SiF^4$, in regular octahedrons, distorted so as to resemble hexagonal prisms.

Thallic Fluoride, TlF^3, is obtained, by the action of strong hydrofluoric acid on thallic oxide, as a dark-green precipitate, insoluble in water and in cold hydrochloric acid. When heated, it turns brown, melts, and, at a higher temperature, volatilises, probably as thallious fluoride. (Willm.)

THALLIUM, IODIDES OF. The *protoiodide*, or *Thallious iodide*, TlI, is formed by direct combination of its elements, or by double decomposition. It forms a beautiful yellow powder, rather darker than sulphur, and melting, below redness, to a scarlet liquid, which, as the mass cools, remains scarlet for some time after solidification, then changes to bright-yellow. The dried precipitate, when spread on paper with a little gum-water, undergoes a similar but opposite change to that experienced by mercuric iodide when heated, the yellow surface when held over a flame suddenly becoming scarlet, and frequently remaining so for several days after cooling; hard friction with a glass rod, however, changes the scarlet colour back to yellow (Crookes). According to Werther, thallious iodide precipitated from dilute solutions, is lemon-yellow; but when precipitated from hot concentrated solutions, it is orange-yellow at first, and afterwards becomes lemon-yellow. When precipitated from a hot solution of thallious acetate, it retains its orange-yellow colour, and forms anhydrous microscopic cubes, or cubo-octahedrons, which, when heated, melt to a black liquid, and partially sublime. Thallious iodide is very sparingly soluble in water, requiring, according to Crookes, 4,453 pts. of water at 17·2°, and 842·4 pts. at 100°, to dissolve it; according to Hebberling, 1 pt. of it dissolves in 11,676 pts. of water at 16° to 17°, in 864 pts. at 100°, and in 18,934 pts. of 98 per cent. alcohol at 19°; according to Werther, in 20,000 pts. water at 13·5°, in 10,000 pts. at 23·4°, in 5,400 pts. at 45°, and 56,330 pts. of 85 per cent. alcohol at 13·5. According to Crookes, it is somewhat more soluble in aqueous iodide of potassium than in pure water; according to Hebberling, on the contrary, it is less soluble in saline solutions, especially in iodide of potassium, than in pure water.

Thallic Iodide, TlI^3.—By the action of iodine on thallium and ether, a brown solution is formed, which gradually deposits crystals of thallic iodide, easily soluble in ether containing iodine. They are rhombic prisms, exhibiting the combination $\infty P . \infty\bar{P}\infty . \bar{P}\infty . n\bar{P}\infty$. Angle $\infty P : \infty P$ (macr.) = 79° 45′; $\infty P : \infty\bar{P}\infty$ = 140° 38′; $\bar{P}\infty : \infty\bar{P}\infty$ = 160° 35′. (Nicklès.)

Ammonio-thallic iodide, $3NH^4I.TlI^3$, forms red rhombic plates, which, when heated, give off water and iodine without melting. (Nicklès.)

When 1 at. thallious iodide is treated with a solution of 2 at. iodine, in alcoholic iodide of potassium, the liquid deposits, on evaporation, large crystals of *potassio-thallic iodide*, $KI.TlI^3$, which are black by reflected, garnet-red by transmitted light, and yield a bright-red powder. This compound is resolved at 56°—60°, and more completely at 100°, into iodide of potassium, thallious iodide, and free iodine; it is also decomposed by water. (Willm, Jahresb. 1864, p. 251.)

THALLIUM, OXIDES OF. Thallium forms two oxides—namely, a protoxide, Tl^2O, and a sesquioxide, Tl^2O^3. It oxidises in the air almost as rapidly as an alkali-metal, the surface soon becoming covered with a thin film of oxide, which protects the metal from further oxidation. The superficial tarnish consists of the protoxide containing a minute quantity of the sesquioxide. If the metal has been oxidised at 100° rather more sesquioxide is formed, and at the melting-point of the metal, the protoxide which forms is mixed with a large quantity of sesquioxide. Thallium, when melted, behaves like lead, the oxide fusing like litharge; the fused oxide is absorbed by bone-ash, and a silver-thallium alloy can be cupelled like silver-lead. Thallium does not decompose pure water, either at the common temperature, or when boiling; but at a red heat the vapour of water is decomposed by thallium, with formation of oxide and separation of hydrogen, which burns with a green flame. Alcohol appears to be decomposed by the metal more readily than water.

(Respecting Schönbein's observations on the reactions of thallium with ordinary oxygen, ozone, and hydric peroxide, see J. pr. Chem. xciii. 35; Bull. Soc. Chim. 1864, i. 180; Jahresb. 1864, p. 170.)

Protoxide of Thallium, or *Thallious Oxide*, Tl^2O.—This oxide may be prepared by allowing granulated thallium to oxidise in warm moist air, and then boiling in distilled water. By repeating this operation two or three times, a saturated hot solution of the oxide is formed. Upon filtering, the small quantity of carbonate which may have formed separates at first in white needles, whilst, upon further cooling, the hydrated oxide crystallises out in yellow needles.

Anhydrous protoxide of thallium is formed by exposing these yellow crystals in a vacuum over sulphuric acid; it then forms a reddish-black mass, retaining the shape of the crystals. When heated to about the melting-point of the metal, it melts to a brown limpid liquid, which, at a higher temperature, evolves reddish-brown vapours, partially oxidising at the same time to the sesquioxide. On cooling, the brown liquid solidifies to an almost black crystalline mass. The fused oxide attacks glass and porcelain, removing the silica. Protoxide of thallium is decomposed by hydrogen at a red heat, forming water and metallic thallium. The decomposition, however, is never perfect, because the oxide melts and volatilises. When fused with sulphur, it forms sulphide of thallium, and in aqueous solution it is reduced to the metallic state by zinc, or by the electric current.

Hydrated Oxide of Thallium, or *Thallious Hydrate*, $Tl^2O.H^2O$ or $TlHO$, is prepared as above described, or it may be obtained, as recommended by Lamy, by decomposing a solution of the sulphate with baryta-water, and evaporating the alkaline solution in a vacuum. This method, however, is somewhat tedious, and there is great difficulty in getting the oxide free from baryta. The best method of obtaining perfectly pure thallious hydrate, is to add water to the oily compound of oxide of thallium and alcohol (p. 757). This at once separates the hydrate in the form of a bright-yellow crystalline mass, which may be separated from water and alcohol by exposure to warm dry air.

Thallious hydrate forms pale-yellow, long, prismatic crystals, which lose water, and become almost black and anhydrous by exposure to the temperature of a water-bath in air, or over sulphuric acid in a vacuum at the common temperature. On the addition of water, the dark oxide immediately becomes hydrated and yellow. It has a slight tendency to absorb oxygen, and after evaporation and re-solution, it always leaves a slight residue of sesquioxide.

Willm, by a method which he does not describe, once obtained thallious hydrate in rather large rhombic crystals, containing $TlHO.H^2O$.

Aqueous Solution.—Protoxide of thallium is a powerful base, dissolving readily in water, and forming a colourless strongly alkaline solution. It has a slight odour, similar to that of potash, dissolves the skin and feels greasy, acts strongly on the hair and nails, staining them a deep and very permanent brown colour. It blues litmus-paper, browns turmeric-paper, has a metallic alkaline taste, and neutralises acids perfectly. It eliminates ammonia from chloride of ammonium, and reacts with hydrochloric acid, iodide of potassium, sulphide of ammonium, &c., in the characteristic manner of a thallium-salt. An aqueous solution of thallious oxide has a greater similarity to potash than to ammonia in its reactions with metallic salts. When added to solutions of salts of magnesium, cerium, manganese, zinc, cadmium, lead, iron (ferrous or ferric), cobalt, nickel, copper, mercury, or silver, or to thallic salts, it precipitates the respective oxides, without redissolving them in excess. From salts of aluminium and chromium it precipitates the hydrated oxides, and easily redissolves them when in excess, forming with alumina a solution which is not altered by boiling, but is precipitated by a current of carbonic anhydride; and with chromium a green solution precipitated on boiling.

Sesquioxide of Thallium, or *Thallic Oxide*, Tl^2O^3. *Peroxide of Thallium.*—This oxide is always formed when metallic thallium is heated, or even when a solution of the protoxide is evaporated in the air. When the metal is burnt in oxygen, the product is chiefly sesquioxide. This oxide is best prepared by adding potash, ammonia (or even protoxide of thallium) to a solution of a thallic salt, and drying the washed precipitate at about 260°. It is also formed when a voltaic current from two cells of Grove's batteries is passed through a solution of thallious sulphate, platinum terminals being used. If the solution is perfectly neutral, thallium slowly makes its appearance at the negative pole, whilst the positive pole becomes coated with a film, presenting at first the most brilliant colours of thin plates, and gradually increasing in thickness until it becomes a cake of thallic oxide. As the sulphuric acid accumulates in the liquid, the thallic oxide at first formed gradually dissolves. If the solution of thallious sulphate is rendered alkaline by ammonia, the thallic oxide is formed in larger quantity, scaling off and falling to the bottom of the liquid. (Crookes.)

Thallic oxide is also precipitated in the anhydrous state, on adding sodic hypochlorite to a solution of thallious chloride in sodic carbonate. (Strecker.)

Anhydrous thallic oxide is a dark-brown powder, fusing with difficulty, and evolving oxygen at a red heat, whereby it is reduced to thallious oxide. It is neutral to test-paper, insoluble in water and in alkalis, but dissolves readily in acids, forming hypometric and unstable salts, from the solutions of which the sesquioxide is completely precipitated by alkalis. According to Werther, the sesquioxide is partially reduced to protoxide in drying.

Thallic hydrate, $Tl^2O^3.H^2O = Tl'''HO^2$, is obtained by drying the precipitated sesquioxide at 100°. It forms a brown powder, a shade lighter than the anhydrous oxide. Deoxidising agents, such as sulphurous or oxalic acid, convert it into a thallious salt; partial reduction also takes place on evaporating its solution in hydrochloric acid. (Werther.)

THALLIUM, OXYGEN-SALTS OF. Both the oxides of thallium dissolve readily in acids, forming definite crystallisable salts, soluble in water; there are also a few insoluble thallium-salts, which are obtained by double decomposition. The general characters, both of the thallious and of the thallic salts, have been already described (p. 749).

a. Thallious Salts.

ACETATE, $C^2H^3TlO^2$.—This salt is obtained, in white silky needles, by dissolving thallious carbonate in a slight excess of strong acetic acid, evaporating, fusing the residue, dissolving it in water, and again evaporating. It begins to decompose at 171°, dissolves easily in water and in alcohol, and deliquesces in moist air. From its solution, the thallium is immediately and completely precipitated by sulphydric acid (Crookes). It crystallises from alcohol in silky needles. (Kuhlmann.)

ARSENATES.—*Dihydro-thallious arsenate*, TlH^2AsO^4, is obtained by boiling thallic oxide with arsenious acid and water, and crystallises from the concentrated solution in hard shining needles, unalterable at 150°. It dissolves readily in water, and the solution, on addition of ammonia, solidifies to a magma of slender crystals, consisting of the *trithallious salt*, Tl^3AsO^4. (Willm.)

BENZOATE.—Crystallises in pearly plates, and is not volatile. (Kuhlmann.)

BORATE.—Boric acid added to a solution of thallious carbonate, or borax added to the sulphate, throws down a white granular precipitate of thallious borate, insoluble in an excess of the precipitant, and in cold dilute sulphuric acid; soluble in boiling water.

BROMATE, $TlBrO^3$.—Resembles the iodate.

CARBONATE, Tl^2CO^3.—The film of oxide which forms upon the surface of metallic thallium, when exposed to the air, gradually absorbs carbonic acid, and becomes converted into carbonate, which frequently appears in the form of crystalline needles. A saturated aqueous solution of thallious oxide absorbs carbonic acid rapidly, and deposits the carbonate in crystals. Thallious carbonate may be prepared in quantity by allowing granulated thallium, slightly moistened with water, to oxidise in a warm atmosphere. Upon boiling out with water containing an excess of ammonium-carbonate, and filtering, thallious carbonate is deposited, as the solution cools, in yellowish crystals which may be rendered colourless by recrystallisation.

Thallious carbonate crystallises in groups of prisms, exhibiting faces comprised in one zone, and apparently belonging to the trimetric system. Observed faces $\infty\breve{P}\infty$, ∞P, $\infty\breve{P}2$, $\infty\bar{P}2$. Angle $\infty\breve{P}\infty : \infty P = 128° 32'$; $\infty\breve{P}\infty : \infty\breve{P}2 = 147° 53'$; $\infty\breve{P}\infty : \infty\bar{P}2 = 111° 3'$; $\infty P : \infty P = 102° 56'$. The crystals appear to be twins with the combination-face ∞P; they cleave parallel to the same face (W. H. Miller, Proc. Roy. Soc. xiv. 555).—The crystals are brilliant, highly refractive, and very heavy, resembling those of a lead-salt. The salt is anhydrous; its taste is mildly caustic and somewhat metallic, remaining on the tongue for a considerable time. When heated, it melts much below redness to a clear liquid, which solidifies to a dark-grey crystalline mass. It may be kept fused for a considerable time without decomposition or loss of weight, but, when heated to dull redness, evolves white vapours and bubbles of gas. The specific gravity of the fused salt is 7·06 (Lamy). It is not very soluble in cold water; 100 pts. of water dissolve 4·02 pts. at 15·5°, 11·7 pts. at 60°, and 27·21 pts. at the boiling-point. The specific gravity of a cold saturated solution is 1·0377 (Crookes). The solution has a slightly caustic, metallic taste and alkaline reaction, which is not completely removed by supersaturation with carbonic acid. (Crookes; compare Werther, Jahresb. 1864, p. 249.)

CHLORATE, $TlClO^3$.—Prepared by dissolving thallium in chloric acid, or by mixing the saturated solutions of potassium-chlorate and thallious nitrate. It is sparingly soluble in water, and crystallises in long anhydrous needles. Its solution, when heated, turns yellow, and gives off oxygen-compounds of chlorine; and the liquid, evaporated to a syrup, deposits small, brilliant, colourless crystals, which are instantly decomposed by water, alcohol, or ammonia, with formation of brown thallic oxide. (Crookes.)

CHROMATES.—The *neutral salt*, $TlCrO^2$ or $Tl^2O.Cr^2O^3$, is a pale-yellow precipitate, obtained by adding yellow chromate of potassium to a neutral solution of a thallious salt, rendered slightly alkaline by ammonia. It is very sparingly soluble in water.—The *dichromate*, $Tl^2O.2Cr^2O^3 = 2TlCrO^2.Cr^2O^3$, is obtained as an orange-yellow precipitate, on adding dichromate of potassium to a neutral thallious salt (Crookes). According to Willm, it is deposited, in microscopic orange-yellow crystals, from a solution of the neutral salt in boiling dilute sulphuric acid.

By boiling either of the preceding salts with moderately strong nitric acid, a solution is obtained, which on cooling deposits cinnabar-coloured crystals, probably consisting of the *trichromate*, $Tl^2O.3Cr^2O^3$, or $TlCrO^2.Cr^2O^3$. They are very sparingly soluble in water, 100 pts. of water dissolving only 0·0354 pts. at 15·5°, and 0·2279 pts. at 100° (Crookes).—A *sesquichromate*, $2Tl^2O.3Cr^2O^3$ or $4TlCrO^2.Cr^2O^3$, separates from a solution of the neutral salt in moderately concentrated sulphuric acid. (Willm.)

All the chromates of thallium are decomposed by strong hydrochloric acid, with evolution of chlorine, and formation of soluble chromic and thallious chlorides: on treating them with hydrochloric acid and alcohol, the whole of the thallium is separated as insoluble protochloride, while chromic chloride passes into the solution. Sulphate of sodium likewise separates the whole of the thallium as protochloride. (Crookes.)

CITRATE, $C^6H^5Tl^3O^7$.—Very deliquescent; crystallises with difficulty; soluble in alcohol. (Kuhlmann.)

CYANATE.—Precipitated on mixing the alcoholic solutions of potassium-cyanate and thallious acetate, in small brilliant plates, very soluble in water, slightly soluble in alcohol. (Kuhlmann.)

FORMATE, $CHTlO^2$.—Prepared by dissolving the carbonate in formic acid. It is very soluble in water, and melts, without decomposition, below 100°. (Kuhlmann.)

HYPOSULPHATE or DITHIONATE, $Tl^2S^2O^6$.—Very soluble in water, from which it separates in vitreous tabular crystals, probably isomorphous with the corresponding potassium-salt. (Werther.)

HYPOSULPHITE.—*Sodio-thallious hyposulphite*, $3Na^2S^2O^3.2Tl^2S^2O^3$, obtained by dissolving thallious chloride in a boiling solution of sodic hyposulphite, crystallises in long, silky, interlaced needles, containing 10 at. water; or from a small quantity of water in small grains, the quantity of crystallisation-water in which has not been determined. At a red heat it is resolved into sulphide and sulphate of sodium, and fused, brightly glowing sulphide of thallium. (Werther.)

IODATE, $TlIO^3$.—Precipitated, on mixing iodide of potassium with nitrate of thallium, as a white powder, slightly soluble in cold, more easily in warm water. (Oettinger.)

MALATE.—Deliquescent; crystallises with difficulty; melts below 100°. (Kuhlmann.)

MOLYBDATE, $TlMoO^2$, or $Tl^2O.Mo^2O^3$.—Obtained by double decomposition with molybdate of sodium and nitrate of thallium, and separates in nacreous scales, which dissolve sparingly in pure, easily in ammoniacal water. (Oettinger, Zeitschr. Ch. Pharm. 1864, p. 440.)

NITRATE, $TlNO^3$.—Crystallises from a solution of thallium in nitric acid, in dull white needles, which melt at 205°, with separation of a small quantity of thallic oxide. The salt thus purified gives no precipitate with ammonia. It has a specific gravity of 5·8, is insoluble in alcohol, but soluble in water, the saturated solution containing 9·7 per cent. of the salt at 18°, 43·7 per cent. at 58°, and 55 per cent. at 100° (Crookes). The crystals are trimetric, exhibiting the several combinations $\infty\breve{P}\infty . P$; $\infty P . P . 2\breve{P}2$; $\infty\breve{P}\infty . \bar{P}\infty . P . 2\breve{P}2$; $\infty\bar{P}\infty . \infty P . \infty\breve{P}2 . P . 2\breve{P}2$; $\infty\breve{P}\infty . \bar{P}\infty . \infty P . \infty\breve{P}2 . P . 2\breve{P}2$. Angle $\infty\breve{P}\infty : \bar{P}\infty = 141° 51·9'$; $\infty\breve{P}\infty : \infty P = 117° 3·7'$; $\bar{P}\infty : \bar{P}\infty$ (macr.) $= 76° 16'$; $P : P$ (brach.) $= 136° 13'$; $P : P$ (macr.) $= 86° 15·2'$; $P : P$ (basal) $= 110° 5'$. No distinct cleavage. The index of refraction, for the brightest part of the spectrum, in the plane of the basal principal section, and for the ray polarised in this plane, is about 1·817. (W. H. Miller.)

OXALATES, $C^2Tl^2O^4$ and C^2HTlO^4.—Already described under OXALIC ACID (iv. 265).—*Cuprico-thallious oxalate*, $C^4Cu''Tl^2O^8.2H^2O$, crystallises from a solution of cupric carbonate in acid thallious oxalate, or from a mixed solution of cupric oxalate and neutral thallious oxalate, in slender flattened needles; it is partly decomposed by recrystallisation. (Willm.)

PHENATE, C^6H^5TlO.—Precipitated as a crystalline powder, on mixing a thallious salt with phenic acid. It is sparingly soluble in cold water, and crystallises from hot water in beautiful slender needles; melts without decomposition (F. Kuhlmann, Jun., Bull. Soc. Chim. [1864], i. 330).—The *phenylsulphamate*, or *sulphanilate*, is deliquescent, slightly soluble in alcohol, insoluble in ether, and crystallises very easily from a mixture of water, alcohol, and ether.

PHOSPHATES (Lamy, Ann. Ch. Phys. [4], v. 410).—The phosphates of thallium form a series nearly as complete as those of the alkali-metals, which they also resemble in their behaviour when heated. They are all colourless, nearly all easily soluble in water, and insoluble in alcohol. Their concentrated aqueous solutions yield, with nitric acid, a precipitate of thallious nitrate, and with caustic alkalis (but not with alkaline carbonates, or even with caustic alkalis in presence of carbonates), a precipitate of sparingly soluble trithallious orthophosphate.

Metaphosphate, $TlPO^3$.—This salt exists in two different modifications. The first remains on igniting monothallious orthophosphate, (TlH^2PO^4), as a vitreous opaline mass, very slightly soluble in water; its solution does not precipitate albumin directly, but only after addition of orthophosphoric acid. The second modification is obtained by igniting ammonio-thallious orthophosphate, as an easily soluble glass, whose solution is strongly acid, yields no crystals, but precipitates albumin immediately. It is also produced by fusing the insoluble modification with a few drops of orthophosphoric acid.

Orthophosphates.—The *monothallious salt*, TlH^2PO^4, is formed on mixing the dithallious salt with a quantity of phosphoric acid sufficient to give it an acid reaction. It crystallises from a solution concentrated by evaporation, in nacreous laminæ, easily soluble in water, insoluble in alcohol. It melts without alteration at 190°, and is converted, at a stronger heat, first into acid pyrophosphate, then, at a red heat, into metaphosphate.

The *dithallious salt*, Tl^2HPO^5, is produced by neutralising dilute phosphoric acid, at the boiling heat, with carbonate of thallium. The solution evaporated to a syrup first deposits crystals of the anhydrous salt, then other crystals containing $2TlHPO^4.H^2O$.—α. This hydrate, on account of its easy solubility, is difficult to obtain in well-defined crystals. It melts at 145°, without loss of weight, gives off its crystallisation-water with tumefaction at 170° (becoming also less soluble), and is converted, at a dull red heat, into vitreous pyrophosphate.—β. The anhydrous salt, Tl^2HPO^4, is easily soluble in the warm concentrated mother-liquor, but very sparingly in pure water, apparently suffering partial decomposition at the same time into monothallious and trithallious orthophosphate.

The *trithallious* or *normal salt*, Tl^3PO^4, first obtained by Crookes, is formed as a crystalline precipitate having a silky lustre, on mixing the saturated solutions of ordinary disodic phosphate and thallious sulphate (probably together with double phosphates of sodium and thallium, inasmuch as the liquid, after precipitation, exhibits an alkaline reaction); also, together with ammonio-thallious phosphate, on treating the mono- or di-thallious salt with excess of ammonia. By fusing 1 at. thallious metaphosphate with 2 at. thallious carbonate, as long as gas continues to escape, and pouring out the mass before it is quite solidified, trithallious orthophosphate is obtained, in needle-shaped crystals, one or two centimetres long. It melts, at a red heat, to a yellowish-red liquid, which solidifies at 10° to a white crystalline mass, of specific gravity 6·89. It is but sparingly dissolved by water, even at the boiling heat. According to Crookes, 100 pts. water dissolve 0·497 pt. of it at 15·5°, and 0·6712 pt. at 100°.

Ammonio-thallious orthophosphate crystallises from the mother-liquor of the trithallious salt in large transparent prisms. When ignited it leaves thallious metaphosphate.

Pyrophosphates.—The *dithallious* or *acid salt*, $Tl^2H^2P^2O^7$, produced by carefully heating monothallious orthophosphate, is extremely soluble in water, and crystallises from the acid solution in short prisms.—The *tetrathallious* or *neutral salt*, $Tl^4P^2O^7$, remains, on strongly heating hydrated dithallious orthophosphate (α), as a vitreous mass very soluble in water, and crystallises from the solution evaporated to a syrup, in confused needles, which are decomposed by water, with separation of a white precipitate. The anhydrous dithallious orthophosphate (β) yields the pyrophosphate with different properties—namely, as an opaque crystalline mass, whose solution yields, by evaporation, large prisms which are likewise decomposed by pure water. (Lamy.)

Picrate, $C^6H^2Tl(NO^2)^3O$.—Soluble in water, nearly insoluble in alcohol; crystallises, like the potassium-salt, in yellow needles, which have a silky lustre, and detonate strongly when heated.—The *picramate*, $C^6HTl(NH^2)(NO^2)^2O$, is a black-red crystalline precipitate, nearly insoluble in alcohol, and separating from boiling water in small regular crystals. (F. Kuhlmann, Jun.)

Racemate or **Paratartrate**, $C^4H^4Tl^2O^6$.—Very soluble in water; forms groups of crystals apparently belonging to the dimetric system. (Kuhlmann.)

Selenates and **Selenites**.—See pp. 229, 231.

Sulphates.—See p. 614.

Tartrates.—See p. 680.

Tungstate.—White powder, sparingly soluble in water; obtained like the molybdate. (Oettinger.)

Urate.—Obtained by double decomposition; almost insoluble in water. (Kuhlmann.)

Valerate, C^5H^9TlO.—Very soluble in water and in alcohol; resembles the acetate. (Kuhlmann.)

β. *Thallic Salts.*

Acetate, $Tl^2O^3.C^4H^6O^3.3H^2O$, or $Tl'''(C^2H^3O^2)^3.2Tl'''H^3O^3.\frac{3}{2}H^2O$.—Crystallises by spontaneous evaporation of a solution of thallic oxide in strong acetic acid prepared at the boiling heat, in colourless plates belonging to the rhombic system (sometimes accompanied by small prismatic crystals, probably of thallious acetate). These crystals, when exposed to the air, quickly turn brown on the surface; and are decomposed more quickly, at a gentle heat, into acetic acid and thallic oxide, the decomposition being nearly complete at 100°. The salt is also immediately resolved into its constituents by water. (Willm.)

Arsenate, $Tl'''AsO^4.2H^2O$.—Obtained, like the phosphate, as a lemon-yellow gelatinous precipitate, soluble in hydrochloric acid. Ammonia added to the solution throws down, first a bulky crystalline salt, which appears to differ from the preceding by its amount of crystallisation-water; on further addition, a yellow dithallic salt, and finally a brown precipitate. (Willm.)

Nitrate, $Tl'''(NO^3)^3$, separates from a concentrated solution, in colourless well-defined crystals containing 3 at. water (Strecker), 4 at. (Willm). The salt decomposes at 100°, with separation of brown thallic oxide.

Oxalate, $C^6\overset{\prime\prime\prime}{Tl}{}^2O^{12}$.—Obtained (mixed with thallious salt) as a white crystalline powder, nearly insoluble in water, by heating thallic oxide with aqueous oxalic acid or by precipitating a solution of a thallic salt with oxalic acid. (Willm.)

Ammonio-thallic oxalate, $C^4Tl'''(NH^4)O^8.3H^2O$, is formed, on mixing thallic sulphate with ammonium-oxalate, as a white precipitate, quite insoluble in cold water, and converted, by boiling with water, into thallious salt, with evolution of carbonic anhydride; when ignited it leaves fused metal. (Strecker.)

Phosphate, $Tl'''PO^4.2H^2O$. Separates, on diluting the solution of the nitrate mixed with phosphoric acid, "as a gelatinous precipitate, having a crystalline aspect." It is insoluble in water, but dissolves in strong nitric and dilute hydrochloric acid. Ammonia added to the latter solution throws down a green basic salt, $Tl^2O^3.2Tl'''PO^4.5H^2O$; afterwards brown thallic oxide.

Sulphate, already described (p. 614).

THALLIUM, PHOSPHIDE OF. Phosphoretted hydrogen passed through an ammoniacal solution of thallious sulphate, precipitates phosphide of thallium, as a black insoluble powder permanent in the air at ordinary temperatures.

THALLIUM, SELENIDE OF. Tl^2Se.—Obtained as a greyish-black mass, by fusing the two elements together in equivalent proportions (Lamy). By passing selenhydric acid gas into a solution of thallious carbonate, the same compound is precipitated in grey shining laminæ, which turn black on drying. It melts at 340°, and gives off selenhydric acid when treated with sulphuric or hydrochloric acid. (Kuhlmann, Jahresb. 1864, p. 253.)

THALLIUM, SULPHIDE OF. Tl^2S.—This compound is precipitated from all thallious salts by sulphide of ammonium, and from the acetate, carbonate, or oxalate by sulphydric acid (incompletely also from the nitrate, sulphate, or chloride), in dense flocks of a greyish or brownish-black colour. The precipitate oxidises in the air, and must therefore be washed with water containing sulphydric acid. It dissolves easily in dilute sulphuric or nitric acid, but is insoluble in sulphide of ammonium and cyanide of potassium. A cold (not too dilute) solution of thallious sulphate acidulated with a trace of sulphuric acid, yields, with sulphydric acid, shining black-blue laminæ of pure thallium-sulphide, appearing under the microscope to be made up of tetrahedrons, and more permanent than the amorphous sulphide (Hebberling). Thallic salts appear to be reduced to thallious sulphide by boiling with sulphide of ammonium. Sulphate of thallium projected into fused cyanide of potassium, is reduced to sulphide, which then forms a brittle metallic-looking mass, having the lustre of plumbago, and fusing more readily than metallic thallium.

THALLIUM-BENZAMIDE. C^7H^6TlNO.—Benzamide dissolves freely in a hot aqueous solution of thallious oxide, the excess crystallising out on cooling; and on adding a large excess of absolute alcohol to the filtrate, thallium-benzamide separates in fine needles, soluble, with alkaline reaction, both in hot and in cold water. It melts without decomposition. When moderately heated, it becomes dark at a higher temperature, and evolves white inflammable vapours, burning with a smoky greenish flame, and decomposes completely at a red heat, leaving fused oxide of thallium. Hydrochloric acid added to the aqueous solution, throws down protochloride of thallium, together with benzamide. (Church and Crookes, Chem. Soc. J. xvii. 151.)

THALLIUM-ETHERS. *Thallium-alcohols.* (Lamy, Compt. rend. lv. 286; Ann. Ch. Phys. [4], iii. 373; Jahresb. 1864, p. 463.)—Compounds formed by the action of thallium upon alcohols, analogous to those produced in like manner by the alkali-metals.

Thallium-amylate, $C^5H^{11}TlO$, is produced, though slowly, by the action of thallium on amylic alcohol; more readily by heating equivalent quantities of thallium-ethylate and amylic alcohol to 140°—150°, whereupon ethylic alcohol passes over first, then the excess of amylic alcohol, leaving the thallium-amylate in the form of a heavy oil, smelling like amylic alcohol, and having a specific gravity of 2·465 to 2·518. Its index of refraction for the line B is 1·572 at 20°. It does not solidify at 20°; dissolves easily in *amylic*, less easily in *ethylic alcohol*; with *chloroform* and *ether*, it behaves like the ethyl-compound (*infra*). When heated, it first gives off hydrogen, then amylic alcohol, and leaves a mixture of metallic thallium with thallious carbonate and valerate. It also decomposes, but less quickly, in contact with air or water. It burns with a white, moderately luminous flame.

Thallium-ethylate, C^2H^5TlO.—Produced, with evolution of hydrogen, when thallium and ethylic alcohol are heated together to 100° in a sealed tube (Church). Lamy prepares it by suspending thin plates of thallium within an exhausted bell-jar, over a shallow dish containing absolute alcohol, and passing pure oxygen-gas (free from water and carbonic anhydride) into the jar. At 20°—25°, the thallium is converted, within 24 hours, with simultaneous formation of water, into ethylate of thallium, which collects in the dish. After being freed from excess of alcohol, by heating to 100°, it remains as an oil of specific gravity 3·480—3·553, being, next to mercury, the heaviest liquid known. Its expansion-coefficient, between 0° and 100°, is 0·072. At $-3°$ it solidifies, with considerable contraction of volume. By prolonged heating, or by keeping in a vacuum, it suffers partial decomposition, becoming brown, increasing in density to 3·685, and requiring a greater degree of cold to solidify it. In refractive and dispersive power, it exceeds all other liquids, as shown by the following numbers (determined for a temperature of 20°):—

		Refractive power.			Dispersive power.
		Line B.	Line D.	Line H.	
Thallium-ethylate, specific gravity	3·550	1·6615	1·6676	1·7159	0·0975
" " " "	3·612	1·6725	1·7170	1·7678	0·0958
Carbonic disulphide . .	. .	1·6140	1·6330	1·6935	0·0795

Thallium-ethylate dissolves in about 5 pts. of absolute *alcohol*; if the alcohol is not quite anhydrous, white thallious hydrate is deposited. With pure *ether* free from air, it forms a clear solution; with ether containing water, the liquid soon becomes yellowish or brown, and deposits radio-crystalline thallious hydrate, which gradually turns brown. This reaction is so delicate, that it may be used as a test for the purity of ether. Thallium-ethylate likewise dissolves freely in *chloroform*; but the solution soon becomes turbid, and deposits crystallised protochloride of thallium, together with a substance which colours the latter dark-red, and is very sensitive to light; the liquid, which has become strongly acid, contains a salt of formic acid.

Thallium-ethylate, when heated, gives off hydrogen slightly at 130°, regularly between 170° and 180°, alcohol distilling over at the same time, thallium being deposited in shining laminæ, and a strongly alkaline residue being left containing thallious carbonate and acetate. Above 200°, carbonic oxide and carbonic dioxide are given off, together with small quantities of acetone and acetic acid. Thallium-ethylate decomposes when exposed to the *air*, and still more quickly in contact with *water*, yielding alcohol and thallious hydrate. On keeping it (best under a layer of absolute alcohol), the sides of the vessel become gradually coated with black thallious oxide. When set on fire by the flame of a candle, it burns with a green, slightly luminous flame, leaving black thallic oxide and metallic thallium.—*Potassium* and *sodium* slowly separate metallic thallium from it, but it is not decomposed by iron, zinc, lead, or even by the electric current.—With *sulphuric* or *hydrochloric acid*, it yields alcohol and a thallious salt; dry *carbonic dioxide* unites directly with it, forming a white solid body, which is resolved by heat into metallic thallium and empyreumatic products. When thallium-ethylate is suddenly mixed with *carbonic disulphide*, a violent action takes place, resulting in the formation of a black sulphur-compound; but if the thallium-ethylate be slowly dropt into the carbonic disulphide, a bulky, yellowish, gelatinous mass is formed. (Lamy.)

Thallium-methylate, CH^3TlO, is formed, in small quantity only, by the process which yields the ethyl-compound, but it is very easily obtained by treating ethylate or amylate of thallium with excess of methylic alcohol. Considerable rise of temperature then takes place, and methylate of thallium separates as a white solid substance, which, by fusion and cooling under the liquid, may be crystallised in thick oblique prisms. When quickly pressed between filter-paper, and dried in a vacuum in contact with a few lumps of sodium, it forms a white solid mass, alterable in contact with the air, about five times as heavy as water, slightly soluble in *methylic alcohol* and in *ether*, somewhat more soluble in *chloroform*. When heated, it gives off a large quantity of carbonic oxide, together with hydrogen and methylic alcohol; and when set on fire, it burns with a flame strongly tinged with green.

On *thallium-phenylate*, see p. 755; on the compounds of *thallious chloride* and *bromide* with *ethers*, pp. 747, 748.

THALLIUM-GLASS. By substituting thallium for lead, or for potassium, in the preparation of flint-glass, glasses are obtained of great density and refracting power. By fusing together 300 pts. of sand, 200 of minium, and 333 carbonate of thallium, a perfectly homogeneous glass was obtained, having an agreeable yellow tint, and very brilliant. Its density was 4·233, and its index of refraction (for the yellow ray) 1·71; it is therefore denser and more refractive than any glass hitherto known. By altering the proportions of thallium, glasses have been obtained, varying in density from 4·235 to 5·025, and having indices of refraction ranging from 1·71 to 1·965. (Lamy, Bull. Soc. Chim. [1866], i. 164.)

THALLIUM-TRIAMINE. $N^3Tl'''H^6$.—Thallic oxide dissolves in sal-ammoniac at the boiling heat, and the cold concentrated solution yields with ammonia a heavy white precipitate, consisting of $TlCl^3.3NH^3$, or probably *hydrochlorate of thallium-triamine*, $N^3Tl'''H^6.3HCl$. It is decomposed by water, yielding thallic oxide and sal-ammoniac:

$$2(TlCl^3.3NH^3) + 3H^2O = Tl^2O^3 + 6NH^4Cl.$$

When heated in a sealed tube, it is resolved into ammonia, an ammonium-salt, and a chloride of thallium, probably Tl^2Cl^3. Its solution in hydrochloric acid yields cubic or octahedral crystals of the double salt, $3NH^4Cl.TlCl^3$. (Willm, Jahresb. 1863, p. 251; 1864, p. 251.)

THALLOCHLORE. A name applied by Knop and Schnedermann (Ann. Ch. Pharm. lvi. 147, 154) to the green colouring-matter of lichens, which they regard as different from ordinary chlorophyll.

THARANDITE. Syn. with BITTER SPAR (i. 600).

THEBAINE. $C^{19}H^{21}NO^3$. *Paramorphine.* (Pelletier, J. Pharm. xxi. 569.—Couerbe, Ann. Ch. Phys. [2], lix. 155.—Kane, Ann. Ch. Pharm. xix. 9.—Anderson, *ibid.* lxxxvi. 179.)—An organic base existing in opium. It was discovered in 1835 by Pelletier, who obtained it by treating the extract of opium with milk of lime in excess, washing the calcareous precipitate with water, and exhausting it, after drying, with boiling alcohol. The alcoholic solution leaves on evaporation a residue, from which thebaine may be dissolved out by ether.

Anderson obtains thebaine from the mother-liquors of the preparation of narcotine. The alcoholic liquor from which the first strongly-coloured crystals of narcotine have been deposited, yields by evaporation, an amorphous residue consisting of a large quantity of resin, a little narcotine, and all the thebaine contained in the opium. This residue is treated with boiling dilute acetic acid, which dissolves the alkaloïds, together with a small quantity of resin; and on adding basic acetate of lead to this solution, in sufficient quantity to render it distinctly alkaline, all the narcotine and resin are precipitated, while the thebaine remains in solution. The liquid is filtered; the excess of lead removed by sulphuric acid; the thebaine contained in the filtered liquid is precipitated by ammonia; this precipitate, after being washed, is dissolved in boiling alcohol, and the solution is treated with animal charcoal. It then, on cooling, deposits thebaine in shining scales, which may be purified by recrystallisation.

Thebaine crystallises from solution in alcohol or ether, in square scales having a silvery lustre. Its taste is acrid and styptic rather than bitter. It is extremely poisonous; Magendie found that 5 centigrammes of it injected into the jugular vein of a dog produced tetanic convulsions, quickly followed by death. Thebaine is insoluble in water, very soluble in alcohol and ether, especially when warm, insoluble in aqueous potash and ammonia; it dissolves rapidly in acids. It contains, according to the mean of closely-agreeing analyses by Kane and Anderson, 73·10 per cent. carbon, 6·96 hydrogen, and, according to Anderson, 4·43 per cent. nitrogen. The formula $C^{19}H^{21}NO^3$, requires 73·31 per cent. carbon, 6·75 hydrogen, 4·50 nitrogen, and 15·44 oxygen.

Thebaine melts at 12·5°, and decomposes at higher temperatures. It is coloured deep red by strong *sulphuric acid*. According to Dragendorff (Jahresb. 1864, p. 728), sulphuric acid, whether pure or containing nitric acid, colours it deep red to orange, gradually changing to olive-green at 150°. Sulphuric acid of specific gravity 1·3 dissolves it in the cold; but the solution, when gently heated, deposits a resinous substance, which dissolves slowly on boiling with water, and is deposited on cooling in microscopic, slightly soluble crystals, apparently a product of decomposition (Anderson).—Concentrated *nitric acid* acts strongly on thebaine, even in the cold, giving off red vapours, and forming a solution, which, when mixed with potash, becomes dark-coloured and gives off a volatile alkali.—Thebaine also dissolves easily in *hydrochloric acid*; the solution becomes dark-coloured when evaporated, and leaves a resinous residue no longer quite soluble in water.—*Chlorine* and *bromine* act strongly on thebaine, forming resinous products.

Thebaine-salts do not crystallise from aqueous solution.

The *hydrochlorate*, $C^{19}H^{21}NO^3.HCl.H^2O$, is obtained by mixing thebaine with a small quantity of strong alcohol, and adding alcoholic hydrochloric acid till complete solution is effected, avoiding an excess of acid; it then separates on standing in rhombic crystals. It is very soluble in water, the solution resinising on evaporation; slightly soluble in alcohol, and insoluble in ether.—The *chloroaurate* is an orange-red precipitate, which melts to a resinous mass at 100°.—The *chloromercurate* is a white crystalline precipitate, obtained with hydrochlorate of thebaine and mercuric chloride; with free thebaine a bulky precipitate is obtained, which, as well as the crystalline precipitate, is of variable composition.—The *chloroplatinate*, $2(C^{19}H^{21}NO^3.HCl).PtCl^4.2H^2O$, is precipitated on adding platinic chloride to hydrochlorate of thebaine. It is slightly soluble in boiling water, the solution depositing a salt, which appears to be a product of decomposition.

The *sulphate* is obtained by adding sulphuric acid to an ethereal solution of thebaine, partly in the crystalline state, partly as a resin, which becomes crystalline on standing.

THEBOLACTIC ACID. This name is applied, by T. and H. Smith, to an acid, isomeric or identical with lactic acid, discovered by them in the mother-liquors of morphine. To prepare it, the mother-liquor of morphia, after having been freed from all organic bases by precipitation with an alkali, is digested with oxide of lead; the evaporated liquid is mixed with a large quantity of alcohol and sulphuric acid; and the solution filtered from the precipitated sulphates, and saturated with milk of lime, is evaporated to a syrup; this, after some time, solidifies to a crystalline mass of calcic thebolactate. Turkey opium yields about 2 per cent. of this salt.

Thebolactic acid appears, from an analysis of the silver-salt by Dr. Stenhouse, to have exactly the same percentage composition as lactic acid; but (according to T. and H. Smith) its copper- and morphine-salts differ in crystalline character from the corresponding lactates, and the behaviour of ferric thebolactate with ammonia is different from that of ferric lactate. (Pharm. J. Trans. [2], vii. 50; also private communication from Messrs. T. and H. Smith.)

THEINE. Syn. with CAFFEINE (i. 707).—According to Attfield (Pharm. J. Trans. [2] vi. 457), the nuts of the kola-tree (*Cola acuminata*), which in the fresh state are used in the western part of Central Africa as food and medicine, contain theine, the dried nuts yielding about 2 per cent.

THEIOTHERMIN. Syn. with BAREGIN (i. 500).

THENARDITE. Native anhydrous sulphate of sodium. (See SULPHATES p. 610.)

THENARD'S BLUE. A blue colour prepared by igniting a mixture of cobalt phosphate or arsenate and alumina. (See PHOSPHATES, iv. 500.)

THEOBROMA. See CACAO (i. 700).—The ash of several parts of the cacao-tree, from the plantations of Manado, in Celebes, has been examined by Rost van Tonningen (Rép. Chim. app. ii. 261), with the following results:

	Bark.	Leaves.	Fruit.	Seed.
Ash per cent. of the dried substance (? at 100°)	12·86	14·58	13·34	3·87
Composition of the ash:				
Silica	34·60	42·65	trace	0·99
Sulphuric anhydride	4·85	10·22	3·50	4·30
Chlorine	0·63	0·25	0·30	0·45
Phosphoric anhydride	23·01	5·21	7·14	38·18
Lime	11·65	14·38	3·76	1·94
Magnesia	4·56	6·19	3·21	trace
Carbonate of calcium	19·53	20·13	69·70	44·44
Carbonate of sodium	trace	trace	8·66	7·83
	98·83	99·03	96·27	98·13

THEOBROMINE. $C^7H^8N^4O^2$. (Woskresensky, Ann. Ch. Pharm. [1841], xli. 125.—Glasson, *ibid.* lxi. 335.—Keller, *ibid.* xcii. 71.—Rochleder, *ibid.* xxi. 9; lxxxix. 124.—Strecker, *ibid.* cxviii. 151.)—An organic base existing in cacao-beans. To prepare it, the beans are treated with water for some time at the heat of the water-bath; the solution is strained through linen, and carefully precipitated by neutral acetate of lead; the precipitate, which is abundant, is separated by filtration; and the filtered liquid is freed from excess of lead by sulphuretted hydrogen. The filtrate then yields by evaporation a brown residue, which is boiled with alcohol, and filtered at the boiling heat; the liquid, on cooling, deposits a reddish-white crystalline powder, which is obtained colourless by repeated crystallisation (Woskresensky; Glasson). Keller heats the theobromine, obtained as above, between two watch-glasses, whereby a small quantity of charcoal is separated, and a dazzling white sublimate formed.

Properties.—Theobromine is a colourless crystalline powder, composed of microscopic trimetric crystals, exhibiting the combination $\infty \bar{P}2 . P$, and arranged in club-shaped groups (Keller). It tastes very bitter, but the flavour is very slowly developed. Sublimes, without decomposition, between 290° and 295°. Its composition is shown by the following analyses:—

		Calculation.	Woskresensky.	Glasson.	Keller.
C^7 . . .	84	46·67	46·33	47·13	46·28
H^8 . . .	8	4·44	4·55	4·60	4·80
N^4 . . .	56	31·11	35·38	31·27	30·86
O^2 . . .	32	17·78	13·74	17·00	18·06
$C^7H^8N^4O^2$ . .	180	100·00	100·00	100·00	100·00

Theobromine is sparingly soluble in *hot water*, still less soluble in *alcohol* and in *ether*. The aqueous solution forms, with *mercuric chloride*, a white crystalline precipitate, slightly soluble in water and in alcohol. (Woskresensky.)

Decompositions.—1. Theobromine heated with *peroxide of lead* and dilute *sulphuric acid*, gives off carbonic anhydride, the decomposition, when once begun, going on without further application of heat; and if the right quantity of peroxide of lead be added, and the heating not too long-continued, there is obtained, after separating the sulphate of lead by filtration, a transparent colourless liquid, which gives off ammonia when treated with potash, separates sulphur from sulphuretted hydrogen, colours the skin purple-red, and immediately turns blue when treated with magnesia. An excess of magnesia destroys this colour, which may, however, be restored by cautious addition of sulphuric acid. The liquid, mixed with excess of magnesia, becomes reddish, and gives off ammonia during evaporation to dryness; boiling alcohol extracts from the residue a body which crystallises from the solution in rhombic prisms, is soluble in alcohol, has an acid reaction, and does not precipitate chloride of mercury, nitrate of silver, or tetrachloride of platinum. (Glasson.)

2. It dissolves in boiling *baryta-water* without evolution of ammonia; the solution, on cooling, solidifies to a white jelly.

3. With *chlorine*, in presence of water, it forms amalic acid and hydrochlorate of methylamine (Rochleder and Hlasiwetz, Wien. Akad. Ber. 1850, i. 266).—4. Heated with *potash*, it gives off methylamine.

5. The silver-compound of theobromine, heated to 100° with *iodide of methyl*, yields silver-iodide and caffeine:

$$C^7H^7AgN^4O^2 + CH^3I = AgI + C^8H^{10}N^4O^2.$$

Hence caffeine may be regarded as methylated theobromine. (Strecker.)

Argentic Theobromine, $C^7H^7AgN^4O^2$.—When theobromine is dissolved in ammonia (in which it dissolves much more easily than in water), and nitrate of silver is added, a gelatinous precipitate is obtained, which dissolves easily in warm ammonia. On boiling the solution for some time, ammonia escapes, and a colourless granular precipitate of argentic theobromine is formed, which is nearly insoluble in water. The precipitate contains water, which is given off slowly over oil of vitriol, or at 100°, more quickly at 120°—130°. The residue may be heated to 160° without alteration; at a higher temperature it does not melt, but decomposes, and gives off vapours, which condense to unaltered theobromine. (Strecker.)

Theobromine Salts.—Theobromine is a weak base, but nevertheless forms salts which crystallise well, though they are somewhat unstable, the neutral salts being decomposed by water, and converted into basic salts.

Hydrochlorate, $C^7H^8N^4O^2.HCl$.—Theobromine dissolves readily in concentrated hydrochloric acid; and as the warm solution cools, the salt separates in crystals, which may be dried over oil of vitriol and caustic potash. It gives off all its hydrochloric acid at 100°, and decomposes with water, forming a basic salt (Glasson).—The *chloroplatinate*, $2(C^7H^8N^4O^2.HCl).PtCl^4.4H^2O$, separates from a mixture of the hydrochlorate and platinic chloride, in monoclinic prisms, exhibiting the faces ∞P and oP. It is efflorescent, gives off its water of crystallisation at 100°, decomposes at a stronger heat, and, when ignited in the air, leaves pure platinum.

The *nitrate*, $C^7H^8N^4O^2.HNO^3$, separates from a solution of theobromine in warm nitric acid, on cooling, in monoclinic prisms, which give off their acid at 100°, and are easily decomposed by water.

The *argentic nitrate*, $C^7H^8N^4O^2.AgNO^3$, separates from a very dilute solution of nitrate of theobromine mixed with nitrate of silver, in shining silver-white needles, very sparingly soluble in water. It does not undergo any perceptible loss at 100°, but at a higher temperature, it melts and gives off nitrous acid, and on ignition leaves metallic silver.

THERMOBAROMETER. This name was applied by Bellani to a syphon-barometer having its two wide legs united by a narrow tube, so that it could be used either in its ordinary position as a barometer, or in the reversed position as a thermometer, the wide sealed leg of the barometer then serving as the bulb of the thermometer.

The same name is sometimes applied to a thermometer which indicates the atmospheric pressure by the boiling-point of water.

THERMO-ELECTRICITY. See ELECTRICITY (ii. 412).

THERMOMETER (θερμός, hot; μέτρον, measure).—The thermometer measures the *temperature*, or *degree of hotness*, of a body; it thus determines one dimension, so to speak, of the quantity of heat within the body—the specific heat and the weight of the body being the other dimensions. The measurement is founded on the law, that perfect gases tend to expand with equal increments of volume for equal increments of heat. Mercury, being compared with gases, is found to follow nearly the same law at ordinary temperatures. It is likewise almost perfectly adapted for thermometric purposes, from its wide range of liquidity (390° C.), its low specific heat, its high conducting power, and its uniform purity.

As the thermometer is the most important and indispensable of all instruments in most physical researches, too much attention cannot be paid to attaining perfection in its manufacture and use.

Thermometer Tube.—In making a mercurial thermometer, a capillary glass-tube, usually of flat or elliptical bore, is first to be selected, as free as possible from all visible defects. It must be of almost perfectly uniform bore throughout. That it is so is to be ascertained by introducing enough mercury to fill about one inch of the tube, and observing if the length of this mercurial column remains almost unchanged as the mercury is forced through the tube. If the tube be not perfectly clean internally, nitric acid or other solvents may be introduced, the interior of the tube being afterwards thoroughly washed with distilled water, and dried by drawing air through it when hot.

A bulb is now to be formed by sealing and softening the tube at one end, in the blowpipe-flame, and then forcing dry air in by means of a small elastic bottle fixed to the open end, and compressed by the fingers. Much skill, of course, is required in this operation, and the ultimate character of the instrument will vary with every particular manner of heating the glass.

The form of the bulb, too, is a matter for much consideration. Its capacity must have such a ratio to the capacity of the tube, that the degrees may be long enough to read with the required precision, and not much longer. Thus, thermometers intended to show the $\frac{1}{10}$ of a degree (Fahr.), should have degrees not less than $\frac{1}{10}$ inch in length.

Fig. 799.

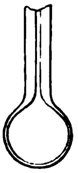

Fig. 800.

Fig. 801.

Fig. 802.

Fig. 803.

The required capacity of the bulb may be calculated as afterwards shown. The ordinary shape of the bulb is spherical (*fig.* 799), and this is the best suited to bear the pressure of the atmosphere without shrinking. But an elongated bulb, either pear-shaped (*figs.* 800 and 801), or tubular (*figs.* 802 and 803), exposes a much larger surface for the conduction of heat, in proportion to its capacity, and is therefore favourable to sensitiveness. A bulb, too, of no greater diameter than the tube, is less liable to be broken, and, for chemical purposes especially, is convenient and neat. The thickness of the glass is an important point; if too thin, it may yield to the atmospheric pressure, so as to raise the zero of the instrument; if too thick, the instrument will be insensitive. In all these points a thermometer should be specially adapted to its intended employment.

Fig. 804.

Fig. 805.

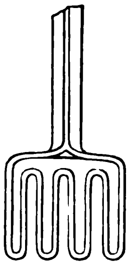

Fig. 806.

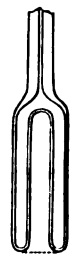
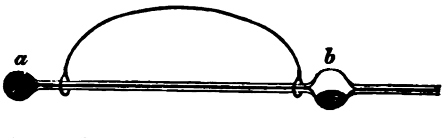


Extremely sensitive and yet exact thermometers have lately been prepared by the best London makers. In these, either the bore of the tube is very minute, and the bulb consequently small (as in *fig.* 804), or the bulb is made to contain much mercury, and shaped into a long cylindrical tube, bent into some convenient form, as in the *Gridiron* thermometer of Negretti and Zambra (*fig.* 805). In *fig.* 806 is shown a suggestion of Mr. Beckley, of the Kew Observatory, for increasing the surface of thermometer-bulbs without impairing their inflexibility. The mercury is contained between two concentric glass-cylinders, of which the inner one is open at the bottom.

Filling the Tube.—The following is the most perfect mode of filling the thermometer with mercury:—A sufficient length of the tube, *a b*, is marked off to form the stem of the thermometer, and a second bulb, rather larger than the first, is roughly blown at *b*. When the bulb is half-cooled, the open end of the tube is held in pure and well-boiled mercury, which gradually rises into the first bulb. By inverting the position of the tube, and alternately heating and cooling the lower bulb (*a*), sufficient mercury may be made to pass from *b* into *a*, almost to fill *a*, a little remaining over in *b*. The whole tube is now held by the wire-handle shown in *fig.* 807, over a charcoal-fire or a series of powerful gas-burners, so as to be strongly and uniformly heated throughout its whole length. The mercury boils easily, and its vapour drives out every trace of air or moisture. When this is thoroughly accomplished, and the mercury yet boiling, the open end of the tube, which must not be very hot, is thrust against a piece of sealing-wax, and then at once withdrawn from the heat. As the tube cools, a little wax is drawn in, and, in time becoming solid, prevents the entrance of any air. When quite cool, the mercury perfectly fills the whole of the lower bulb and tube. Let the tube be now inclined, and the lower bulb raised to a temperature rather higher than the thermometer is intended ever to indicate. A part of the mercury is thus expelled, and as the column

Fig. 807.



begins to retreat again on cooling, the tube is to be melted and hermetically sealed, just below the bulb *b*, which is drawn off. The perfection of the vacuum thus produced within part of the tube, may be known by the mercury running freely up and down, especially if the tube be not very fine. This process is more simply but less perfectly performed by some makers, who omit the second bulb, and place the mercury in a little funnel of glass or paper affixed to the open end of the tube.

Graduation.—A common thermometer is usually graduated by determining two points of the scale, by comparison with a standard thermometer, and dividing the interval into the proper number of equal parts. The thermometric scales usually employed are well known to be three in number, and are thus defined:—

	Temperature of melting ice.	Interval.	Temperature of boiling water.
Centigrade scale (C.)	0·0°	100·0°	100·0°
Fahrenheit's scale (F.)	32·0°	180·0°	212·0°
Reaumur's scale (R.)	0·0°	80·0°	80·0°

Of these, the Centigrade is in general use on the Continent, and is so far superior to our own Fahrenheit's scale, that all scientific chemists should at once adopt it. It is already adopted in many English scientific treatises. Reductions from one scale to the other are easily made by the following formulæ:—

Fahrenheit to Centigrade	$\frac{5}{9}(F.^\circ - 32) = C.^\circ$
Centigrade to Fahrenheit	$\frac{9}{5}C.^\circ + 32^\circ = F.^\circ$
Reaumur to Fahrenheit	$\frac{9}{4}R.^\circ + 32^\circ = F.^\circ$

The Reaumur scale being seldom met with, the numbers 5, 9, and 32, which are sufficient for the reduction of Fahrenheit and Centigrade, may be easily remembered and applied.

Mounting of the Thermometer.—For chemical purposes, the simple tube-thermometer, with the divisions etched upon it, is by far the best. For accurate purposes, indeed, divisions upon the glass are alone to be trusted; and if an ivory scale is attached at all, it must only be used to show the whole degrees with quickness and security from mistake.

For meteorological use, the degrees should still be etched on the glass, but may be repeated on the metal scale. In this respect the Kew Observatory common thermometer leaves nothing to be desired. It may be had from the best opticians, with a certificate of its comparison at Kew, at the price of about half-a-guinea. More sensitive instruments are mentioned in describing the Dry and Wet Bulb Hygrometer. (See HYGROMETER, iii. 228.)

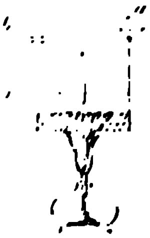
Standard Thermometer.—We shall describe the graduation of a standard thermometer as it was practised by Mr. Welsh at the Kew Observatory of the British Association, on the principles proposed by Regnault, and described at considerable length by Pierre (Ann. Ch. Phys. [3], v. 428).—Welsh. (*Report to Royal Society* Phil. Mag. [4], iv. 306.)

Calibration of the Tube.—A tube, having been selected as tolerably free from all visible defects, a short column of mercury, generally less than one inch long, is introduced. The tube is then attached to a dividing-engine, and either end put in communication with an elastic bag compressed by a screw, by which means the mercury can be moved at will. Commencing at one end of the desired scale, the mercury is made to coincide with cross-wires in the focus of a microscope carried by the cutting slide of the engine. By turning the screw until the wires correspond with the other end of the column, we learn the length of the column in revolutions of the screw. The mercury is now moved until its other end exactly coincides with the cross-wires which have remained stationary. The length of the column is again measured, the difference, if any, indicating inequality of the tube. The same process is repeated, until the column has been measured for each length of itself through the whole extent of the proposed scale. Permanent marks are made on the glass, at the points of commencement and ending of the calibration.

Graduation.—The measured lengths of the column of mercury, in its successive steps along the tube, corresponding to equal volumes, we may assume, unless the tube is a very faulty one, that the calibre of the tube is uniform throughout each length. Hence we may divide the length of each, as expressed in revolutions of the screw, into any convenient number of parts, and proceed to the graduation, starting from one end, and successively adding on the requisite number of revolutions. The divisions are cut with a fine needle-point upon a coating of engravers' wax, and afterwards etched with hydrofluoric acid. By weighing a measured column of mercury, we have data to calculate the capacity of the bulb most suitable for our intended thermometer.

[illegible] placed in [illegible]

[illegible] zero [illegible], Pierre [illegible] taken before the freezing-point, but we think that, for most purposes, the order should be reversed. It is best, however, to take the freezing- and boiling-points with as long an interval between as possible, the thermometer being left undisturbed at the ordinary temperature of the air before each determination.



As the boiling point of water depends entirely on the pressure of the air at the time, the barometer must be properly read. If it stand at 0·760 millimetre (or 30 English inches) when properly corrected (see BAROMETER, i. 512), the temperature of boiling water is exactly 100° C. (212° Fahr.). If not, the temperature must be calculated, allowing a change of ± 1° C. for every divergence of pressure equal to ± 26·7 millimetres (or 1·71° Fahr. for every inch of pressure). It is better, however, to use the following table, which gives the barometer reading (corrected) corresponding to every tenth of a degree near 100° Centigrade:—

Boiling-point °Cent.	Reading of Barometer. Millim.	Boiling-point °Cent.	Reading of Barometer. Millim.
98·8	727·96	99·5	746·50
98·9	730·58	99·6	749·18
99·0	733·21	99·7	751·87
99·1	735·85	99·8	754·57
99·2	738·50	99·9	757·28
99·3	741·16	100·0	760·00
99·4	743·83	100·1	762·73

To obtain a still nearer approximation, proportional parts of the differences may be taken. Thus, suppose a thermometer with an arbitrary scale to read 187·5 in the boiler with the barometer at 755·03; the corresponding temperature is $99{\cdot}8 + \frac{755{\cdot}03 - 754{\cdot}57}{757{\cdot}28 - 754{\cdot}57} \times {\cdot}1 = 99{\cdot}82$. Suppose the freezing-point on the arbitrary scale to be 25·4: then 187·5 − 25·4, or 162·1 arbitrary divisions, are equal to 99·82° Cent., or 162·4 divisions to 100°. Thus, 25·4 + 162·4, or 187·8, is the true degree 100, or the boiling-point for the pressure 760 millim.; and the value of any arbitrary degree n is $(n - 25{\cdot}4)\frac{100}{162{\cdot}4}$.

Examination of a Thermometer.—Any good thermometer, of which the scale extends from 32° to 212°, may be made to serve as a correct standard thermometer, by direct experiment, if it be worth while to take the necessary trouble. We will suppose the thermometer to be already graduated. By placing it in melting ice and above boiling water, with the precautions already described, we first ascertain the errors of the degree 32°, and of some point near 212°. At the intermediate points, the error is then found by the following process of Professor Forbes (Phil. Trans. cxxvi. [1836], p. 578), which is that of Bessel (Tilloch's Phil. Mag. [1824], lxiii. 307) simplified and improved:—

Detach a column of mercury from the rest, of such a length as to be nearly an aliquot part of 180°. In a tube of moderately wide bore, the length of the column may be adjusted, with great accuracy, by bringing it just into contact with the remainder of the mercury, and at the same time heating or cooling the bulb. A part of the mercury will then slowly pass over, one way or the other. This column is then caused to *step* along the tube, beginning at 32°, the one end being brought to the exact point which the other had previously occupied, this point being carefully noted in respect to the nearest graduation-mark. The capacity of the tube is thus measured out into exactly equal portions, just as a length is measured by a carpenter's rule. The column may be moved and adjusted to its position, with any degree of accuracy, by tapping one end or other of the tube or scale.

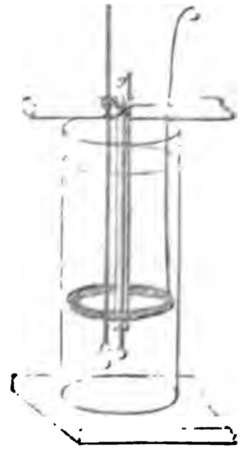
The end of the measuring column will finally fall near to 212°. Let it fall at $212 + c$, in which c is either + or −. Also let the number of intervals measured be n, and the corrections for 32° and 212°, already determined, be a and b (+ or −) Then, neglecting the very slight error which may exist in the portion of the tube by which the small quantity c was measured, the true interval corresponding to the length of the column will be $\frac{180^\circ - a + b + c}{n} = \mathrm{I}$, and the true temperatures corresponding to the divisions noted in the scale at the successive steps will be $32^\circ + a + \mathrm{I}$, $32^\circ + a + 2\mathrm{I}$, and so on up to $32^\circ + a + n\mathrm{I}$.

Several determinations may be made in this way with columns of different lengths. The results may then be projected into a curve.

This process of Professor Forbes may be performed in two or three hours, the freezing- and boiling-points having previously been determined, and the Professor considers it easier than comparison with a standard. It is scarcely applicable, however, to thermometers of very fine bore.

Comparison of Thermometers.—The mode in which thermometric accuracy will doubtless be most generally attained, is by comparing each thermometer used against a standard one, or even against a good thermometer, previously carefully compared with a standard. This comparison is very easily performed at all ordinary temperatures, as follows:—The standard thermometer and that which is to be compared, are firmly tied to a cross-piece of wood or other support, in such a manner that the bulbs shall hang in exactly the same level plane, and as near each other as is safe. They are then placed in the axis of a cylindrical glass vessel 12 or 15 inches deep, and 8 or 9 in diameter. Sufficient water is poured in to cover the whole of the mercurial columns, and it must be of the highest temperature at which it is desired to make the comparison. As water tends to arrange itself in layers of different temperature, agitation must be actively maintained, by moving up and down within the vessel, the ring-shaped agitator shown in *fig.* 809. This may be formed of stout wire, with a strip of calico roughly twisted round the ring part, which, being made nearly of the same diameter as the glass vessel, cannot touch the thermometer.

Fig. 809.



After brisk agitation, the readings of the thermometers are rapidly taken through the water, almost in the same moment, and at once recorded. In doing this, the observer should give his chief attention to the decimal parts of degrees, for the number of whole degrees can be taken afterwards at leisure, and any mistake in these will easily be apparent on taking the differences. The purpose of this haste is, of course, to avoid any error from the cooling of the water between the two readings. This error may be further eliminated by inverting the order of the readings each time. The water having been allowed to cool a few degrees, it must again be briskly agitated before the next pair of readings are taken, and so on with each successive step. Error might be still further eliminated, if necessary, by repeating the whole operation with a rising instead of a falling temperature, produced either by successive additions of hot water, or by a source of heat placed under the glass vessel.

It is, of course, possible to compare two or more thermometers with the standard at the same operation; but the chances of mistake and error from cooling increase in such a high degree with the number compared, that we strongly recommend the reader never to read more than two thermometers and the standard at the same time. In the Kew Observatory, indeed, where large numbers of thermometers are constantly compared for meteorological purposes, Mr. Welsh has devised a revolving vessel and stand, by which, with the aid of an assistant, he was able to read six thermometers at once. (Phil. Mag. [4], iv. 309.)

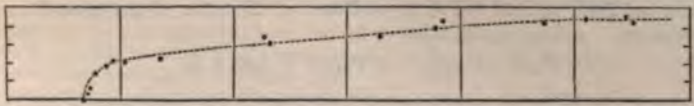
We think that the results of this process, performed rigorously as we have described it, are capable of almost any degree of accuracy, from the boiling point of water down to low temperatures, at which solutions or other liquids cooled by freezing mixtures may be used. **Professor Forbes**, however, objects to it (Brit. Assoc. Report, 1840, p. 49), and remarks that where the investigation is an important one, constant sources of heat, natural or artificial, cannot be too carefully sought. Bark-pits, natural hot springs, waste hot water of steam-engines, and the boiling-points of some liquids, such as alcohol, may be usefully employed.

When some determinations of especial importance and exactness, as of a melting- or boiling-point, have to be made at or about a particular temperature, the best mode is to compare the thermometers used with one or more standards, in media of the constant but required temperature, such as boiling alcohol diluted up to a certain point. **Herschel** (Admiralty Manual of Scientific Enquiry, p. 293) states that the best mode of ensuring perfect identity of temperature in comparisons is long rest of the thermometers in contact, in a box stuffed with cotton, the parts of the scales to be read off being occasionally uncovered for that purpose. This process would be a very slow one, but otherwise unexceptionable. It is almost needless to mention that comparisons of thermometers in the open air are useless for exact purposes.

Mr. Welsh gives a mode of examining the lower part of a thermometer *scale* without the use of freezing mixtures, but it is open to exception.

Change of the Zero-point.—A serious difficulty is thrown in the way of thermometric accuracy by the fact, that the zero of the instrument, by which may be meant any determinate point selected for verification, but generally the position of the mercury in melting ice (32° Fahr.), can seldom be considered invariable in the best instruments, and is more properly described by Despretz as in *continual oscillation*. These movements are of two kinds:—1. A gradual, continued, and permanent rise of the zero-point. This phenomenon has been studied by **Despretz** (Ann. Ch. Phys. [2], lxiv. 312), who, among other experiments, frequently determined the freezing-point of a thermometer during five years. We have shown the results graphically in *fig.* 810, and in spite of irregularities, due to the fact that the thermometer was in constant and various use during the period, the curve produced is sensibly a parabola. Professor W. H. Miller, in correcting the readings of a standard thermometer, found that the rise of the zero-point was represented with sufficient accuracy by a formula

Fig. 810.



($0{\cdot}0044 \times m^2$), which would give a hyperbolic curve. It is generally supposed that the rise of the zero-point is due to the atmospheric pressure, although Legrand (Ann. Ch. Phys., &c., [2], lxiii. 372) disputes this, and attributes it to molecular changes.

In consequence of this rise of the zero, it is usual for thermometer-makers to keep the tubes of standard thermometers for a year or more before graduating them. It is obviously necessary that all thermometers used in accurate researches should be verified and recompared at their zero-points, or at parts of their scales, from time to time.

2. The second kind of movement of the zero is a temporary fall when the thermometer has been much heated, and a temporary rise when much cooled. Legrand considers that at the temperature of boiling mercury, the zero-point remounts temporarily to its position just after the thermometer was completed, but the details of his observations are not given. Despretz makes the curious remark, that every thermometer must read rather too low in summer, and too high in winter. Different thermometers are affected in very different degrees, as shown in the following observations, the thermometer-makers' names being enclosed in brackets. The degrees are Centigrade. Legrand [Bunten], 0·3° to 0·5°; Despretz, 0·23° to 0·6°; Lamont, 9 thermometers, 0·25° to 0·45°, and one, 0·62°; Forbes [Troughton], 0·3° and 0·2°, [Adie] 0·23°, [Crichton] 0·3° [Collardeau] 0·2°; Sheepshanks, average, 0·17°; Welsh, average, 0·09° to 0·11°. In making the above observations, the thermometers were boiled, and soon afterwards placed in melting ice.

The position of a thermometer, especially a very long one, when a reading is taken, is not always a matter of indifference, for at a high temperature the column of mercury may exert such a pressure as to expand the bulb slightly, and lower the reading. As thermometers are generally compared and graduated when vertical, it is obvious that the vertical reading will generally be the correct one. Professor Forbes (Phil. Trans. [1836], p. 577) detected a difference from this cause by placing the thermometer in a cylindrical vessel filled with sand, the bulb being protected from external pressure by a small stiff paper tube, and the upper part of the scale projecting out of the vessel. The whole having been very gradually raised to as high a temperature as is thought desirable, readings may be taken many times in succession, horizontally and vertically. A standard thermometer of Troughton, thus tested, gave a difference of 0·15° Fahr. If in making a standard thermometer it be known that it will have to be used both in the vertical and horizontal positions, it will be best to take the determinations of the freezing- and boiling-points in both positions.

As the mercury in a thermometer-tube is always removed some little distance from the scale to which we refer it, an obvious error, called parallax, will arise, unless the line of sight be perpendicular to the scale. With a little care, parallax may be avoided by moving the head backwards and forwards till the eye is opposite the right point. But, in making frequent or important readings, especially comparisons, it is best to use a telescope, fixed or moving at right-angles to the plane of the scale. M. Valz, of Marseilles, ingeniously proposed to plunge two-thirds of the thickness of the tube into the substance of the scale, so that the plane on which graduation is made is advanced in front of the mercurial column to the amount of one-third of the radius of the tube, in which case the error of refraction will exactly correct the error of parallax.

A light frame may easily be contrived to slide upon the scale or tube, and prevent parallax. Thus Professor Miller (Phil. Trans. [1856], cxlvi. 779), describes thermometers with arbitrary scales divided to $\frac{1}{10}$ inch, subdivided by a sliding glass scale to $\frac{1}{100}$ inch, the division of the sliding scale which is brought into apparent coincidence with the extremity of the thread of mercury being viewed through a hole in a plate of brass attached to the very light brass frame which carries the scale, so that the line of sight may be at right-angles to the axis of the tube.

Capacity and Dilatation of the Bulb.—It is necessary in certain researches to determine the coefficient of dilatation of the glass employed. This may be found, after the method of Pierre (Ann. Ch. Phys. [3], xv. 332), by constructing a thermometer of the same kind of glass, the tube being calibrated and graduated before it is filled, and the capacity of every part being ascertained by introducing mercury several times into the tube, and comparing the weight of this mercury with the number of degrees occupied. The thermometer having been completed, we easily determine, from the known capacity of its degrees, and the coefficient of dilatation of mercury, the capacity of the bulb. Taking the expansion of mercury from 32° to 212° as $\frac{1}{55{\cdot}5}$ after Dulong and Petit, we shall find k, the coefficient of dilatation of the glass from the equation:—

$$V_{32}\left(1 + \frac{1}{55{\cdot}5}\right) = V_{212}(1 + 180 \times k)$$

in which V_{32} is the actual space occupied by mercury at the temperature of 32° Fahr., and V_{212} the *apparent* volume at the temperature of boiling water.

The coefficient, Δ, of the apparent dilatation of mercury in the glass is, then, approximately for each degree Fahr.

$$\Delta = \frac{1}{55{\cdot}5 \times 180} - k.$$

The values which will thus be generally found are, for k about ·000012 for each degree Fahr; and for Δ about ·000088.

Spirit Thermometers are required for measuring temperatures which approach or sink below the freezing-point of mercury (−39° Fahr.). In their graduation we encounter the difficulty that the increments of volume of alcohol for equal increments of temperature, cannot be assumed equal, as in the case of mercury. Welsh, however (*Op. cit.* p. 315), shows how to deduce a law of expansion, by which an approximately correct scale may be graduated.

Alcohol is also used in many register thermometers; but it is an objection to such that the spirit often distils over from the end of the column, collecting in the other parts of the tube, leading an observer who is not very vigilant into error.

Register Thermometers are mercurial or spirit instruments furnished with a small index sliding in the tube, which for this purpose must have a large bore, and therefore also a large bulb. The figures (811 to 816) will sufficiently exhibit the various registering contrivances. In *fig.* 811, *a* is a small piece of steel wire, and *b* the end of the mercurial column, which forces it forward, and then leaves it at the maximum point. The tube must remain nearly horizontal, and the steel index is moved back by means of a small magnet. The chief defect of this maximum thermometer is, that a quantity of air must be left in the tube, to prevent the mercury flowing about; and the mercury in time becoming foul, the whole is thrown out of order. In *fig.* 812 the index is of wire, covered with enamel, and is *within* the column of a spirit thermometer, the end of which column carries it back by force of adhesion, but does not carry it forward. It thus gives a minimum temperature. This thermometer works very well, but is open to all the objections against a spirit thermometer. The above two instruments are known as Rutherford's, and have till lately been generally used.

Fig. 811.

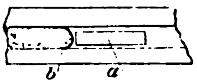


Fig. 812.

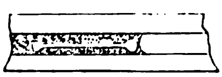
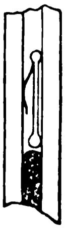


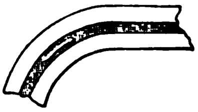
Six's Maximum and Minimum Thermometer consists of a large bulb full of alcohol joined to a tube in the form of an inverted syphon, in the lower part of which lies a short column of mercury. The extreme point reached either way by the mercury, as it is moved by the expansions and contractions of the alcohol, is marked by a small enamelled wire index sliding in the leg of the bent tube (*fig.* 813), but secured against falling from its own weight by a small spring. This instrument is very convenient for many purposes, but cannot be rendered very accurate or sure.

Fig. 813.



The Mercurial Maximum Thermometer of Negretti and Zambra seems to be the best yet invented. In this the tube is horizontal, and but little wide in bore than that of an ordinary thermometer. The bulb is bent downwards, and at the bend, the bore of the tube is nearly stopped up with an enamelled plug (*fig.* 814), which prevents the mercury from running back, as the temperature falls, provided the tube remains nearly level. The maximum reading is thus given by the end of the mercurial column remaining in the tube, and the instrument is reset, simply by inclining it until the mercury runs back and fills the bulb.

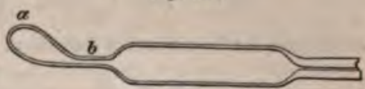
Fig. 814.



The Mercurial Minimum Thermometer, invented by Casella, is a highly ingenious instrument. The bulb is provided with a small overflow-chamber, into which the mercury freely expands during a rise of temperature. When the temperature falls again, the mercury is still retained in the chamber by adhesion to a flat surface of glass provided for the purpose. The minimum reading at the end of any period is given by the extremity of the mercurial column in the stem of the instrument. To reset the thermometer, it is inclined until all the mercury runs out of the overflow-chamber.

A very similar instrument has been devised by Negretti and Zambra. The bulb is shown in *fig.* 815, in which *a* is the overflow-chamber, and the mercury is retained in it, after once entering, by adhesion to a platinum-plug, which nearly stops up the narrow communication at *b*. These instruments are so recently invented that their relative excellence is yet unknown, but they are far superior to any of the old spirit thermometers. It is not necessary here to describe a form of mercurial minimum thermometer patented by Negretti and Zambra several years since. Although ingenious, it is a large costly instrument, open to several important objections.

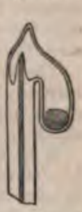
Fig. 815.



The indications of a registering thermometer can never be quite so accurate as those of an ordinary instrument. The usual process of comparison is scarcely applicable to many such thermometers, and Sir J. Herschel directs us to record the errors thus determined, but not to apply them.

The maximum thermometer of Walferdin is well adapted for taking the temperature of the sea, or of hot springs. It consists of an ordinary tube-thermometer, the upper end of which is furnished with an overflow-bulb (*fig.* 816). A corresponding but less satisfactory minimum thermometer, containing alcohol instead of mercury, is also described. (Pouillet, *Élémens de Physique*, 7me ed. tome ii. p. 689; Compt. rend. xxxviii. 770.)

Fig. 816.



A number of maximum and minimum thermometers, suited for taking the temperature of the sea, are described by Aimé. (Ann. Ch. Phys. [3], xv. 1.)

Temperature of the Air.—To place a thermometer, so that it shall accurately show the temperature of the atmosphere, is an exceedingly difficult problem. It must be shielded from radiant heat of the sun, sky, and earth's surface; also from nocturnal radiation, from rain, and the influence of any large neighbouring masses of matter, and yet must be freely exposed to the air. Meteorologists have devised various kinds of screens (Drew, *Practical Meteorology*, pp. 79—81). The difficulty might always be quite overcome, however, by placing the thermometers (*Dry and Wet Bulb*, see HYGROMETER, iii. 227), in a bright metal tube or case, and drawing a constant stream of air through it mechanically, a method tried by Welsh. (Phil. Trans. [1853], cxliii. 313.) W. S. J.

THERMOMETRIC ANALYSIS. This term is applied to certain approximative methods of quantitative analysis, depending on the observation of the temperature at which a phenomenon takes place, or of the changes of temperature accompanying chemical reactions. The following examples will be sufficient to illustrate the nature of these methods:—

1. The temperature at which a salt begins to crystallise from solution varies with the quantity of salt dissolved: hence, by observing the temperature at which crystallisation begins, the quantity of salt present in a given quantity of the solution may be inferred. This method is applied in Austria for the purpose of testing the purity of saltpetre. A known weight of the ammoniacal salt is dissolved in a certain quantity of water, and the temperature at which it begins to crystallise from the solution is compared with a table containing the crystallising temperatures of solutions of pure nitrate of potassium of various strengths. (See NITRATES, iv. 102.)

2. Many salts, in dissolving in water, produce a depression of temperature, the amount of refrigeration being different for each salt. Hence, when this amount is known for two pure salts, the proportions of them present in a mixture may be found from the fall of temperature which takes place in the solution of that mixture. This method has been applied by Gay-Lussac (Ann. Ch. Phys. [2], xii. 14; xxxix. 356) to mixtures of the chlorides of potassium and sodium.

This particular application is based upon the observation that 50 grms. of chloride of potassium, on being dissolved in 200 grms. of water, contained in a glass vessel whose weight is 185 grms. and capacity 300 cubic centimetres, produce a fall of temperature amounting to 11·4° C., while the same quantity of chloride of sodium, dissolved under exactly similar circumstances, lowers the temperature only 1·9° C.

Now let a mixture of the two salts, weighing 50 grms., be dissolved in water under exactly the same conditions; and let x be the quantity of chloride of potassium therein contained, and consequently $50-x$ the quantity of chloride of sodium. Then the fall of temperature produced by the x parts of chloride of potassium is $\frac{11·4}{50}x$, and that produced by the $50-x$ grms. of chloride of sodium is $\frac{1·9}{50}(50-x)$. The observed depression of temperature (t) is the sum of these quantities; hence the equation:

$$\frac{11·4}{50}x + \frac{1·9}{50}(50-x) = t,$$

which gives, for the amount of chloride of potassium in the mixture:

$$x = 50 \cdot \frac{t - 1·9}{11·4 - 1·9} = \frac{50\,t - 95°.}{9·5}$$

To obtain good results, it is necessary to use a delicate thermometer, capable of indicating tenths of a degree; to pulverise the mixture very finely, and accelerate the solution by shaking the flask, holding it only by the neck in so doing, in order that as little extraneous heat as possible may be communicated by the hand; and, lastly, to observe exactly the preceding stipulations as to the weights of the salt and the water, and the weight and size of the vessel. The original temperature of the water has likewise some influence on the result. Gay-Lussac used water of 20·4° C. With these precautions, the method may be depended upon for giving results of sufficient accuracy for manufacturing purposes—as, for example, in testing samples of commercial chloride of potassium used for the preparation of alum or of saltpetre. To minute scientific accuracy it has of course no pretensions.

The same method may be applied to other mixtures of salts which depress the temperature in dissolving, and likewise to such as raise it. It is more exact in proportion as the amounts of depression produced by the two salts differ more widely from one another.

3. Fixed oils (*e.g.*, olive-, poppy-, and rape-oil) evolve different degrees of heat when treated with strong sulphuric acid, and the temperatures thus produced may be applied, in like manner, to determine the proportions of two of them existing in a mixture, especially when one is a drying and the other a non-drying oil. According to Maumené (Compt. rend. xxxv. 572), 50 grms. olive-oil mixed with 10 cub. cent. sulphuric acid of 60° Baumé, become heated from 25° to 67°, that is 42°; and 50 grms. poppy-oil similarly treated are heated from 26° to 100°, or 74°.

According to Faisst and Knauss (Dingl. polyt. J. cxxxix. 53), 15 grms. of different fixed oils mixed with 5 grms. strong sulphuric acid (freed from excess of water by boiling) exhibited the following degrees of heating:

Olive-oil	from 16°—54°,	therefore	38°.
Almond-oil	„ 12°—52°	„	40°.
Rape-oil	„ 14°—69°	„	55°.
Poppy-oil	„ 17°—87°	„	70°.

With linseed-oil the rise of temperature was more than 100°, but not constant, because decomposition took place at the same time. When 15 grms. of oil were treated with 7·5 grms. of sulphuric acid containing 90 per cent. H^2SO^4, the following rises of temperature were observed:

Olive-oil	from 12°—40°,	therefore	28°
Rape-oil	„ 17°—54°	„	37°
Linseed-oil	„ 16°—91°	„	75°;

mixtures of olive-oil and poppy-oil, and of linseed-oil and rape-oil or palm-oil, exhibiting a rise of temperature nearly equal to the means of the numbers given by the individual oils. This method might therefore be applied, in default of a better, for examining mixtures of fixed oils; it requires, however, that the process be always conducted in the same way, and especially that the glasses used shall be of the same size and thickness. It would be necessary also to ascertain whether the same oil, linseed-oil for example, exhibits the same rise of temperature, when recently expressed, as when old, and under other conditions.

THERMO-MULTIPLIER. A thermo-electric pile connected with a delicate galvanometer for indicating slight changes of temperature by the thermo-electric currents produced on exposing one end of the pile to a source of heat or cold. (ELECTRICITY, ii. 413.)

THERMONATRITE. Monohydrated carbonate of sodium, $Na^2CO^3.H^2O$. (See CARBONATES, i. 795.)

THERMOPHYLLITE. A mineral occurring at Hopoovaara, in Finland, in grains or rounded indistinct crystals, cleaving easily in one direction, white to yellowish-brown, soft, of specific gravity 2·56 (Hermann). When heated, it exfoliates, and swells up to a greater bulk, but melts only on the thin edges. It is decomposed, but with difficulty, by sulphuric acid.

Analyses: *a*. By Arppe (Analyser af. finska min. p. 27).—*b*. By Hermann (J. pr. Chim. lxxiii. 213).—*c*. By Northcote (*ibid.* lxxvi. 253):

	SiO^2.	Al^2O^3.	FeO.	MgO.	K^2O.	Na^2O.	H^2O.	SnO^2. *a*.CuO.		
a.	41·20	1·71	1·20	39·58	3·19	0·46	10·84	1·00	=	99·18
b.	43·12	4·91	1·79	34·87	. .	1·33	13·14	. .	=	99·16
c.	41·48	5·49	1·59	37·42	. .	2·84	10·88	. .	=	99·70

According to the first analysis, the mineral consists essentially of $2(3MgO.2SiO^2).3H^2O$; that is to say, it differs from serpentine only in its amount of water. The second analysis leads nearly to the formula $6MgO.5SiO^2.5H^2O$, and the third to $4MgO.3SiO^2.2H^2O$. According to this last formula, the mineral is related to hydrophite and gymnite.

THERMOSTAT. An apparatus serving to maintain a body at a constant temperature. Contrivances of this sort were invented by Ure, in which two rods of different metals soldered together, being bent by change of temperature, were made to act upon a valve or stopcock, so as to regulate the draught of a furnace, the rate of escape of steam, or the influx of cold water into a boiler. (See *Ure's Dictionary of Arts*, &c., iii. 880; also Handw. d. Chem. viii. 129.)

THERYTHRIN. One of the products obtained, according to Zeise, by the simultaneous action of ammonia and sulphur upon acetone.

THIACETIC ACID. $C^2H^4OS = \left.\begin{matrix}C^2H^3O\\H\end{matrix}\right\}S.$ *Sulphydrate of Acetyl.* (Kekulé, Ann. Ch. Pharm. xc. 311.—Ulrich, *ibid.* cix. 272.—Kekulé and Linnemann, ibid. cxxiii. 273.)—This acid, discovered by Kekulé in 1854, is related to acetic acid in the same manner as mercaptan to alcohol, or sulphydric acid to water. It is produced: 1. By the action of trisulphide or pentasulphide of phosphorus on glacial acetic acid, in which case the typical oxygen of the acetic acid is replaced by sulphur:

$$3\left.\begin{matrix}C^2H^3O\\H\end{matrix}\right\}O + P^2S^3 = P^2O^3 + 3\left.\begin{matrix}C^2H^3O\\H\end{matrix}\right\}S.$$

2. By the action of acetic chloride on sulphydrate of potassium, in which case the acetyl takes the place of the potassium:

$$C^2H^3OCl + KHS = KCl + C^2H^3O.H.S.$$

3. By the action of water or alkalis on disulphide of acetyl (Kekulé and Linnemann).—4. By the action of nascent hydrogen on sulphacetylic chloride (Vizet, Ann. Ch. Pharm. cxix. 142):

$$C^2H^3ClSO^4 + 4H^2 = C^2H^4OS + HCl + 3H^2O.$$

Preparation.—300 grms. pentasulphide of phosphorus and 108 grms. glacial acetic acid are heated in a retort as nearly as possible half-filled with the mixture, till reaction commences; and the portion of the product driven over by the heat resulting from the action is collected apart. 650 grms. acetic acid and 1,800 grms. pentasulphide of phosphorus, thus treated, yield, after one rectification of the product, 250 grms. of pure thiacetic acid. (Kekulé and Linnemann.)

Properties.—Thiacetic acid is a colourless liquid, which becomes yellow by keeping, has an unpleasant odour like that of acetic and sulphydric acids together, boils at 95°, and dissolves in *alcohol* and *ether*. It is decomposed by strong *nitric acid* at a gentle heat and by the fuming acid, even in the cold, with explosion.—With *pentachloride of phosphorus* it yields chloride of acetyl and sulphochloride of phosphorus:

$$C^2H^3O.H.S + PCl^5 = C^2H^3OCl + HCl + PSCl^3.$$

Thiacetates.—Thiacetic acid is monobasic, the general formula of its salts being C^2H^3MOS for monatomic, and $C^4H^6M''O^2S^2$ for diatomic metals. Most of the thiacetates dissolve easily in water and in alcohol, and may be obtained by dissolving an oxide or carbonate in thiacetic acid, or by decomposing the barium-salt with soluble sulphates. The lead-salt, which is but slightly soluble in water, is obtained by precipitation. Thiacetic acid dissolves potassium, with evolution of hydrogen;

also zinc when heated therewith. Thiacetates are decomposed by iodine, with formation of metallic iodide and acetic disulphide (Kekulé and Linnemann):

$$2C^2H^3MOS + I^2 = 2MI + (C^2H^3O)^2S^2.$$

The *potassium-salt*, C^2H^3NaOS, the *sodium-salt*, $C^2H^3NaOS.\frac{1}{2}H^2O$, the *barium-salt*, $C^4H^6Ba''S^2O^2.3H^2O$, the *strontium-salt*, $C^4H^6Sr''S^2O^2.2H^2O$, and the *calcium-salt*, $C^4H^6Ca''S^2O^2.2H^2O$, are crystallisable (Ulrich).—The *lead-salt*, $C^4H^6Pb''O^2S^2$, obtained by precipitating acetate of lead with thiacetic acid, crystallises from hot water or alcohol, in colourless silky needles. It is very unstable, decomposing quickly, both in the dry state and in solution, with separation of lead-sulphide (Kekulé). The *mercuric salt* is obtained, by double decomposition with mercuric chloride and potassic thiacetate, as a white precipitate which soon turns black.—The *silver-* and *copper-salts* are still more unstable.—Recently precipitated *ferric hydrate* dissolves in thiacetic acid, forming a greenish solution, which deposits sulphide of iron when warmed.

Ethylic thiacetate, $C^4H^8OS = \left.\begin{matrix} C^2H^3O \\ C^2H^5 \end{matrix}\right\} S$. Obtained by the action of phosphoric pentachloride on ethylic acetate. It is a liquid lighter than water, and insoluble therein; smells like ethylic acetate and sulphydric acid. Boils at about 80°. (Kekulé.)

THIACETIC ANHYDRIDE. $(C^2H^3O)^2S$. *Acetic Monosulphide* or *Protosulphide*. (Kekulé, *loc. cit.*)—Produced by the action of phosphoric pentasulphide on acetic anhydride. On gently heating the mixture, a violent reaction takes place, and thiacetic anhydride distils over. When purified by redistillation, it forms a colourless liquid, having a peculiar odour, and boiling at 121°. It sinks in water at first, without decomposition, but afterwards decomposes, yielding acetic and sulphydric acids.

Acetic Disulphide, $(C^2H^3O)^2S^2$. (Kekulé and Linnemann, *loc. cit.*)—Produced by the action of iodine on metallic thiacetates (p. 771). Iodine is gradually added to the slightly acidulated solution of a thiacetate, till the liquid becomes brown, and the excess of iodine is removed by adding a little more of the thiacetate. Acetic disulphide then separates as a yellow liquid, which may be purified by washing with cold water, drying over chloride of calcium, filtering, and leaving it in a cold place, whereupon it solidifies in the crystalline state. The last trace of admixed sulphur may be removed by dissolving the crystals in the smallest possible quantity of carbonic disulphide, and mixing the well-cooled solution with a small additional quantity of solid acetic disulphide; the liquid then gradually deposits the pure compound in large, colourless, well-defined crystals.

Pure acetic disulphide melts at 20°; it has a peculiar, slightly hepatic odour, is insoluble in *water*, but dissolves readily in *alcohol*, *ether*, and *carbonic disulphide*. By *water* it is decomposed, gradually in the cold, quickly at the boiling heat, into sulphur and thiacetic acid; with *alkalis* the same decomposition takes place immediately. It is violently attacked by strong *nitric acid*; with more dilute nitric acid, it yields sulphuric and acetic acids. When distilled, it gives off thiacetic acid at 93°; afterwards, at 160°, a dark-coloured distillate resembling the last portion of liquid obtained in the rectification of thiacetic acid. Acetic disulphide is decomposed by mercury, even at temperatures below 100°, but the removal of the sulphur is not complete.

THIALDINE. $C^6H^{13}NS^2 = N\left\{\begin{matrix} C^2H^4.SH \\ C^2H^4.SH. \\ C^2H^3 \end{matrix}\right.$ (Wöhler and Liebig [1847], Ann. Ch. Pharm. lxi. 1.—Hofmann, *ibid.* ciii. 93.—Brusewitz and Cathander, Bull. Soc. Chim. [1867], i. 450.—Schiff, Laboratory, i. 404.)—An organic base obtained by the action of sulphydric acid on an aqueous solution of aldehydate of ammonium:

$$3C^2H^3(NH^4)O + 3H^2S = C^6H^{13}NS^2 + (NH^4)^2S + 3H^2O.$$

To prepare it, aldehydate of ammonium, free from ether and alcohol, is dissolved in 12 to 16 pts. of water; 10 or 15 drops of ammonia are added to every 30 grms. of the solution; and a gentle current of sulphydric acid gas is passed through the mixture, which then becomes milky in about half an hour, and deposits thialdine in large crystals, having the appearance of camphor; in four or five hours, it the liquid becomes clear again, and the operation is finished. The crystals are collected on a filter, washed with cold water, dried, and dissolved in ether mixed with a third of its volume of alcohol, which, when left to evaporate, deposits thialdine in rhombic tables often half an inch in diameter.—Sometimes this process yields no crystals, but a colourless fetid oil, consisting for the most part of thialdine kept in the liquid state by an oily body. To obtain the thialdine from this liquid, it is shaken up with half its volume of ether in a stoppered bottle, and then mixed with hydrochloric acid, whereupon the mixture solidifies to a crystalline mass of hydrochlorate of thialdine, which is to be washed with ether, to remove the last portions of oil, then dried, moistened with a little ammonia, and redissolved in ether.

Thialdine is likewise obtained by passing ammonia-gas into the compound of acetyl-mercaptan with sulphydric acid (i. 107):

$$C^{12}H^{26}S^7 + 8NH^3 = 2C^6H^{13}NS^2 + 3(NH^4)^2S.$$

Thialdine forms large, strongly refracting crystals, having the form of gypsum, and a density of 1·191 at 18°. It has an aromatic odour, becoming disagreeable after a while; melts at 43°, and volatilises without residue at ordinary temperatures. When distilled with water, it passes over without alteration; but when distilled alone, it decomposes, giving off a fetid oil, which partly concretes, after a while, into a brown syrupy residue containing sulphur.

Thialdine is very slightly soluble in *water*, but dissolves very easily in *alcohol* and *ether*. It does not act on vegetable colours, but dissolves easily in *acids*.

An alcoholic solution of thialdine is not immediately precipitated by *acetate of lead*, but, after some time, a yellow precipitate is formed, which changes to red, and ultimately to black.—*Nitrate of silver* forms a white precipitate, changing to yellow and black; *mercuric chloride* a white precipitate, changing to yellow; *platinic chloride* gradually forms a dingy yellow precipitate.

Thialdine and its salts, heated with a solution of *silver-nitrate*, are decomposed, with formation of silver-sulphide. Thialdine calcined with *calcic hydrate*, yields an oily alkali having the characters of chinoline. It is quickly decomposed by chloric acid. According to Gössmann, thialdine treated with *silver-oxide* and *water*, is converted into the analogous compound, leucine, $C^{12}H^{13}NO^2$; but Hofmann has shown that in this reaction, the whole of the nitrogen in the thialdine is converted into ammonia, acetic acid being formed at the same time.

Salts of Thialdine.—Thialdine unites with acids, forming soluble and crystallisable salts. The acid salts decompose when dried in a vacuum over oil of vitriol, the sides of the vessel becoming covered with slender needles, perhaps consisting of allylic sulphide, formed according to the equation, $C^6H^{13}NS^2 - NH^3 = 2C^3H^5S$. (Brusewitz and Cathander.)

Hydriodate of Thialdine, $C^6H^{13}NS^2.HI$, separates in small prisms or laminæ, on mixing the solutions of potassium-iodide and thialdine-sulphate. It is slightly soluble in cold water, but dissolves easily in boiling water, alcohol, and ether.—The *hydrobromate*, $C^6H^{13}NS^2.HBr$, crystallises in rhomboïdal prisms, resembling the hydriodate (Brusewitz and Cathander).—The *hydrochlorate*, $C^6H^{13}NS^2.HCl$, obtained by dissolving thialdine in hydrochloric acid, crystallises in fine, colourless, highly lustrous prisms, moderately soluble in cold water, less soluble in alcohol, insoluble in ether, decomposed by heat (Wöhler and Liebig).—The *hydrocyanate* is formed on adding cyanide of potassium in sufficient quantity to sulphate of thialdine, partly as a white precipitate, partly as an oil which floats on the surface of the liquid; the precipitate and the oil gradually form into crystals, which may be purified by recrystallisation from ether. (Brusewitz and Cathander.)

The *nitrate*, $C^6H^{13}NS^2.HNO^3$, is easily obtained by agitating the ethereal solution of crude thialdine with moderately strong nitric acid, the mixture solidifying to a crystalline pulp, which may be purified by recrystallisation. It forms colourless needles, more soluble in water than the hydrochlorate, soluble in alcohol, insoluble in ether. (Wöhler and Liebig.)

The *oxalate*, probably an acid salt, separates from a solution of thialdine in oxalic acid, in large quadrangular prisms, which are easily decomposed by evaporation. (Brusewitz and Cathander.)

The *acid phosphate*, $C^6H^{13}NS^2.H^3PO^4$, is obtained like the sulphate, and its solution is decomposed by heat nearly in the same manner. It crystallises in slender needles, very soluble in water, alcohol, and ether, and melting at a high temperature. Phosphate of sodium, added to a solution of sulphate of thialdine, throws down a white precipitate, consisting of free thialdine. (Brusewitz and Cathander.)

Acid sulphate, $C^6H^{13}NS^2.H^2SO^4$.—A solution of thialdine in excess of sulphuric acid, is decomposed by heat, yielding a number of products, among which are sulphate of thialdine and needle-shaped crystals, probably consisting of sulphide of allyl (*supra*). The solution, evaporated in a dry vacuum, yields the acid sulphate in large prisms, soluble in water, alcohol, and ether. When sulphocyanate of potassium is added to the solution of this salt, a precipitate is formed, and a gas is given off, not consisting either of carbonic anhydride or of sulphydric acid. (Brusewitz and Cathander.)

Tartrate of thialdine crystallises in large prisms.

Derivatives and Analogues of Thialdine.

Ethyl-thialdine, $C^8H^{17}NS^2 = C^6H^{12}(C^2H^5)NS^2$.—Obtained, though not in the pure state, by saturating aldehyde with ethylamine, and treating the syrupy liquid with sulphydric acid; it then separates as a neutral, easily decomposible oil. (Flückiger, Jahresb. 1856, p. 519.)

Methyl-thialdine, $C^6H^{12}(CH^3)NS^2$, is obtained in a similar manner, by the action of sulphydric acid on aldehydate of methylamine. (Flückiger.)

Methyl-thialdammonium, $C^7H^{16}NS^2$.—Thialdine unites directly with iodide of methyl (mixed with an equal volume of ether), forming the compound $C^6H^{13}NS^2.CH^3I = C^7H^{16}NS^2.I$, which solidifies in a crystalline mass. This compound, when purified by washing with ether, and recrystallisation (avoiding a boiling heat), behaves like iodide of tetramethylammonium. It is insoluble in ether, soluble in alcohol, somewhat soluble in water, and is precipitated therefrom, without decomposition, by cold caustic potash; by boiling potash, however, it is completely decomposed, forming a brown resinous substance, smelling of aldehyde, which is likewise produced when thialdine is strongly heated with iodide of methyl. The acid-reacting aqueous solution of the iodide, treated with recently precipitated silver-oxide, becomes alkaline, and gives a precipitate of silver-iodide; but quickly undergoes complete decomposition, yielding silver-sulphide, aldehyde, ammonia, and hydrate of tetramethylammonium:

$$4C^7H^{16}NS^2I + 10Ag^2O + 3H^2O = 4AgI + 8Ag^2S + 12C^2H^4O + 3NH^3 + \left.\begin{matrix}N(CH^3)^4\\H\end{matrix}\right\}O$$

From its behaviour with iodide of methyl, Hofmann infers that thialdine is a nitrile base, $N(C^6H^{12}S^2)'''$. But, from recent experiments by Schiff (the details of which are not yet published), it appears most probable that thialdine, and its homologues and analogues, may be represented by the general formula $N\left\{\begin{matrix}C^nH^{2n}.SH\\C^nH^{2n}.SH.\\C^nH^{2n-1}\end{matrix}\right.$ By the action of ammonium-sulphide on acrylic and œnanthic aldehydes, Schiff has obtained acrothialdine, $C^9H^{13}NS^2 = N\left\{\begin{matrix}C^3H^4.SH\\C^3H^4.SH,\\C^3H^3\end{matrix}\right.$ and œnanthothialdine, $C^{21}H^{43}NS^2 = \left\{\begin{matrix}C^7H^{14}.SH\\C^7H^{14}.SH.\\C^7H^{13}\end{matrix}\right.$

THIAMETHALDINE. Syn. with METHYL-THIALDINE.

THIANISOIC ACID. $C^{10}H^{14}SO^4 = C^{10}H^{12}O.H^2SO^3$. (Städeler and Wächter, Ann. Ch. Pharm. cxvi. 163.)—An acid containing the elements of anethol or anise-camphor (i. 297) and sulphurous acid, and (according to Städeler and Wächter) identical with Limpricht and Ritter's anisoic acid (i. 305). To prepare it, anethol is boiled with nitric acid of specific gravity 1·1; the oil thereby produced (together with oxalic and a small quantity of anisic acid) is rectified; and the distillate, which passes over between 215° and 245°, is left for some time in contact with a concentrated solution of acid sodium-sulphite and a small quantity of alcohol; the sodium-salt of thianisoic acid then crystallises out.

The pure acid is separated from the barium-salt by addition of sulphuric acid, and remains in the crystalline form, when the filtered solution is left to evaporate. It has a strongly acid and astringent taste, with sweet aftertaste, dissolves easily in water, alcohol, and ether; its dilute solution may be boiled without decomposition.

The crystals, which contain $C^{10}H^{14}SO^4.2H^2O$, melt below 200°, and the acid, if not more strongly heated, solidifies again in the crystalline form on cooling; but on raising the temperature to 100°, the water of crystallisation is given off, and the acid then solidifies in the amorphous state on cooling. At a stronger heat, it blackens and decomposes, giving off sulphurous anhydride, with an odour somewhat like that of anise, but of a fetid character.

Thianisoates.—Thianisoic acid is monobasic, and mostly forms crystallisable salts, easily soluble in water, sparingly soluble in alcohol, insoluble in ether.

The *ammonium-salt* forms crystals resembling those of the sodium-salt, and containing 1 at. water.

The *barium-salt*, $C^{20}H^{26}Ba''S^2O^8.3H^2O$, separates on mixing the concentrated solution of the sodium-salt with barium-chloride, in delicate laminæ, and crystallises from a hot aqueous solution in beautiful stellate groups; it may be recrystallised, without alteration, from hot hydrochloric acid. It dissolves in 12 pts. of cold water. The crystals give off 2 at. water at 103°, and the remainder at 130°.—The *calcium-salt*, $C^{20}H^{26}Ca''S^2O^8.2H^2O$, separates from a mixture of the concentrated solution of the sodium-salt with chloride of calcium, in shining needles, which dissolve in water more readily than the barium-salt, and are moderately soluble in warm alcohol.

The *cupric salt* crystallises from a mixture of the sodium-salt with cupric sulphate, in black shining laminæ.

The *lead-salt* crystallises from a solution of the sodium-salt, mixed with neutral acetate of lead, in thick well-defined tables and prisms.—A *basic lead-salt* separates, as a white amorphous precipitate, on mixing the sodium-salt with basic acetate of lead.

The *magnesium-salt*, $C^{20}H^{26}Mg''S^2O^8.5H^2O$, is likewise obtained by double decomposition, and crystallises in rectangular tables, moderately soluble in water and in alcohol. They give off 3 at. water at 100°, and the remaining 2 at. at 130°.

The *silver-salt* forms delicate prismatic laminæ, moderately soluble in water, and not decomposed by boiling water.

The *sodium-salt*, $C^{10}H^{13}SO^4.H^2O$, prepared as above described, crystallises in warty groups of shining laminæ, or in thin rhombic tables. It dissolves in 6·5 pts. water at mean temperature, sparingly in cold, easily in boiling alcohol. The crystals are slightly efflorescent, and give off their water at 100°.

THIANISOL. C^8H^8SO. *Hydride of Sulphanisyl.*—A white pulverulent substance, formed by the action of ammonium-sulphide on anishydramide (i. 299).

THIERSCHITE. The name applied by Liebig to a deposit of calcic oxalate found on some parts of the Parthenon at Athens. (See OXALATES, iv. 254.)

THIETHALDINE. Syn. with ETHYL-THIALDINE (p. 773).

THIET-SIE. A resinous substance used as a varnish by the Burmese. It exudes from a tree in the form of a light-brown, very viscid liquid, of the consistence of treacle, but on exposure to the air for a few minutes, becomes quite black, and hard on the surface. The same change takes place instantly in contact with caustic potash. The resin spread in a thin layer, on wood or other solid bodies, quickly forms a hard deep-black coating of great brilliancy.

On digesting the unaltered substance with alcohol of 80 per cent. at a gentle heat, the greater part gradually dissolves; and on decanting the clear liquid from the insoluble residue, and distilling off the alcohol, there remains a very tenacious gummy residue of a rich brown colour, which undergoes no change of colour on exposure to the air, but very slowly hardens. In contact with caustic potash, however, it blackens like the original substance.

The residue, insoluble in alcohol, dissolves for the most part in ordinary ether, forming a dark-brown solution, and leaving a light-brown solid resin. The ethereal solution, when evaporated, leaves a residue which, on exposure to the air, instantly becomes quite black, and after a short time nearly solid. This then is the portion of the original substance to which the property of blackening on exposure to the air is due.

The solid resin, insoluble in alcohol and ether, which forms but a small part of the original substance, is quite unalterable in the air. When heated with nitric acid, it yields a crystalline sublimable acid, exhibiting the characters of succinic acid. (H. Watts, *Unpublished Experiments.*)

THIOBENZALDINE. Syn. with HYDRIDE OF SULPHAZOBENZOYL (p. 481).

THIOBENZOIC ACID. C^7H^6OS = $\left.\begin{matrix}C^7H^5O\\H\end{matrix}\right\}S$. (Cloez, Ann. Ch. Pharm. cxv. 27.)—This acid, analogous to thiacetic acid, is produced by mixing an alcoholic solution of potassium-monosulphide with chloride of benzoyl till the liquid no longer blackens lead-paper. A brisk action then takes place, chloride of potassium is deposited, and thiobenzoate of potassium remains in solution, together with ethylic sulphide, ethylic benzoate, and other products. On distilling off the alcohol over the water-bath, and mixing the aqueous solution of the residue with dilute hydrochloric acid, an oily liquid separates, which smells of mercaptan, and, when left to stand in a cool place, deposits thiobenzoic acid in colourless crystals.

Thiobenzoic acid, when purified by recrystallisation from carbonic disulphide, forms small rhombic tables, inodorous and tasteless. It melts at 120°, becomes rose-coloured and gives off sulphydric acid between 160° and 180°, and decomposes further at 300°, yielding an oily distillate which solidifies on cooling. The acid is quite insoluble in water, slightly soluble in alcohol and ether, easily soluble in mercaptan, ethylic sulphide, and carbonic disulphide. It dissolves without decomposition in alcoholic potash, soda, or ammonia, and forms definite salts with bases. The alkaline thiobenzoates precipitate *ferric salts.* —The *lead-salt* is a white precipitate.—*Ethylic thiobenzoate* appears to be contained in the oily liquid from which the acid is deposited in the course of preparation above described.

THIOBENZOL, or **THIOBENZOYL-HYDRIDE.** See DERIVATIVES OF BENZOYL-HYDRIDE (i. 571).

with sulphydric acid; it then separates as a neutral, easily decomposible oil. (**Flückiger**, Jahresb. 1856, p. 519.)

Methyl-thialdine, $C^6H^{12}(CH^3)NS^2$, is obtained in a similar manner, by the action of sulphydric acid on aldehydate of methylamine. (**Flückiger.**)

Methyl-thialdammonium, $C^7H^{16}NS^2$.—Thialdine unites directly with iodide of methyl (mixed with an equal volume of ether), forming the compound $C^6H^{13}NS^2.CH^3I = C^7H^{16}NS^2.I$, which solidifies in a crystalline mass. This compound, when purified by washing with ether, and recrystallisation (avoiding a boiling heat), behaves like iodide of tetramethylammonium. It is insoluble in ether, soluble in alcohol, somewhat soluble in water, and is precipitated therefrom, without decomposition, by cold caustic potash; by boiling potash, however, it is completely decomposed, forming a brown resinous substance, smelling of aldehyde, which is likewise produced when thialdine is strongly heated with iodide of methyl. The acid-reacting aqueous solution of the iodide, treated with recently precipitated silver-oxide, becomes alkaline, and gives a precipitate of silver-iodide; but quickly undergoes complete decomposition, yielding silver-sulphide, aldehyde, ammonia, and hydrate of tetramethylammonium:

$$4C^7H^{16}NS^2I + 10Ag^2O + 3H^2O = 4AgI + 8Ag^2S + 12C^2H^4O + 3NH^3 + \left.\begin{array}{r}N(CH^3)^4\\ H\end{array}\right\}O$$

From its behaviour with iodide of methyl, Hofmann infers that thialdine is a nitrile base, $N(C^6H^{13}S^2)'''$. But, from recent experiments by Schiff (the details of which are not yet published), it appears most probable that thialdine, and its homologues and analogues, may be represented by the general formula $N\left\{\begin{array}{l}C^nH^{2n}.SH\\ C^nH^{2n}.SH.\\ C^nH^{2n-1}\end{array}\right.$ By the action of ammonium-sulphide on acrylic and œnanthic aldehydes, Schiff has obtained **acrothialdine**, $C^9H^{15}NS^2 = N\left\{\begin{array}{l}C^3H^4.SH\\ C^3H^4.SH,\\ C^3H^5\end{array}\right.$ and **œnanthothialdine**, $C^{21}H^{43}NS^2 = \left\{\begin{array}{l}C^7H^{14}.SH\\ C^7H^{14}.SH.\\ C^7H^{13}\end{array}\right.$

THIAMETHALDINE. Syn. with METHYL-THIALDINE.

THIANISOIC ACID. $C^{10}H^{14}SO^4 = C^{10}H^{12}O.H^2SO^3$. (**Städeler** and **Wächter**, Ann. Ch. Pharm. cxvi. 163.)—An acid containing the elements of anethol or anise-camphor (i. 297) and sulphurous acid, and (according to **Städeler** and **Wächter**) identical with Limpricht and Ritter's anisoic acid (i. 305). To prepare it, anethol is boiled with nitric acid of specific gravity 1·1; the oil thereby produced (together with oxalic and a small quantity of anisic acid) is rectified; and the distillate, which passes over between 215° and 245°, is left for some time in contact with a concentrated solution of acid sodium-sulphite and a small quantity of alcohol; the sodium-salt of thianisoic acid then crystallises out.

The pure acid is separated from the barium-salt by addition of sulphuric acid, and remains in the crystalline form, when the filtered solution is left to evaporate. It has a strongly acid and astringent taste, with sweet aftertaste, dissolves easily in water, alcohol, and ether; its dilute solution may be boiled without decomposition.

The crystals, which contain $C^{10}H^{14}SO^4.2H^2O$, melt below 200°, and the acid, if not more strongly heated, solidifies again in the crystalline form on cooling; but on raising the temperature to 100°, the water of crystallisation is given off, and the acid then solidifies in the amorphous state on cooling. At a stronger heat, it blackens and decomposes, giving off sulphurous anhydride, with an odour somewhat like that of anise, but of a fetid character.

Thianisoates.—Thianisoic acid is monobasic, and mostly forms crystallisable salts, easily soluble in water, sparingly soluble in alcohol, insoluble in ether.

The *ammonium-salt* forms crystals resembling those of the sodium-salt, and containing 1 at. water.

The *barium-salt*, $C^{20}H^{26}Ba''S^2O^8.3H^2O$, separates on mixing the concentrated solution of the sodium-salt with barium-chloride, in delicate laminæ, and crystallises from a hot aqueous solution in beautiful stellate groups; it may be recrystallised, without alteration, from hot hydrochloric acid. It dissolves in 12 pts. of cold water. The crystals give off 2 at. water at 103°, and the remainder at 130°.—The *calcium-salt*, $C^{20}H^{26}Ca''S^2O^8.2H^2O$, separates from a mixture of the concentrated solution of the sodium-salt with chloride of calcium, in shining needles, which dissolve in water more readily than the barium-salt, and are moderately soluble in warm alcohol.

The *cupric salt* crystallises from a mixture of the sodium-salt with cupric sulphate, in black shining laminæ.

The *lead-salt* crystallises from a solution of the sodium-salt, mixed with neutral acetate of lead, in thick well-defined tables and prisms.—A *basic lead-salt* separates, as a white amorphous precipitate, on mixing the sodium-salt with basic acetate of lead.

The *magnesium-salt*, $C^{20}H^{26}Mg''S^2O^8.5H^2O$, is likewise obtained by double decomposition, and crystallises in rectangular tables, moderately soluble in water and in alcohol. They give off 3 at. water at 100°, and the remaining 2 at. at 130°.

The *silver-salt* forms delicate prismatic laminæ, moderately soluble in water, and not decomposed by boiling water.

The *sodium-salt*, $C^{10}H^{13}SO^4.H^2O$, prepared as above described, crystallises in warty groups of shining laminæ, or in thin rhombic tables. It dissolves in 6·5 pts. water at mean temperature, sparingly in cold, easily in boiling alcohol. The crystals are slightly efflorescent, and give off their water at 100°.

THIANISOL. C^8H^8SO. *Hydride of Sulphanisyl.*—A white pulverulent substance, formed by the action of ammonium-sulphide on anishydramide (i. 299).

THIERSCHITE. The name applied by Liebig to a deposit of calcic oxalate found on some parts of the Parthenon at Athens. (See OXALATES, iv. 254.)

THIETHALDINE. Syn. with ETHYL-THIALDINE (p. 773).

THIET-SIE. A resinous substance used as a varnish by the Burmese. It exudes from a tree in the form of a light-brown, very viscid liquid, of the consistence of treacle, but on exposure to the air for a few minutes, becomes quite black, and hard on the surface. The same change takes place instantly in contact with caustic potash. The resin spread in a thin layer, on wood or other solid bodies, quickly forms a hard deep-black coating of great brilliancy.

On digesting the unaltered substance with alcohol of 80 per cent. at a gentle heat, the greater part gradually dissolves; and on decanting the clear liquid from the insoluble residue, and distilling off the alcohol, there remains a very tenacious gummy residue of a rich brown colour, which undergoes no change of colour on exposure to the air, but very slowly hardens. In contact with caustic potash, however, it blackens like the original substance.

The residue, insoluble in alcohol, dissolves for the most part in ordinary ether, forming a dark-brown solution, and leaving a light-brown solid resin. The ethereal solution, when evaporated, leaves a residue which, on exposure to the air, instantly becomes quite black, and after a short time nearly solid. This then is the portion of the original substance to which the property of blackening on exposure to the air is due.

The solid resin, insoluble in alcohol and ether, which forms but a small part of the original substance, is quite unalterable in the air. When heated with nitric acid, it yields a crystalline sublimable acid, exhibiting the characters of succinic acid. (H. Watts, *Unpublished Experiments.*)

THIOBENZALDINE. Syn. with HYDRIDE OF SULPHAZOBENZOYL (p. 481).

THIOBENZOIC ACID. $C^7H^6OS = \left.\begin{matrix}C^7H^5O\\H\end{matrix}\right\}S$. (Cloez, Ann. Ch. Pharm. cxv. 27.)—This acid, analogous to thiacetic acid, is produced by mixing an alcoholic solution of potassium-monosulphide with chloride of benzoyl till the liquid no longer blackens lead-paper. A brisk action then takes place, chloride of potassium is deposited, and thiobenzoate of potassium remains in solution, together with ethylic sulphide, ethylic benzoate, and other products. On distilling off the alcohol over the water-bath, and mixing the aqueous solution of the residue with dilute hydrochloric acid, an oily liquid separates, which smells of mercaptan, and, when left to stand in a cool place, deposits thiobenzoic acid in colourless crystals.

Thiobenzoic acid, when purified by recrystallisation from carbonic disulphide, forms small rhombic tables, inodorous and tasteless. It melts at 120°, becomes rose-coloured and gives off sulphydric acid between 160° and 180°, and decomposes further at 300°, yielding an oily distillate which solidifies on cooling. The acid is quite insoluble in water, slightly soluble in alcohol and ether, easily soluble in mercaptan, ethylic sulphide, and carbonic disulphide. It dissolves without decomposition in alcoholic potash, soda, or ammonia, and forms definite salts with bases. The alkaline thiobenzoates precipitate *ferric salts*.—The *lead-salt* is a white precipitate.—*Ethylic thiobenzoate* appears to be contained in the oily liquid from which the acid is deposited in the course of preparation above described.

THIOBENZOL, or **THIOBENZOYL-HYDRIDE.** See DERIVATIVES OF BENZOYL-HYDRIDE (i. 571).

THIOBUTYRIC ACID. C^4H^8OS.—An acid homologous with thiacetic acid, produced by the action of phosphoric protosulphide on butyric acid (i. 694).

THIOCAPRINALDINE. A compound, analogous to thialdine, formed, according to Wagner (Pharm. Centr. 1861, p. 32), by the action of sulphydric acid on the ammonia-compound of capric or rutic aldehyde (i. 742).

THIOCHRONIC ACID. A product of the action of sulphurous acid on tetrachloroquinone (p. 29).

THIOCINNOL. C^9H^8S.—A pulverulent substance formed, together with sulphide of ammonium, by the action of sulphydric acid on hydrocinnamide (Cahours, Compt. rend. xxv. 458):

$$C^{27}H^{24}N^2 + 4H^2S = 3C^9H^8S + (NH^4)^2S.$$

THIOCUMOL, or **THIOCUMINOL.** $C^{10}H^{12}S$.—A body produced from cuminol (cuminic aldehyde, $C^{10}H^{12}O$) by the action of ammonium-sulphide (ii. 183).

THIOCYANIDES, or *Hydrothiocyanates.*—Salts formed by boiling persulphocyanogen with alkalis. (See PERSULPHOCYANOGEN, iv. 381.)

THIODIACETIC ACID. See THIODIGLYCOLLIC ACID.

THIODIGLYCOLLAMIC ACID, $C^4H^7NSO^3 = \left.\begin{matrix}H^2\\(C^2H^2O)''\\(C^2H^2O)''\\H\end{matrix}\right\}\begin{matrix}N\\O\\S\end{matrix}$, or *Thiodiacetamic Acid,* $\left.\begin{matrix}H^2\\(C^4H^4SO^2)''\\H\end{matrix}\right\}\begin{matrix}N\\O\end{matrix}$. (E. Schulze, Zeitschr. f. Chem. 1866, p. 181; Jahresb. 1865, p. 345.)—The *barium-salt* of this acid, $C^8H^{12}Ba''N^2S^2O^6.H^2O$, produced by treating thiodiglycollimide with cold baryta-water, crystallises, by evaporation over sulphuric acid, in needles, or forms a gummy mass if quickly dried. The acid, $C^4H^7NSO^3$, separated from the barium-salt by sulphuric acid, or obtained by heating the acid ammonium-salt for several days to 145°, crystallises in colourless prisms, permanent in the air, melting at 125°, and converted at higher temperatures into thiodiglycollimide. It dissolves slowly in cold, easily in boiling water, forming an acid solution which is not precipitated by lead- or silver-salts.—The *calcium-salt*, $C^8H^{12}Ca''N^2S^2O^6.H^2O$, crystallises from a syrupy solution in small needles.—The *silver-salt*, $C^4H^6AgNSO^3$, may be crystallised from hot water.

THIODIGLYCOLLAMIDE, $C^4H^8N^2SO^2 = \left.\begin{matrix}(C^2H^2O)''\\(C^2H^2O)''\\H^4\end{matrix}\right\}\begin{matrix}N^2\\S\end{matrix}$, or *Thiodiacetodiamide,* $\left.\begin{matrix}(C^4H^4SO^2)''\\H^4\end{matrix}\right\}N^2$. (Schulze, *loc. cit.*)—This compound is obtained by the action of neutral sulphide of ammonium on chloracetamide in alcoholic solution. The reaction, which consists in the substitution of 1 at. S for 2 at. Cl in a double molecule of chloracetamide, seems to show that the second of the above formulæ is the more correct expression of the composition of the product:

$$\underbrace{\left.\begin{matrix}C^4H^4Cl^2O^2\\H^2\end{matrix}\right\}N^2}_{\text{2 mol. chloracetamide.}} + (NH^4)^2S = 2NH^4Cl + \underbrace{\left.\begin{matrix}(C^4H^4SO^2)''\\H^2\end{matrix}\right\}N^2}_{\text{Thiodiacetodiamide.}}.$$

The product, after washing with alcohol and recrystallisation from water, forms small, white, quadratic octahedrons, which melt when heated, and then decompose, giving off the odour of ammonium-sulphide.

THIODIGLYCOLLIC or **THIODIACETIC ACID.** $C^4H^6SO^4 = \left.\begin{matrix}C^2H^2O\\C^2H^2O\\H^2\end{matrix}\right\}\begin{matrix}S\\O^2\end{matrix}$ or $\left.\begin{matrix}(C^4H^4SO^2)''\\H^2\end{matrix}\right\}O^2$. (Schulze, Zeitschr. f. Chem. 1865, p. 73; 1866, p. 181; Jahresb. 1864, p. 325; 1865, p. 345.—Wislicenus, Zeitschr. f. Chem. 1865, p. 621; Jahresb. 1865, p. 344.)—This acid, which has the composition of diglycollic acid (ii. 912), with 1 at. oxygen replaced by sulphur, or of a double molecule of acetic acid ($C^4H^8O^4$) in which 2 at. hydrogen are replaced by 1 at. sulphur, is produced: 1. By boiling thiodiglycollamide with baryta-water as long as ammonia is evolved:

$$C^4H^8N^2SO^2 + 2H^2O = 2NH^3 + C^4H^6SO^4.$$

By precipitating the solution of the resulting barium-salt with acetate of lead, decomposing the lead-salt with sulphydric acid, and evaporating the filtrate, thiodiglycollic acid is obtained in crystals. (Schulze.)

2. Ethylic thiodiglycollate, $C^4H^4(C^2H^5)^2SO^4$, is produced by the action of potassium-sulphydrate on ethylic chloracetate:

$$2C^2H^2(C^2H^5)ClO^2 + KHS = C^4H^4(C^2H^5)^2SO^4 + KCl + HCl.$$

This ether, treated with alcoholic potash, yields thiodiglycollate of potassium, which may be converted into a lead- or silver-salt by precipitation, and from this the acid may be obtained. (Wislicenus.)

Thiodiglycollic acid crystallises in large, thin, rhombic plates (Schulze). It melts at 129° (Schulze), at 126° (Wislicenus), volatilises completely when cautiously heated, dissolves in 2·37 pts. of water at 18°, and is soluble in alcohol. The aqueous solution is precipitated by lead- and silver-salts. The acid is not attacked by fuming hydrochloric acid, even at 150°—180°; but when heated to 150°, with excess of *hydriodic acid* (boiling at 125°), it is reduced to acetic acid:

$$C^4H^6SO^4 + 4HI = 2C^2H^4O^2 + H^2S + 2I^2.$$

The thiodiglycollates are mostly soluble in water, insoluble in alcohol, and easily crystallisable.—The *acid ammonium-salt*, obtained by treating monochloracetate of ammonium with alcoholic sulphide (? sulphydrate) of ammonium, crystallises in octahedral forms, mostly prismatically distorted. When heated to 180°—200°, it gives off water and ammonia, and leaves thiodiglycollimide, $C^4H^5NSO^2$ (Schulze).—The *neutral potassium-salt* crystallises in broad colourless prisms, which give off 1 at. water at 120° (Schulze). Wislicenus, by the action of alcoholic potash on ethylic thiodiglycollate, obtained it in thin needles, containing $C^4H^4K^2SO^4.H^2O$.—The *acid potassium-salt* is anhydrous, permanent in the air, and less soluble than the neutral salt. (Schulze.)

The *barium-salt*, $C^4H^4Ba''SO^4$, in the anhydrous state, forms sparingly soluble crystalline crusts. By leaving it for some time in contact with the mother-liquor, a hydrated salt, $C^4H^4Ba''SO^4.5H^2O$, is obtained in prismatic crystals, which are permanent in the air, but become opaque and anhydrous when immersed in hot water. (Schulze.)

The *cupric salt*, $C^4H^4Cu''SO^4.H^2O$, is formed, on mixing moderately concentrated solutions of the ammonium-salt and cupric sulphate, as a bluish-white crystalline precipitate, which, on heating the liquid, is converted into blue crystals of the anhydrous salt. (Schulze.)

The *neutral lead-salt*, $C^4H^4Pb''SO^4$, is crystalline, soluble in hot water and in dilute nitric acid.—A *basic lead-salt*, $C^4H^4Pb''SO^4.Pb''O$, is formed when the ammonium-salt is mixed with basic lead-acetate at the boiling heat.—The *silver-salt* is a flocculent precipitate.—The *zinc-salt* crystallises with 4 at. water in sparingly soluble rhombic plates.

Ethylic Thiodiglycollate, $C^4H^4(C^2H^5)^2SO^4$, is obtained:—1. By saturating the alcoholic solution of the acid with hydrochloric acid (Schulze).—2. Together with other products, by the action of potassium-sulphydrate on ethylic monochloracetate. On treating the product of this reaction with water, a fetid oil is separated, which, when rectified, yields ethylic thiodiglycollate between 267° and 268° (Wislicenus). This ether is a colourless liquid, which has a faint ethereal odour, is insoluble in water, distils, for the most part undecomposed, at 240°—250°, and, when treated with alcoholic ammonia, yields thiodiglycollamide. (Schulze.)

THIODIGLYCOLLIC CHLORIDE. Thiodiglycollic acid, treated with pentachloride of phosphorus, forms a colourless chloride, difficult to purify, which yields with alcohol a sulphuretted oil, insoluble in water, and apparently not identical with ethylic thiodiglycollate, inasmuch as it is decomposed by ammonia, with formation of ammonium-sulphide. (Schulze.)

THIODIGLYCOLLIC ETHER. Syn. with ETHYLIC THIODIGLYCOLLATE (*vid. sup.*).

THIODIGLYCOLLIMIDE, $C^4H^5NSO^2 = \left.\begin{matrix}(C^2H^2)''\\(C^2H^2O)''\\H\end{matrix}\right\}\begin{matrix}N\\S\end{matrix}$, or **THIODIACETIMIDE,** $\left.\begin{matrix}(C^4H^4SO^2)''\\H\end{matrix}\right\}N$, is formed by the dehydration of acid thiodiglycollate of ammonium, and is deposited from a hot aqueous solution, decolorised by animal charcoal, in thin prismatic needles or laminæ. It is sparingly soluble in cold water, melts at 128°, and sublimes undecomposed at a higher temperature. On mixing its slightly ammoniacal solution with nitrate of silver, argento-thiodiglycollimide, $C^4H^4AgNSO^2$, is precipitated in white flocks, which are decomposed by boiling.—By *baryta-water*, at the boiling heat, the imide is converted, with evolution of ammonia, into thiodiglycollate of barium; in cold baryta-water, on the other hand, it dissolves as thiodiglycollamate of barium (p. 776). (Schulze.)

THIOFORMIC ACID. A compound, probably homologous with thiacetic acid, produced in small quantity by the action of sulphydric acid on formate of lead, at 200°—300°. It forms small transparent crystals, which have an alliaceous odour, are insoluble in water, may be recrystallised from alcohol, melt at 120°, and sublime at a lower temperature. They are insoluble in sulphide of ammonium, and dissolve but slightly in boiling potash-ley. Their alcoholic solution, which does not redden litmus, forms with acetate of lead a yellowish, and with silver-salts a whitish precipitate, both of which are blackened and decomposed by heat. (Limpricht, Ann. Ch. Pharm. xcvii. 361.)

THIOFUCUSOL. A body analogous and very similar to thiofurfurol, produced by treating fucusol in alcoholic solution with sulphydric acid. By dry distillation, it yields a product of decomposition called pyrofucusol, which crystallises in needles, and has probably the same composition as pyrofurfurol, $C^8H^6O^2$. (Stenhouse, Ann. Ch. Pharm. lxxiv. 293.)

THIOFURFOL, or **THIOFURFUROL.** C^5H^4OS.—A compound formed by the action of ammonium-sulphide on furfurol, or of sulphydric acid on furfuramide dissolved in alcohol. (See FURFUROL, ii. 753.)

THIOMELANIC ACID. The black mass produced by heating alcohol with excess of sulphuric acid. It was formerly supposed to consist of carbon, but, according to Erdmann (J. pr. Chem. xxi. 291), it is a sulphuretted acid, capable of forming salts with potash and other bases. It has not been obtained in a sufficiently definite state to enable its composition to be determined with accuracy, and is probably a mixture. (See *Gmelin's Handbook*, viii. 240.)

THIOMETHALDINE. Syn. with METHYL-THIALDINE (p. 774).

THIONAMIC ACID.  $NH^3SO^2 = \left.\begin{matrix}H^2\\(SO)''\\H\end{matrix}\right\}\begin{matrix}N\\O\end{matrix}$. *Sulfit-ammon.*—This acid, which differs from acid sulphite of ammonium ($NH^4.H.SO^3$) by the want of 1 at. water, is produced by the action of dry ammonia-gas on an excess of sulphurous anhydride. It is a crystalline volatile substance, of a yellowish colour (perhaps due to impurity), and very soluble in water. In the moist state, or in solution, it quickly undergoes a complete decomposition into sulphate of ammonium, trithionate of ammonium, and other products. When sulphurous anhydride is mixed with excess of dry ammonia-gas, two volumes of the former unite with four volumes of the latter, forming thionamate of ammonium,  $\left.\begin{matrix}H^2\\(SO)''\\NH^4\end{matrix}\right\}\begin{matrix}N\\O\end{matrix}$, which is an amorphous, volatile, neutral, deliquescent salt, speedily decomposing in solution. (H. Rose, Pogg. Ann. xxxiii. 275; xlii. 425; Gm. ii. 455.)

THIONAMIDE. $N^2H^4(SO)''$.—Produced by the action of sulphurous chloride on dry ammonia:

$$4NH^3 + SOCl^2 = 2NH^4Cl + N^2H^4SO.$$

The sulphurous chloride should be well cooled, and the ammonia-gas passed in slowly. The product is a white, pulverulent, non-crystalline solid, from which the sal-ammoniac may be extracted by cold water. Thionamide is converted by hot water into neutral sulphite of ammonium, from which it differs by 2 at. water: $(NH^4)^2SO^3 - 2H^2O = N^2H^4SO$. It is instantly decomposed by alkalis with evolution of ammonia, and by acids with evolution of sulphurous anhydride. (Schiff, Ann. Ch. Pharm. cii. 111.)

THIONAPHTHALIC ACID. Syn. with NAPHTHYLSULPHUROUS ACID. (See SULPHUROUS ETHERS, p. 560.)

THIONAPHTHAMIC ACID, more properly, **NAPHTHYLSULPHAMIC ACID,** $C^{10}H^9NSO^3$ =  $\left.\begin{matrix}C^{10}H^7.H\\(SO^2)''\\H\end{matrix}\right\}\begin{matrix}N\\O\end{matrix}$. (Piria, Ann. Ch. Phys. [3], xxxi. 217.)—This acid is produced, together with naphthionic acid, with which it is isomeric, by the action of ammonium-sulphite on nitronaphthalene. The orange-yellow crystals obtained in the preparation of naphthionic acid (iv. 17), consist of naphthylsulphamate of ammonium. The acid has not been obtained in the free state; on attempting to decompose a thionaphthamate with an acid, even with acetic acid, it is resolved into naphthylamine and sulphuric acid.

The naphthylsulphamates are generally prepared by double decomposition from the ammonium-salt. They are all soluble, and resemble each other in appearance and colour. They usually crystallise in large nacreous laminæ of an amethyst or reddish colour.

They undergo decomposition by exposure to the air, their solutions becoming reddish-brown. Heat and light assist this decomposition, while the presence of alkalis confers stability on the solutions. Distilled with lime in excess, the naphthylsulphamates yield naphthylamine in the form of an oil which crystallises on cooling.

The *ammonium-salt* is obtained in crystals by dissolving the crude salt, prepared as above described, in 2 pts. of boiling water containing a few drops of ammonia, and cooling the solution. It forms small, reddish, nacreous laminæ, the solution of which becomes more rapidly coloured than those of the other salts. It dissolves very easily in water, and in alcohol. When its perfectly neutral solution is heated between 80° and 90°, the water being replaced as it evaporates, it becomes coloured, and strongly acid, deposits a brown resin, and yields sulphate of naphthylamine.

The *potassium-salt*, $C^{10}H^8KNSO^3$, is obtained by boiling the ammonium-salt with excess of potassium-carbonate, till it ceases to evolve ammonia. On cooling, large nacreous laminæ crystallise out, resembling boric acid. The salt is very soluble in water, but only slightly soluble in alcohol, and in aqueous potash or carbonate of potassium.—The *sodium-salt*, $C^{10}H^8NaSO^3$, prepared in like manner, forms reddish laminæ, easily soluble in hot, but sparingly in cold water, especially in presence of sodium-carbonate.

The *barium-salt*, $C^{20}H^{16}Ba''N^2S^2O^6.6H^2O$ (?), is prepared by double decomposition with chloride of barium and naphthionate of potassium. — The *calcium-salt*, $C^{20}H^{16}Ca''N^2S^2O^6$, and the *magnesium-salt*, $C^{20}H^{16}Mg'N^2S^2O^6$, are very soluble.

The *lead-salt*, $C^{20}H^{16}Pb''N^2S^2O^6$, is prepared by decomposing a boiling solution of the potassium-salt with nitrate of lead, taking care that the potassium-salt is in excess. When the nitrate of lead is in excess, a double salt is produced, which appears to contain equal numbers of atoms of thionaphthamate and nitrate of lead. The thionaphthamate of lead is deposited from its boiling solution in crystalline grains, which may be purified by a second crystallisation. It then forms a light, crystalline, reddish powder, very slightly soluble in water, and almost insoluble in alcohol.

Acetato-thionaphthamate of lead, $C^4H^6Pb''O^4.C^{20}H^{16}Pb''N^2S^2O^6$.—When concentrated and nearly boiling solutions of potassium-thionaphthamate and lead-acetate are mixed, the latter being in excess and acidified with acetic acid, there is deposited on cooling a double salt, crystallising in reddish micaceous laminæ grouped around a common centre. It is very slightly soluble in cold, more soluble in hot water.

THIONESSAL, $C^{26}H^{18}S$. *Schwefelessal. Schwefelesyl.* (Laurent, Ann. Ch. Phys. [3], i. 292).—A compound produced, together with stilbene, by the dry distillation of thiobenzol:

$$\underset{\text{Thiobenzol.}}{8C^7H^6S} = \underset{\text{Thionessal.}}{C^{26}H^{18}S} + \underset{\text{Stilbene.}}{2C^{14}H^{12}} + 2CS^2 + 3H^2S.$$

It is obtained, from the portion of the distillate insoluble in ether, by solution in petroleum, and crystallises from the hot solution in silky needles. It is very sparingly soluble in alcohol and ether, more soluble in petroleum. It melts at 178°, often remains liquid till cooled down to the ordinary temperature of the air, and then solidifies without assuming a crystalline structure. When heated to 233°, it crystallises as soon as a crystal is thrown into the liquid mass. It is decomposed by potassium, with formation of potassium-sulphide. Alcoholic potash-solution does not decompose it, even at the boiling heat. By boiling *nitric acid*, it is slowly converted into a yellow crust of tetranitrothionessal, $C^{26}H^{14}(NO^2)^4S$.—*Bromine* attacks it violently, forming a solid mass of tetrabromothionessal, $C^{26}H^{14}Br^4S$, insoluble in alcohol, ether, and petroleum.

THIONURIC ACID. *Alloxanosulphurous acid* (Laurent). $C^4H^5N^3SO^6$. (Liebig and Wöhler, Ann. Ch. Pharm. xxvi. 268, 314, 331.)—An acid formed by the simultaneous action of ammonia and sulphurous acid on alloxan (i. 137). It is obtained by decomposing its lead-salt with sulphuretted hydrogen, and evaporating the filtrate at a gentle heat. It forms a crystalline mass, consisting of fine needles: it is permanent in the air, reddens litmus strongly, and has a very sour taste. It is readily soluble in water; when the solution is boiled, it is decomposed into dialuramide, which separates out, and sulphuric acid:

$$C^4H^5N^3SO^6 + H^2O = C^4H^5N^3O^3 + H^2SO^4.$$

It is a dibasic acid.

The *normal ammonium-salt*, $C^4H^3(NH^4)^2N^3SO^6.H^2O$, is obtained by boiling for some time a mixture of aqueous alloxan and sulphurous acid, saturated with ammonia; or a mixture of aqueous sulphite and carbonate of ammonium, and alloxan; the salt crystallises, on cooling, in four-sided tables, which lose 6 per cent. (1 at.) water at 100°, assuming a rose-colour. It is slightly soluble in cold, readily in hot water; the solution reduces metallic silver from nitrate of silver, in the specular form. When fused with solid potash, it yields sulphite of potassium. Mineral acids decompose it at a boiling heat (not in the cold), into dialuramide and sulphuric acid. By prolonged heating to 200°, it is for the most part resolved into sulphate of ammonium and xanthinine, $C^4H^3N^3O^2$ (Finck, Ann. Ch. Pharm. cxxxii. 298):

$$C^4H^3(NH^4)^2N^3SO^6 = (NH^4)^2SO^4 + C^4H^3N^3O^2.$$

The *acid ammonium-salt*, $[C^4H^4(NH^4)N^3SO^6]$, is obtained in fine white needles, by evaporating in a water-bath an aqueous solution of the normal salt with a small quantity of sulphuric acid: if the sulphuric acid is in excess, dialuramide, uramilic acid, and finally dialuric acid, is formed. The aqueous solution of this salt is decomposed by boiling into sulphate of ammonium and dialuric acid:

$$C^4H^8N^4SO^6 + 2H^2O = \underset{\text{Dialuric acid.}}{C^4H^4N^2O^4} + (NH^4)^2SO^4.$$

The *barium-salt* is obtained as a flocculent precipitate, which gradually becomes crystalline, when the ammonium-salt is added to chloride of barium. It is readily soluble in hydrochloric acid; boiled with nitric acid, it yields sulphate of barium, but no free sulphuric acid.

The *lead-salt* is obtained by adding thionurate of ammonium to neutral acetate of lead. It is a gelatinous precipitate, which, on cooling, aggregates into tufts of white or rose-coloured needles. By dry distillation, it yields urea, and another crystalline product.

With sulphate of copper, thionurate of ammonium gives a yellowish-brown precipitate, whith is probably a cuprous salt.

Gregory (Compt. chim. 1845, p. 118) mentions a peculiar acid, containing the elements of thionuric acid minus ammonia. F. T. C.

THIONYL. SO.—The radicle of the sulphurous compounds: *e.g.*, sulphurous chloride, $(SO)''Cl^2$ = chloride of thionyl (p. 542).

THIONYLAMIC ACID. Syn. with THIONAMIC ACID (p. 778).

THIONYLAMIDE. Syn. with THIONAMIDE (p. 778).

THIOPHOSPHAMIC ACID. $PH^4NSO^2 = \left.\begin{matrix}H^2\\(PS)'''\\H^2\end{matrix}\right\}\begin{matrix}N\\O^2\end{matrix} = P(NH^2)H^2SO^2.$

Sulphoxyphosphamic Acid. (Gladstone and Holmes, Chem. Soc. J. xviii. 7.)—This acid is formed by the action of aqueous ammonia on sulphochloride of phosphorus. (Respecting the mode of formation of this and the following acid, see iv. 606.) The sulphochloride added to strong aqueous ammonia diluted with an equal bulk of water, dissolves slowly on agitation, and forms an acid liquid containing sal-ammoniac and thiophosphamic acid. The latter has not been isolated, but its neutralised solution yields, with solutions of heavy metallic salts, a series of salts resembling the thiophosphodiamates (*infra*), and represented by the formula $PNH^2M''SO^2$. No precipitates are obtained with solutions of nickel, cobalt, iron, aluminium, barium, calcium, or magnesium. A solution of potassio-stannous chloride forms a white bulky precipitate, soluble in hydrochloric acid. Mercuric chloride throws down yellow mercuric sulphochloride, which, in presence of excess of thiophosphamic acid, turns black—a reaction which may serve to distinguish this acid from the following.

THIOPHOSPHODIAMIC ACID. $PH^5N^2SO = \left.\begin{matrix}H^4\\(PS)'''\\H\end{matrix}\right\}\begin{matrix}N^2\\O\end{matrix} = P(NH^2)^2HSO.$

Sulphoxyphosphodiamic Acid. (Gladstone and Holmes, *loc. cit.*)—A monobasic acid formed, together with sal-ammoniac, by the action of ammonia-gas, or of the strongest aqueous solution of ammonia, on sulphochloride of phosphorus. The sulphochloride takes up about 4 at. ammonia (40 per cent. of its weight), and is converted into a white mass, easily soluble in water, and forming an acid solution, which, when neutralised, yields thiophosphodiamates, $P(NH^2)^2M''SO$ and $P^2(NH^2)^4M''S^2O^2$, by double decomposition. These salts decompose when heated, giving off ammonia and sulphide of ammonium.—The *cupric salt*, $P^2N^4H^8Cu''S^2O^2$, is a yellowish-white precipitate, insoluble in dilute hydrochloric acid and in ammonia, soluble in cyanide of potassium, and turning brown when heated.—The *zinc-salt*, $P^2N^4H^8Zn''S^2O^2$, is a white flocculent precipitate, easily soluble in dilute acids and in ammonia.—The *cadmium-salt*, $P^2N^4H^8Cd''S^2O^2$, exhibits similar properties.—The *lead-salt* is obtained, on adding chloride of lead to the neutralised solution of the acid, as a white precipitate, soluble in dilute nitric acid, and turning black when heated with water.—The *silver-salt* was obtained, mixed with silver-chloride, as a white precipitate, insoluble in dilute nitric acid, turning black in presence of excess of silver.—*Stannous chloride* and *mercuric chloride* form white precipitates, the latter of which quickly passes into the yellow compound, $HgS.HgCl^2$, but is not under any circumstances converted into black sulphide of mercury—a character which distinguishes thiophosphodiamic from thiophosphamic acid. The filtered solution contains an acid not yet examined.—*Cobalt-salts* give a bluish-white, *nickel-salts* a greenish-white precipitate, both of which are soluble in dilute acids and in ammonia.—*Barium-, calcium-, magnesium-, aluminium-,* and *ferric salts* give no precipitate. On attempting to isolate the acid from its silver- or copper-salt, a liquid was obtained, which, when evaporated over oil of vitriol, decomposed with separation of sulphur.

THIOSALICOL. C^7H^6OS. *Sulphosalicylic Hydride.*—A compound produced by the action of sulphydric acid on hydrosalicylamide (iii. 218).

THIOSINAMINE. $C^4H^8N^2S = N^2\left\{\begin{matrix}(CS)'' \\ C^3H^5 \\ H^3\end{matrix}\right.$ *Allyl-sulphocarbamide. Rhodalline.*—This compound is formed by the union of the elements of 1 at. allylic sulphocyanate with 1 at. ammonia, just as allyl-carbamide is formed by the union of ammonia and allylic cyanate. It was discovered, in 1834, by Dumas and Pelouze (Ann. Ch. Phys. [2], liii. 181), afterwards examined by Aschoff (J. pr. Chem. iv. 314), Löwig and Weidmann (*ibid.* xix. 218), Robiquet and Bussy (*ibid.* xix. 232), and more completely by Will (Ann. Ch. Pharm. lii. 1).

Preparation.—By saturating oil of mustard with ammonia-gas, or mixing it with 3 or 4 times its bulk of strong aqueous ammonia, and leaving the mixture to stand till it is converted into a crystalline mass. If the mother-liquor filtered from these crystals be evaporated, to expel the excess of ammonia, and boiled with animal charcoal, a colourless liquid is obtained, which, on evaporation, yields crystals of pure thiosinamine to the last drop. It is best to use pure mustard-oil in the preparation, as the crude oil, when treated with ammonia, likewise forms a yellow resinous substance, which cannot be removed without loss.

Properties.—Thiosinamine, purified, if necessary, by recrystallisation, forms white shining prisms, which (according to Schabus) belong to the monoclinic system, and are cleavable parallel to $+P\infty$ and oP. It is inodorous, but has a bitter taste. Melts at 70·6° (Dumas and Pelouze), at 74° (Wertheim), forming a colourless liquid, which cannot be volatilised without decomposition. In moderate doses, it does not exert a poisonous action on the human organism, but nevertheless produces sleeplessness, palpitation of the heart, &c. (Wöhler and Frerichs, Ann. Ch. Pharm. lxv. 342). It is neutral to vegetable colours, but nevertheless exhibits some of the characters of ammonia, especially in the facility with which it dissolves oxide and chloride of silver. It dissolves in hot much more readily than in cold water, and is easily soluble in alcohol and ether.

Thiosinamine exhibits the same properties, whether prepared from natural or from artificial mustard-oil.

Decompositions.—1. Thiosinamine is completely decomposed at high temperatures, sulphocyanic acid and other volatile products being formed, and charcoal remaining behind.—2. By *electrolysis*, it yields sulphurous and hydrocyanic acids, and a yellow sulphuretted organic compound, which is deposited at the negative pole (Schlagdenhauffen, J. Pharm. [3], xliv. 100).—3. *Chlorine* decomposes it in aqueous solution, forming large quantities of hydrochloric and sulphuric, but no sulphocyanic acid (Aschoff).—4. *Bromine* (according to Aschoff) forms a white precipitate with thiosinamine; but, according to Maly (Bull. Soc. Chim. [1867], ii. 129), this takes place only when the thiosinamine is impure. An alcoholic solution of pure thiosinamine dissolves bromine, without elimination of hydrobromic acid, and the solution yields, by evaporation, crystals of hydrobromate of bromothiosinamine.—5. *Iodine* added in sufficient quantity to aqueous thiosinamine separates a brown oil; the watery liquid then exhibits acid reaction, and when boiled deposits a white substance containing iodine and sulphur.—6. Dilute *phosphoric* and *sulphuric acids*, heated with thiosinamine, evolve sulphocyanic acid.—7. *Nitric acid* oxidises it.—8. *Potassium*, heated with it to the melting-point, decomposes it with explosion.—9. *Baryta-water* decomposes thiosinamine at the boiling heat, forming sulphide and carbonate of barium. But little ammonia is evolved, and the filtrate, when evaporated, leaves a non-crystalline and scarcely alkaline syrup, which appears to be a base different from sinamine. The other fixed alkalis act like baryta.—10. The *protoxides* of *lead* and *mercury* abstract from thiosinamine sulphur and hydrogen, a metallic sulphide and water being formed, together with sinamine:

$$\underset{\text{Thiosinamine.}}{C^4H^8N^2S} + Hg''O = \underset{\text{Sinamine.}}{C^4H^6N^2} + Hg''S + H^2O.$$

11. The aqueous solution of thiosinamine forms a white precipitate with mercuric salts, grey with mercurous salts, brownish-yellow with trichloride of gold, white with

nitrate of silver, &c. It gradually decolorises ferric chloride, and forms a flocculent precipitate on boiling. It likewise decolorises a moderately strong solution of cupric sulphate, the liquid then depositing blue flocks on addition of alcohol. When warm, it dissolves recently precipitated chloride of silver, the liquid becoming milky as it cools, and depositing a pitchy substance, containing thiosinamine and chloride of silver.

Combinations.—Thiosinamine does not form crystallisable salts with ***sulphuric, nitric,*** *acetic*, or *oxalic acid.*

The *hydrochlorate*, $C^4H^8N^2S.HCl$, is produced by passing dry hydrochloric acid gas over dry thiosinamine at a gentle heat. The product gives off vapours of hydrochloric acid when exposed to moist air. (Will.)

The *chloroplatinate*, $2(C^4H^8N^2S.HCl).PtCl^4$, is obtained by saturating thiosinamine with hydrochloric acid gas, and mixing the cold aqueous solution of the resulting hydrochlorate with platinic chloride. It is a yellowish-red precipitate, consisting of needle-shaped rhombic crystals; melts and blackens at a gentle heat, and decomposes at higher temperatures, leaving sulphide of platinum. If the liquids are mixed hot, or if the platinic chloride contains nitric acid, or if a dark-coloured solution of thiosinamine in aqueous hydrochloric acid is used, precipitates of variable composition are formed. (Will.)

A *chloromercurate*, containing $2Hg''Cl^2.C^4H^8N^2S$, or $Hg''Cl^2 + 2HCl\,.\,N^2\left\{\begin{matrix}CS''\\ C^3H^5\\ H.Hg''\end{matrix}\right.$, is obtained, as a curdy white precipitate, by mixing the aqueous solutions of mercuric chloride and hydrochlorate of thiosinamine. It is soluble in acetic acid. (Will.)

A compound of thiosinamine with nitrate of silver, $NO^3Ag.C^4H^8N^2S$, is produced, by mixing the concentrated aqueous solution of thiosinamine and nitrate of silver, as a white crystalline precipitate, which, after washing with water, and drying at 100°, forms a greenish-white mass, slightly alterable on exposure to light. Boiling water decomposes it into sulphide of silver, and other products not yet examined. Aqueous sulphydric acid converts it into thiosinamine and sulphide of silver. (Will.)

Derivatives of Thiosinamine.

Bromothiosinamine, $C^4H^7BrN^2S$. (Maly, J. pr. Chem. c. 321; Bull. Soc. Chim. [1867], ii. 129.)—The hydrobromate of this base, $C^4H^7BrN^2S.HBr$, is formed, as already observed, by the direct addition of bromine to thiosinamine in alcoholic solution, 1 at. thiosinamine taking up 2 at. bromine without evolution of hydrobromic acid. It separates, on evaporation, as a crystalline mass, soluble in water and in alcohol. It melts at 146°—147°, and at a higher temperature gives off vapours having the irritating odour of allyl-compounds, and leaves a very porous cinder. Its aqueous solution forms, with *nitrate of silver*, a copious precipitate of chloride of silver, and with *platinic chloride*, brilliant orange-yellow scales of the chloroplatinate, $2(C^4H^7BrN^2S.HBr).PtCl^4$.

Chloride of silver added to the aqueous solution of the hydrobromate removes half the bromine, forming bromide of silver and hydrochlorate of bromothiosinamine, $C^4H^7BrN^2S.HCl$, which is soluble in water and in alcohol, and is deposited from the aqueous solution in crystals grouped like wavellite,—from the alcoholic solution in more bulky crystals, apparently belonging to the monoclinic system. It melts at 129°—130°.—With *platinic chloride*, it forms orange-yellow shining scales of the chloroplatinate, $2(C^4H^7BrN^2S.HCl).PtCl^4$, insoluble in boiling alcohol, soluble in boiling water, and partly decomposed thereby; and with *auric chloride* a dark red-purple precipitate of a chloroaurate, together with bromide of gold.

Hydrate of bromothiosinammonium, $C^4H^8BrN^2S.H.O$.—A solution of hydrobromate of bromothiosinamine, treated with oxide of silver, yields bromide of silver and a strongly alkaline bitter liquid, which may be evaporated to a syrupy consistence; and when treated with hydrochloric acid, yields hydrochlorate of bromothiosinamine.

Amyl-thiosinamine, obtained by the direct combination of allylic sulphocyanate with amylamine, is an uncrystallisable syrup, which yields a crystalline chloroplatinate. (Hinterberger, Ann. Ch. Pharm. lxxxiii. 346.)

Ethyl-thiosinamine, $C^6H^{12}N^2S = N^2\left\{\begin{matrix}(CS)''\\ C^3H^5\\ C^2H^5\\ H^2\end{matrix}\right.$.—*Thiosinethylamine.* (Hinterberger, *loc. cit.*—Weltzien, Ann. Ch. Pharm. xciv. 103.)—Formed by the direct combination of allylic sulphocyanate or sulphocarbimide, $N(CS)''(C^3H^5)$, with ethylamine,

$N(C^2H^5)H^2$ (Hinterberger), or as a hydriodate, by the action of ethylic iodide on thiosinamine. (Weltzien.)

Oil of mustard absorbs gaseous ethylamine with considerable rise of temperature. Liquid ethylamine hisses when dropt into mustard; and on adding the oil to liquid ethylamine, it is thrown out by the violence of the action. When ethylamine was passed in excess into mustard-oil cooled with ice, a thin syrupy liquid was formed, having the odour of ethylamine, and a bitter aromatic taste. This liquid, after standing for some time, became red-brown, but did not yield crystals, or form crystallisable salts with acids; when heated, it gave off white fumes, which condensed to oily alkaline drops, exhibiting a blood-red colour with ferric chloride. (Hinterberger.)

The *hydriodate*, $C^6H^{12}N^2S.HI$, is obtained by heating thiosinamine with ethylic iodide in alcoholic solution, and evaporating, as a white, feathery, crystalline mass, resembling sal-ammoniac. It dissolves in water, alcohol, and ether, and turns yellow in the air from separation of iodine (Weltzien).—The *hydrochlorate* is obtained by decomposing the hydriodate with oxide of silver, precipitating the excess of the silver from the filtrate with hydrochloric acid, and evaporating the filtered solution. The residue is a syrupy uncrystallisable mass, soluble in water and in alcohol. (Weltzien.)

Platinum-salt, $2(C^6H^{12}N^2S.HCl).PtCl^4$.—On saturating the syrupy liquid obtained by the action of mustard-oil on ethylamine with dry hydrochloric acid gas, dissolving the resulting viscid mass in absolute alcohol, and adding an alcoholic solution of platinic chloride, yellow needle-shaped crystals of the platinum-salt quickly separated; the mother-liquor, when left to itself for some time, yielded crystals of more definite shape (Hinterberger). Weltzien's hydrochlorate mixed with chloride of platinum, yielded a yellow, easily soluble, indistinctly crystalline mass.

Methyl-thiosinamine, obtained like the ethyl-compound, is a brown uncrystallisable syrup, which yields a crystalline chloroplatinate. (Hinterberger.)

Naphthyl-thiosinamine, $C^{14}H^{14}N^2S = N^2(CS''.C^3H^5.C^{10}H^7.H^2)$. *Thiosin-naphthylamine.* (Zinin, J. pr. Chem. lvii. 173.)—This compound is produced by adding 30 pts. of mustard-oil to a solution of 43 pts. of naphthylamine in eight times that weight of 90 per cent. alcohol, and separates after awhile in crystals, grouped in small, white, radiated hemispheres, the mother-liquor yielding an additional quantity when evaporated. It is white, insoluble in water, sparingly soluble in ether and in cold alcohol, more easily in boiling alcohol. It melts at 130°, forming a clear liquid, which solidifies again in the crystalline form. By careful heating, a portion of it may be distilled without alteration.

Naphthyl-thiosinamine is decomposed by *hydrate of lead*, yielding sulphide of lead, together with a substance which crystallises from boiling alcohol in silky grains, and an unctuous substance, still more soluble in alcohol.

With *acids*, naphthyl-thiosinamine behaves like the phenyl-compound.

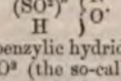
Phenyl-thiosinamine, or **Thiosinaniline,** $C^{10}H^{12}N^2S = N^2(CS''.C^3H^5.C^6H^5.H^2)$. (Zinin, *loc. cit.*)—Obtained by pouring oil of mustard into an equivalent quantity of aniline dissolved in about four times its weight of alcohol of 90 per cent. The mixture becomes hot, and, on cooling, deposits the compound in foliated crystals. If a weaker solution of aniline be used, the crystals sometimes attain the length of four millimetres, and exhibit the form of tables with four or six faces.

Thiosinaniline is colourless, transparent, destitute of taste and smell, insoluble in water, very soluble in alcohol and ether. It melts at 95°, forming a colourless liquid, which solidifies in a radiated mass on cooling. When distilled it yields an oil, which has the odour of leeks, and does not solidify. It is desulphurised by hydrate of lead, yielding a substance which is very soluble in alcohol, and crystallises in silky needles; also as an uncrystallisable resinous body.

Thiosinaniline does not show much tendency to combine with acids. It dissolves in hot concentrated hydrochloric acid, but is precipitated by water in its original state. It likewise crystallises unaltered from an alcoholic solution of sulphuric or hydrochloric acid. Heated with nitric acid, it is decomposed, forming a resinous substance.

THIOSINANILINE. Syn. with PHENYL-THIOSINAMINE (see above).

THIOSIN-NAPHTHYLAMINE. Syn. with NAPHTHYL-THIOSINAMINE (see above).



THIOTOLUIC ACID, $C^7H^9NSO^3$, more properly, **BENZYLSULPHAMIC** or **TOLYLSULPHAMIC ACID,** $\left.\begin{matrix}C^7H^7.H\\(SO^2)''\\H\end{matrix}\right\}\begin{matrix}N\\O\end{matrix}$. (Hilkenkamp, Ann. Ch. Pharm. xcv. 86.)—An acid related to toluene (benzylic hydride, C^7H^8, i. 573), in the same manner as naphthylsulphamic acid, $C^{10}H^9NSO^3$ (the so-called thionaphthamic acid, p. 778), is related to naphthalene, $C^{10}H^8$. To prepare it, 60 grms. of nitrotoluene are boiled, for eight or ten hours, with 400 grms. of a concentrated solution of ammonium-sulphite, a small quantity of ammonium-carbonate, and a litre of absolute alcohol, the ammoniacal distillate being continually poured back, till the liquid assumes an acid reaction; and the cooled solution, filtered from the crystals which separate, is concentrated, with addition of ammonium-carbonate. The red solution, on cooling, deposits benzylsulphamate of ammonium, in radiate groups of slender needles, which may be rendered colourless by repeated levigation with ether. This salt is easily soluble in water and in alcohol, insoluble in ether. It is permanent in dry air, but turns red in contact with moist air. When heated it first melts, and then chars. Its aqueous solution is not perceptibly altered by acids, even at the boiling heat, and for the most part does not yield precipitates with metallic salts. Chlorine separates from it yellow oily drops, having the odour of tetrachloroquinone.

The *barium-salt*, prepared by adding the ammonium-salt to baryta-water, boiling till all the ammonia is expelled, precipitating the excess of barium by carbonic acid, and evaporating the filtrate, forms white crystalline crusts.—The *potassium-salt*, $C^7H^8KNSO^3$, obtained by boiling the ammonium-salt with carbonate of potassium, evaporating to dryness, and exhausting the residue with boiling absolute alcohol, separates from the alcoholic solution, on cooling, in small nodular groups of crystals, less soluble in water and in alcohol than the ammonium-salt.—The *sodium-salt*, prepared in like manner, forms small, white, nodular crystals, easily soluble in water, sparingly soluble in absolute alcohol.

The acid has not been obtained in the pure state. Neither does the mother-liquor of the crude ammonium-salt, when treated with hydrochloric acid, yield a compound analogous to naphthionic acid.

THIOTOLUOLIC ACID, $C^7H^9NS^2O^6$, more properly, *Benzyldisulphamic* or *Tolyldisulphamic acid*, $\left.\begin{matrix}C^7H^7\\(SO^2)^2\\H^2\end{matrix}\right\}\begin{matrix}N\\O^2\end{matrix}$, has been already described (p. 480).

THIOVALERIC ACID. The product of the action of phosphoric pentachloride on valerianic acid.

THJÖRSA LAVA. A lava from Hekla, consisting of a mixture of the true lava-mass with thjörsanite (anorthite) and chrysolite, both of which minerals occur crystallised in distinct cavities of the lava. The greyish-black lava contains silica, alumina, ferrous oxide, lime, and magnesia, as principal constituents, together with small quantities of soda and potash, and traces of manganese-, nickel-, and cobalt-oxides. (Genth.)

THJÖRSANITE. A variety of anorthite occurring in the Thjörsa lava on Hekla, in crystallo-laminar, brittle, transparent masses, of white to grey colour, and vitreous lustre, nacreous on the cleavage-surfaces. Specific gravity = 2·688 at 17°. Hardness = 6. Insoluble in hydrochloric acid. Melts before the blowpipe in thin splinters. Contains, according to Genth's analyses, 48·75 per cent. silica, 30·59 alumina, 1·50 ferric oxide, 17·22 lime, 0·97 magnesia, 1·13 soda, and 0·62 potash.

THOMAITE. A name applied by Mayor (Bergwerksfreund, viii. 6) to a quadratic variety of ferrous carbonate from the Siebengebirge.

THOMSONITE. *Mesolite* (in part). *Mesotype* (in part). *Needle Zeolite* (in part). *Comptonite. Chalilite. Tripoclase. Ozarkite.*—A hydrated silicate of aluminium, calcium, and sodium, occurring in trimetric crystals, exhibiting the combination $\infty P \,.\, \infty\bar{P}\infty \,.\, oP \,.\, 2\breve{P}\infty \,.\, \infty\breve{P}\infty$. Axes $a : b : c = 1 : 1·0117 : 0·7225$. Angle $\infty P : \infty P = 90° 40'$; $oP : \breve{P}\infty = 144° 9'$. Cleavage easy parallel to $\infty\bar{P}\infty$ and $\infty\breve{P}\infty$. The mineral likewise occurs columnar, with radiated structure, and amorphous. Hardness = 5 to 5·5. Specific gravity = 2·35 to 2·4. Lustre vitreous, inclining to pearly. Colour snow-white; brown in impure varieties. Streak uncoloured. Transparent to translucent. Fracture uneven. Brittle. Before the blowpipe it intumesces, becoming white and opaque, the edges only being rounded at a white heat. When pulverised, it gelatinises with nitric or hydrochloric acid.

Analyses:—*a.* Lochwinnock, Renfrewshire (Thomson's *Outlines*, i. 315).—*b.* Dumbarton (Berzelius, Berz. Jahresb. ii. 96).—*c.* Seeberg, near Kaaden, Bohemia: *Comptonite* (Zippe, Verh. d. Ges. d. vat. Mus. in Böhmen, 1836, p. 3).—*d.* Elbogen, Bohemia: *Comptonite* (Melly, J. pr. Chem. xiv. 511).—*e.* The Cyclopean Isles, near Catania; accompanied by analcime and mesolite (Sart. v. Waltershausen, Vulk. Gest. pp. 272, 286).—*f.* Between the Bulandstind and the Berufjörd, Iceland: pale-yellow, intergrown with scolecite; specific gravity = 2·362 (v. Waltershausen).—*g.* Magnet Cove, Arkansas: in elæolite; specific gravity = 2·24 (Smith and Brush, Sill. Am. J. [2], xvi. 41).—*h.* Dalsmypen, Faröe Islands (Retzius, Berz. Jahresb. iv. 151).—*i.* Hauenstein, in Bohemia: formerly called *mesolite*; specific gravity = 2·357 (Rammelsberg, Pogg. Ann. xlvi. 286):

	a.	*b.*	*c.*	*d.*	*e.*	*f.*	*g.*	*h.*	*i.*
Silica . .	37·68	38·30	38·25	37·00	39·27	39·86	36·85	39·20	39·63
Alumina .	31·66	30·70	32·00	31·07	29·50	31·44	29·24	30·05	31·25
Lime . .	15 25	13·54	11·96	12·60	12·38	13·33	13·95	10·58	7·27
Soda . .	. . .	4·53	6·53	6·25	4·46	6·29	3·91	8·11	8·03

	98·99	100·17	100·24	99·16	100·44	102·31	99·30	101·84	99·48

These analyses lead to the formula:

$$\left.\begin{matrix}(\mathrm{Ca}'';\mathrm{Na}^2)\mathrm{O}.\mathrm{SiO}^2\\ \mathrm{Al}^2\mathrm{O}^3.\mathrm{SiO}^2\end{matrix}\right\}.\tfrac{5}{2}\mathrm{H}^2\mathrm{O},\ \text{or}\ 2\left[\left.\begin{matrix}\mathrm{Ca}'';\mathrm{Na}^2\\ \overset{\prime\prime\prime}{\mathrm{Al}}{}^2\end{matrix}\right\}\mathrm{Si}^2\mathrm{O}^8\right].5\mathrm{H}^2\mathrm{O};$$

whence thomsonite may be regarded as consisting of 2 at. of a sodiferous anorthite with 5 at. water. The mineral from Lochwinnoch appears, from Thomson's analysis, to be a nearly pure hydrated calcio-aluminic silicate (i. 308).

Thomsonite occurs also near Kilpatrick, in Scotland. The variety called *Comptonite* is met with in the lavas of Vesuvius, as well as in the localities above mentioned. Thomson's *Scoulerite* from Portrush, in Ireland, is near thomsonite in composition, but contains less alumina and water, and 3½ per cent. soda. The varieties called *carphostilbite*, *chalilite*, *ozarkite*, and *picrothomsonite* are described in their alphabetical places.

THORINA. See THORINUM, OXIDE OF (p. 787).

THORINUM, or **THORIUM.** *Atomic Weight*, 115·72; *Symbol*, Th.—A very rare element belonging to the group of earth-metals. It was discovered in 1828 by Berzelius in thorite from Esmark, on the Norwegian island Lövön, and has since been found by Wöhler in pyrochlore, by Karsten in monazite, by Bergemann and others in the variety of thorite called orangite, by Mosander and Chydenius (Bull. Soc. Chim. 1866, ii. 433) in euxenite from Arendal, and by Bahr (Pogg. Ann. cxix. 572) in gadolinite, orthite, and a mineral resembling the latter. Bahr at first regarded the earth obtained from these three minerals as the oxide of a new metal, *wäsium*; but he has since recognised its identity with thorina. (Ann. Ch. Pharm. cxxxii. 227.)

Metallic thorinum is obtained by heating the anhydrous chloride with potassium or sodium. The decomposition takes place with slight detonation, but with scarcely visible ignition, and may therefore be performed in a glass vessel. The reduced thorinum, when freed from soluble salts, is a grey metallic powder, which may be easily pressed together, and when triturated with polished agate, acquires an iron-grey metallic lustre. Its specific gravity, according to Chydenius, is 7·657 to 7·795. When heated, it burns with great splendour, producing snow-white thorina, which exhibits not the slightest trace of fusion or aggregation. Thorinum is not oxidised by water, either hot or cold. According to Berzelius, it is but slowly attacked by nitric, sulphuric, or hydrofluoric acid, but dissolves easily in hydrochloric acid, especially when gently heated. According to Chydenius, it disolves easily in nitric, slowly in hydrochloric acid, and in sulphuric acid only when heated. It is not attacked by solutions of caustic alkalis. (Berzelius.)

THORINUM, BROMIDE OF. Obtained by dissolving thorina in hydrobromic acid; dries up to a gummy mass on evaporation; forms a double salt with bromide of potassium. (Berzelius.)

THORINUM, CHLORIDE OF. ThCl^2.—Prepared by heating an intimate mixture of thorina and charcoal in a stream of dry chlorine-gas. The decomposition takes place slowly, and the chloride of thorinum, which is not very volatile, is deposited on the cooler part of the tube, as a white crystalline sublimate; by renewed sublimation, it may be obtained in white shining crystals (Berzelius), which, according to Chydenius, are rectangular four-sided tables, having their edges bevelled by planes inclined to the basal faces at angles of 129° 7′ and 143° 8′. They deliquesce in the air, and dissolve in water with rise of temperature (Berzelius). The chloride does not volatilise at 440°. (Chydenius.)

Hydrate of thorinum dissolves easily in hydrochloric acid, and the solution, when concentrated to a certain strength—especially if it contains excess of hydrochloric acid—solidifies to a radio-crystalline mass of the hydrated chloride. The solution, evaporated to dryness, leaves a deliquescent saline mass, which gives off hydrochloric acid at a higher temperature. Chloride of thorinum is soluble in alcohol.

Ammonio-thorinic chloride, $4\mathrm{NH}^4\mathrm{Cl}.\mathrm{ThCl}^2.4\mathrm{H}^2\mathrm{O}$, is obtained by heating a dry mixture of chloride of thorinum and sal-ammoniac in hydrochloric acid gas, dissolving the product in water, and evaporating (Chydenius).—*Potassio-thorinic chloride* is very soluble, almost deliquescent, but may be dehydrated by ignition in hydrochloric acid gas. It is likewise soluble in alcohol. When heated with potassium, it yields metallic thorinum. (Berzelius.)

Oxychloride.—In the preparation of the chloride, as above described, this compound passes over with the excess of chloride as a white cloud, which condenses to a white amorphous powder. It is decomposed by water, which dissolves chloride of thorinum, leaving the oxide.

THORINUM, DETECTION AND ESTIMATION OF. Before the blowpipe, thorinum is distinguished rather by negative than by positive characters, its oxide being unalterable, infusible, and dissolving with great difficulty in borax; the strongly saturated bead becomes milk-white on cooling; it does not form a coloured glass, either with borax or with microcosmic salt.

Thorinum is precipitated from its neutral solutions by *sulphide of ammonium*, by *ammonia*, and by *potash*, as a white hydrate, insoluble in potash.—The *fixed alkaline carbonates*, and *carbonate of ammonium*, precipitate carbonate of thorinum, soluble in excess of the precipitant; *ammonia* forms no precipitate in this solution, as it does in the corresponding solution of zirconia.—A solution of thorinum-chloride is precipitated by *ferrocyanide of potassium*, which does not form any precipitate with chloride of zirconium.—*Sulphate of potassium* produces. with thorinum-salts, a crystalline precipitate of potassio-thorinic sulphate, soluble in boiling water, but insoluble in excess of the potassium-sulphate,—a character which serves to distinguish thorinum from yttrium. From cerium and the allied metals, thorinum is distinguished by the reaction of its solutions with *hyposulphite of sodium*. which precipitates thorina, but not the oxides of the cerium-metals; from cerium and didymium also by not giving any coloured reactions before the blowpipe.—From titanium, tantalum, and niobium. it is also distinguished by its behaviour before the blowpipe, and in solution by its reaction with *oxalic acid*, which forms a white precipitate of thorinum-oxalate.

Thorinum is estimated as oxide. It is precipitated by *ammonia* as a hydrate, which on ignition yields the pure oxide.

The methods of separating thorinum from other metals are indicated in the preceding paragraph. Precipitation with *sulphate of potassium* in excess serves to separate it from all the metals contained in the sulphide of ammonium precipitate, except zirconium and the cerium-metals.—From zirconia it may be separated by treating the mixed solution with *oxalic acid*, which precipitates both the metals as oxalates; but on adding a slight excess of oxalic acid, the oxalate of zirconium dissolves completely, leaving the oxalate of thorinum behind (H. Rose, *Traité de Chimie Analytique*, ii. 101).—From the cerium-metals thorinum may be separated, as already observed, by means of *sodic hyposulphite*, which precipitates the thorinum as hyposulphite (Chydenius). The precipitation, however, is not complete, and, according to Hermann (J. pr. Chem. xciii. 106), every 1,000 pts. of water retain in solution 0·85 pt. of thorina, or in presence of salts rather less. To effect the separation. Hermann converts all the bases into neutral sulphates, dissolves 10 pts. of these mixed sulphates in 1,000 pts. of water, and heats the solution to the boiling-point with 4 pts. of sodic hyposulphite. A precipitate of thorinic hyposulphite is then formed, while the whole of the cerium-metals remain in solution. The precipitate, when ignited, leaves pure thorina, which must be weighed, and its weight corrected for the amount remaining in solution, amounting to, as above stated. 0·85 pt. The cerium must be previously brought to the state of cerous salt, if not already in that state.

From titanium, tantalum, and niobium, thorinum is most easily separated by precipitation with *oxalate of ammonium*.

Atomic Weight of Thorinum.—The atomic weight of this metal has been determined by the analysis of the sulphate, $Th''SO^4$ or $ThO.SO^3$. Berzelius, in two experiments, obtained the numbers 119·32 and 117·75, and from the mean of fifteen analyses of potassio-thorinic sulphate, $Th''K^2(SO^4)^2$, not agreeing very closely, the number 118·2. Chydenius, partly from his own (not very accordant) experiments, and partly from those of Berzelius, calculates the number 118·32. Delafontaine (N. Arch. ph. nat. xviii. 343; Jahresb. 1863, p. 198) found, as a mean of a considerable number of closely-agreeing analyses, that the sulphate crystallised from hot solutions, $4ThSO^4.9H^2O$, contains 52·51 per cent. ThO, 31·92 SO^3, and 15·80 H^2O; and that the salt crystallised at ordinary temperatures, $2ThSO^4.9H^2O$, contains 45·06 per cent. ThO, and 28·68 H^2O: hence the atomic weight of thorinum is found to be 115·72, the number now adopted.

THORINUM, FLUORIDE OF. ThF^2.—Berzelius, by treating hydrate of thorinum with hydrofluoric acid, and evaporating off the excess of acid, obtained the fluoride as an enamel-white, heavy, insoluble powder, not decomposed by ignition, and only imperfectly when heated with potassium.—The *hydrated fluoride*, $ThF^2.2H^2O$, is obtained, by double decomposition, as a white gelatinous precipitate, which is insoluble in water and in hydrofluoric acid, gives off only part of its water at 200°, and is converted by ignition into thorina. (Chydenius.)

Potassio-thorinic Fluorides.—α. The compound $KF.ThF^2.2H^2O$, is produced by boiling recently precipitated hydrate of thorinum with hydropotassic fluoride and free hydrofluoric acid, and separates as a fine heavy powder.—β. The compound $2KF.4ThF^2.H^2O$ is precipitated by hydropotassic fluoride, from a solution of thorina in hydrochloric acid. (Chydenius.)

THORINUM, IODIDE OF. Crystallises with difficulty; turns brown on exposure to light. (Chydenius.)

THORINUM, OXIDE OF, or **THORINA.** ThO.—This, the only known oxide of thorinum, is prepared from thorite or orangite, or from euxenite.—α. Thorite or orangite, in fine powder, is decomposed with hydrochloric acid; the silica is separated in the usual way, by evaporating to dryness, and digesting the residue with acidulated water; the filtered solution is treated with sulphydric acid to separate lead and tin; and the thorina is precipitated by ammonia, together with small quantities of the oxides of iron, manganese, and uranium. The precipitate is redissolved in hydrochloric acid; the nearly neutral solution is mixed with a hot saturated solution of neutral potassic sulphate, whereby the thorinum is precipitated as potassio-thorinic sulphate; and from the solution of this salt in hot water, the thorinum is precipitated by ammonia as a hydrate, which on ignition yields anhydrous thorina. Or the thorinum may be precipitated from the nearly neutral hydrochloric solution by oxalic acid, and the oxalate converted into thorina by calcination.

β. Euxenite, from Arendal,[*] which contains about 6 per cent. thorina, is calcined and finely pulverised, then heated with excess of strong sulphuric acid; the resulting pasty mass is digested with cold water, in which it is almost wholly soluble; and the solution is boiled, whereupon it deposits titanic and niobic acids; but to ensure complete separation of these acids, the ebullition must be continued for several days. The cooled and filtered liquid is then treated with ammonia to precipitate the bases, the precipitate is dissolved in hydrochloric acid, and the liquid is mixed with a hot saturated solution of potassic sulphate in excess, which precipitates the thorinum, leaving the yttrium, &c. in solution. The thorino-potassic sulphate may then be dissolved in hot water, and the thorina precipitated by ammonia. (Chydenius.)

Properties.—Anhydrous thorina is white, and has the high specific gravity 9·402 (Berzelius). According to Chydenius, the oxide obtained by ignition of the hydrate is greyish-yellow. By fusion with borax, in a porcelain furnace, it is obtained in quadratic crystals, probably isomorphous with tinstone and rutile, and having a density of 9·077 to 9·20 (Nordenskjöld and Chydenius, Pogg. Ann. cx. 642; Jahresb. 1860, p. 134). The ignited oxide is insoluble in hydrochloric and nitric acids, and dissolves in strong sulphuric acid only after prolonged heating to the boiling-point of the acid. It is not rendered soluble in nitric or hydrochloric acid by ignition with alkalis or alkaline carbonates.

Hydrate of thorinum is precipitated from solutions of thorinum-salts by caustic alkalis, as a gelatinous mass, which soon sinks to the bottom of the liquid. When left to dry in the air, it absorbs carbonic acid, and cakes into hard vitreous lumps; under the air-pump it dries up to a white powder (Berzelius). It dissolves readily in all acids, excepting oxalic, molybdic, and hydrofluoric acids. (Chydenius.)

THORINUM, OXYCHLORIDE OF. See p. 786.

THORINUM, OXYGEN-SALTS OF. These salts are colourless, and have a strongly astringent taste; those which contain volatile acids give up their acid on ignition. The behaviour of the solutions with reagents has been already described (p. 786).

Acetate of Thorinum, $Th''(C^2H^3O^2)^2$ (at 100°), forms groups of fine needle-shaped crystals, insoluble in water, and only slightly soluble in dilute acetic acid.—The *carbonate,* $Th''CO^3.3Th''H^2O^2.H^2O$, is obtained by treating the hydrate suspended in water with carbonic acid, or by precipitating a solution of the chloride with an alkaline carbonate, as an amorphous precipitate, which aggregates together in drying.—The *chromate,* $Th''CrO^4.4H^2O$, crystallises indistinctly on evaporating a solution of thorina in chromic acid. A solution of thorinum-chloride gives, with acid potassic chromate, on addition of ammonia, a yellow precipitate of a basic salt.—The *citrate* and *tartrate* are gelatinous precipitates, obtained by adding citric or tartaric acid to a neutral thorinum-salt.—The *formate,* $Th''(CHO^2)^2.2H^2O$, forms tabular efflorescent crystals, which give off 9·77 per cent. water in drying.—The *molybdate* is a white flocculent precipitate, soluble in hydrochloric acid (Chydenius).—The *nitrate*, *oxalate*, *phosphate*, and *sulphate* are described under their respective acids.

---

[*] This mineral contains (according to Chydenius) 54·28 per cent. niobic and titanic oxides, 34·58 yttria and erbia, 6·28 thorina, with small quantities of ferrous and uranous oxides, and 2·60 matter volatilised by ignition (= 97·74).

THORINUM, OXYSULPHIDE OF. See below.

THORINUM, PHOSPHIDE OF. When thorinum is heated in phosphorus-vapour, the two unite with incandescence, forming a grey metallically lustrous mass, which is not attacked by water, and burns to phosphate when heated. (Berzelius.)

THORINUM, SULPHIDE OF. ThS.—Thorinum, heated with sulphur, burns in the vapour with the same splendour as in the air, forming a yellow pulverulent sulphide, which acquires metallic lustre by pressure, and is but slightly attacked by acids; nitromuriatic acid, however, oxidises it to sulphate (Berzelius). Chydenius, by igniting thorina in a mixture of hydrogen-gas and vapour of carbonic disulphide, obtained sulphide of thorinum as a black mass of specific gravity 8·29, becoming grey and metallically lustrous by trituration. It is converted by roasting into thorina, is not attacked by hydrochloric, and only slowly by nitric acid, but dissolves completely in nitromuriatic acid. By fusion with potassium-hydrate it is converted into thorina, and by heating in chlorine-gas into chloride of thorinum; it is not altered by ignition in hydrogen.

When thorina is heated only to low redness in the mixture of hydrogen and carbonic disulphide, an oxysulphide is formed, probably ThS.2ThO. (Chydenius.)

THORITE. *Orangite.*—A hydrated silicate of thorinum, occurring on the island of Lövön, not far from Brevig in Norway. It is massive and compact, of black colour, with vitreous lustre, opaque to translucent on the edges; streak greyish-red. Brittle. Hardness = 4·5 to 5. Specific gravity = 4·63. Before the blowpipe it becomes brown-red, does not melt when heated by itself, but forms, with borax, a glass coloured by iron, and on addition of soda, exhibits the manganese reaction. In its natural state, it dissolves in hydrochloric acid, with evolution of chlorine and separation of gelatinous silica, but after ignition it is scarcely attacked by hydrochloric acid.

The variety called *orangite*, found in the zircon-syenite near Brevig, is yellowish or yellow to brown, yields an orange-yellow powder, is translucent or transparent in thin splinters, has a specific gravity = 5·2 to 5·4, and hardness = 4·5.

Analyses: —*a*. Thorite (Berzelius, Pogg. Ann. xvi. 385).—*b*. Thorite, black, almost glassy: specific gravity = 4·686 (Bergemann, *ibid*. lxxiii. 561; lxxxv. 558).—*c*, *d*, *e*. Orangite: *c* by Bergemann, *d* by Damour (*ibid*. lxxxv. 555), *e* by Berlin (*ibid*. lxxxv. 556):

	SiO^2.	ThO.	U^2O^3.	Fe^2O^3.	Mn^2O^3.	CuO.	MgO	K^2O.	Na^2O.	PbO.	SnO^2.	Al^2O^3.	H^2O.		
a.	19·31	58·91	1·64	3·46	2·43	2·62	0·36	0·15	0·11	0·82	0·01	0·06	9·66	=	99·54
b.	19·21	57·00	..	..	..	..	..	..	..	..	..	..	9·17	=	
c.	17·69	71·25	..	0·31	0·21	4·04	..	0·30		..	..	..	6·90	=	100·70
d.	17·52	71·65	1·13	0·31	0·28	1·59	..	0·14	0·33	0·88	..	0·17	6·14	=	100·14
e.	17·78	73·29	0·96 *		..	0·92	..	..	..	..	..	..	7·12	=	100·07

The analysis of thorite by Berzelius leads to the formula $Th^2SiO^4.2H^2O$; those of orangite to the formula $3Th^2SiO^4.4H^2O$; but the difference of composition is most probably only apparent, and due to impurity in the thorite; indeed, orangite frequently occurs so intimately intergrown with thorite as to show that the two minerals are essentially identical, the orangite being merely the purer variety.

THORIUM. Syn. with THORINUM.

THRAULITE. A variety of hisingerite from Bodenmais in Bavaria (iii. 102).

THRIDACIUM. (from θρίδαξ, lettuce).—The inspissated milky juice of the common lettuce, *Lactuca sativa* (that obtained from *L. virosa* is called lactucarium (iii. 464). It is a grey-brown or yellow bitter substance, having an odour like that of opium, and forming with water a solution which has a brown-yellow colour and acid reaction. Tannin forms in it a copious precipitate; ammonia throws down phosphate of calcium; nitrate of barium, nitrate of silver, oxalate of ammonia, and alcohol produce turbidity. It is said to produce a sedative action, but the nature of the active principle is not exactly known. (Handw. d. Chem. viii. 821).

THROMBOLITE. A cupric phosphate occurring at Retzbanya in Hungary.

THSING-HOA-LIAO. The Chinese name for a cobaltiferous aluminic silicate used in the manufacture of porcelain; also applied to a cobaltiferous manganese-ore, used for producing a blue colour on porcelain.

THUJA. The branches of *Thuja occidentalis*, the North-American *Arbor vitæ*, contain an essential oil, wax, resin, several acids (probably including citric acid), a bitter principle, sugar, and two peculiar yellow colouring-matters, called thujin and thujigenin.

---

* With traces of stannic and vanadic oxides.

When the green branches of *Thuja occidentalis* are boiled with strong alcohol, the decoction on cooling deposits a waxy substance in yellow flocks, becoming white when purified. This body, whose percentage composition is represented by the formula $C^8H^{16}O$, is a mixture of a more soluble and a less soluble substance; when saponified by lime, it yields several acids not yet examined.

When the alcoholic extract of the branches, which likewise contains volatile oil, is distilled, there remains a green resinous mass, said to contain kinovous acid, the acid likewise occurring in the needles of the Scotch fir (iv. 650). The watery liquid separated from the resin yields, on addition of neutral lead-acetate, a yellow precipitate containing thujin, together with pinitannic acid (iv. 651). The liquid filtered from this precipitate gives, with basic lead-acetate, a precipitate probably containing a little citric acid, together with an amorphous tannin, and thujigenin. The filtrate from this last precipitate contains sugar, and a bitter principle, said to be identical with the pinipicrin of the Scotch fir (iv. 651).

If the branches, after treatment with boiling alcohol, are exhausted with water containing a small quantity of alkali, the resulting solution deposits, on addition of an acid, a gelatinous substance having the composition $C^8H^{12}O^{12}$.

The leaves of thuja are said to possess medicinal properties. *Tinctura Thujæ* has been recommended as a remedy for rheumatism, gout, intermittent fever, &c.

The essential oil of thuja, which passes over on distilling the ends of the branches and the leaves with water, is, according to Schweizer (Ann. Ch. Pharm. li. 398), a mixture of several oils, and contains 77 per cent. carbon, 10·9 hydrogen, and 11·4 oxygen. It is colourless when fresh, but soon turns yellow in contact with the air; it has the odour of thuja, is lighter than water, and only slightly soluble therein, but dissolves easily in alcohol and in ether. On fractional distillation, the greater part passes over between 190° and 197°, the boiling-point quickly rising to 206°, and ultimately a brown residue is left.

Crude oil of thuja dissolves large quantities of iodine; and on heating the solution, a violent action takes place, hydriodic acid and a very volatile oil being given off. The residue, when further heated, gives off a dark viscid oil, then vapour of iodine, and leaves a residue of charcoal.

When the volatile oil just mentioned is repeatedly distilled over iodine, then over quicklime and potassium in succession, it becomes colourless, free from oxygen, like turpentine-oil in taste and odour, lighter than water, and boils between 165° and 175°. Thus purified, it constitutes Schweizer's thujene or thujone. The viscid oil, agitated with potash-ley, yields to that liquid, carvacrol (i. 808), separable by sulphuric acid. The portion insoluble in potash appears to be colophene (i. 1086).

Oil of thuja is not sensibly altered by distillation with *phosphoric acid*.—By *oil of vitriol* it is immediately resinised.—Commercial *nitric acid* turns it dark-yellow, without setting it on fire; with *potassium* it resinises without giving off hydrogen.—*Hydrate of potassium* blackens thuja-oil immediately, and resinises a portion of it, whilst another portion passes over unaltered. Repeated distillation of the portion which has gone over with hydrate of potassium diminishes its quantity, but does not perceptibly alter its external characters; after five distillations, the distillate contains 78·87 per cent. C, 10·98 H, and 10·15 O. From the black residue, water separates a resin-soap, soluble in pure water, while carvacrol remains in the alkaline solution. (Schweizer.)

THUJENE. Syn. with THUJONE.

THUJETIC ACID. $C^{28}H^{22}O^{13}$. (Rochleder and Kawalier, Wien. Akad. Ber. xxix. 14.)—This acid, which contains the elements of 3 at. water less than thujetin (*infra*), is prepared: 1. By boiling thujetin with baryta-water, adding sulphuric acid after a while, then alcohol, and filtering the liquid while hot; it then separates in microscopic crystals.—2. Together with crystallisable sugar, by boiling thujin for some hours with baryta-water in an atmosphere of hydrogen, till a reddish-yellow precipitate is formed. On passing carbonic anhydride through the liquid, filtering, and treating the washed precipitate with acetic acid to dissolve the baryta, thujetic acid remains undissolved. It forms lemon-yellow microscopic needles, soluble in alcohol, and precipitated by water.

THUJETIN. $C^{28}H^{28}O^{16}$. (Rochleder and Kawalier, Wien. Akad. Ber. xxix. 12.)—A compound obtained, together with crystallisable sugar, by heating thujin with dilute acids; the liquid, which is green at first, becomes yellow after some time, then colourless, and deposits thujetin after evaporation of the alcohol. Thujetin is likewise obtained in the preparation of thujin and thujigenin, in the manner presently to be described.

Thujetin is nearly insoluble in *water*, but dissolves in *alcohol* and in *ether*. It is not altered by dilute *hydrochloric* or *sulphuric acid*. Its alcoholic solution assumes a splendid blue-green colour on addition of *ammonia*; green with *potash*, becoming yellow, and finally red-brown on standing, and then yielding red flocks with acids. It forms red precipitates with the *neutral* and *basic* acetates of lead, colours *ferric chloride* like ink, and after a while throws down a dark-coloured precipitate. It colours *stannic chloride* dark-yellow, *nitrate of silver* blackish-grey, and *platinic chloride* gradually yellowish-brown.

By boiling with *baryta-water*, it is converted into thujetic acid: $C^{28}H^{28}O^{16} - 3H^2O = C^{28}H^{22}O^{13}$.

THUJIGENIN. $C^{28}H^{24}O^{14}$. (Rochleder and Kawalier, Wien. Akad. Ber. xxix. 10).—A compound occurring in very small quantity in *Frondes Thujæ*, the green parts of *Thuja occidentalis*, and produced, together with sugar, when thujin is heated with hydrochloric acid (p. 791).

Preparation.—Comminuted *Frondes Thujæ* are boiled with alcohol; the decoction is strained and left to cool; the deposited wax is separated; the alcohol is distilled from the filtrate; and the residue is mixed with water, a few drops of solution of neutral acetate of lead being added to facilitate the filtration. The filtrate is completely precipitated by neutral acetate of lead, and the yellow precipitate (*a*), containing thujin and thujetin, is used for the preparation of these substances. The filtered liquid, mixed with basic acetate of lead, yields a second precipitate (*b*) containing thujigenin.

a. Preparation of Thujin.—The precipitate *a* is washed with water, and dissolved in dilute acetic acid; the liquid is filtered from undissolved matter; the filtrate precipitated with basic acetate of lead; the washed precipitate decomposed under water by sulphydric acid; the liquid heated with the sulphide of lead, and filtered hot; the sulphide of lead washed with a small quantity of hot water; and the filtrate, after being freed from sulphydric acid by heating it in a stream of carbonic anhydride, is evaporated in a vacuum over oil of vitriol. The liquid, after standing for some days, deposits crystals of thujin, which are collected, dissolved in boiling water, with addition of alcohol, again left to crystallise, and recrystallised till the solution of the substance in weak spirit no longer turns green on addition of ammonia. The sulphide of lead still retains a small portion of thujin, which may be obtained by boiling with alcohol.

b. Preparation of Thujigenin.—The precipitate *b*, formed by basic acetate of lead, is washed, suspended in water, and decomposed by sulphydric acid: and the liquid is heated with the sulphide of lead, and filtered hot through a warmed filter. The filtrate, heated as above in a stream of carbonic anhydride, and evaporated in a vacuum, deposits flocks of thujigenin.

c. If the chief object is to obtain thujigenin, the liquids obtained by decomposing with sulphydric acid the two precipitates (*a* and *b*) produced by neutral and basic acetate of lead, are evaporated till thujin and thujetin separate out from them: these substances are removed, and the filtrate is mixed with hydrochloric acid, warmed in the water-bath till it begins to show turbidity, and then quickly cooled. It then deposits thujigenin, which must be collected, dissolved in alcohol, and precipitated by water.

By further heating the liquid from which the thujigenin has separated, and then cooling it, thujetin is obtained, contaminated with a red substance, from which it may be freed by repeated solution in alcohol and precipitation with water.

Properties and Reactions.—Thujigenin forms microscopic needles very slightly soluble in water, but soluble in alcohol, and precipitated almost completely by water. When boiled with *chloride of acetyl*, it turns red, and after prolonged action, is converted into acetyl-thujigenin, $C^{28}H^{22}(C^2H^3O)^2O^{14}$, a resinous body precipitable by water.

The investigation of thujigenin is still incomplete; it remains to be determined whether this substance can be formed artificially, and how far it differs from thujetin.

THUJIN. $C^{20}H^{22}O^{12}$. (Rochleder and Kawalier, *loc. cit.*)—A crystallisable glucoside, occurring in the green parts of *Thuja occidentalis*. The mode of preparing it has just been described. 240 lbs. of *Frondes Thujæ* yield only a few grammes of thujin.

Thujin forms shining lemon-yellow crystals, appearing under the microscope as four-sided tables. It has an astringent taste, and is soluble in alcohol.

The alcoholic solution is coloured yellow by *ammonia* or *potash*, red-brown with access of air, and yields a fine yellow precipitate with *neutral* or *basic acetate of lead*. It is coloured dark-green by *ferric chloride*, does not precipitate *cupric sulphate*, *platinic chloride*, or *nitrate of silver*, but the silver-solution becomes blackish-grey on addition of ammonia.

positions.—1. Thujin heated on platinum-foil burns, and leaves a carbonaceous residue, which burns away slowly, but completely.—2. When heated in alcoholic solution with dilute *hydrochloric* or *sulphuric acid*, it turns green, then yellow, and is resolved into thujetin, which separates out, and sugar. 100 pts. thujin take up 7·3 pts. water, and yield 40·48 pts. sugar and 66·78 pts. thujetin:

$$2C^{20}H^{22}O^{12} + 4H^2O = 2C^6H^{12}O^6 + C^{28}H^{28}O^{16}.$$

Thujigenin appears also to be formed when thujin is heated for a short time with hydrochloric acid (p. 790).—3. Thujin dissolves in *baryta-water*, forming a yellow solution, which, when heated, deposits an orange-yellow precipitate of thujetic acid, becoming dark reddish-yellow by continued boiling, while sugar remains in solution:

$$2C^{20}H^{22}O^{12} + H^2O = C^{28}H^{22}O^{13} + 2C^6H^{12}O^6.$$

THUJONE. A volatile hydrocarbon, obtained by the action of iodine on oil of thuja (p. 789).

THULITE. See EPIDOTE (ii. 490).

THUMITE. Syn. with AXINITE (i. 477).

THURINGITE. *Owenite.*—A silicate of iron and aluminium, occurring as an aggregate of minute scales, which are distinctly cleavable in one direction, have an olive-green colour, and nacreous lustre. Hardness = 2·5. Specific gravity = 3·18 to 3·20. Before the blowpipe it melts, with moderate facility, to a black magnetic glass; gives off water when heated in a tube; and dissolves in hydrochloric acid, with separation of gelatinous silica.

Analyses.—*a.* From Reichmannsdorff, near Saalfeld, in Thuringia (Rammelsberg, *Mineralchemie*, p. 851).—*b.* The same (Smith, Sill. Am. J. [2], xviii. 372).—*c.* Schmiederberg, near Saalfeld (Genth and Keyser, *ibid.* xvi. 167; xviii. 410).—*d.* Potomac river: *Owenite* (Smith).—*e.* The same (Genth and Keyser):

	SiO^2.	Al^2O^3	Fe^2O^3.	FeO.	MgO.	Na^2O and K^2O.	H^2O.		
a.	22·35	18·39	14·86	34·34	1·25	. .	9·81	=	101·00
b.	22·05	16·40	17·66	30·78	0·89	0·14	11·44	=	99·36
c.	23·55	15·63	13·79	34·20	1·47	. .	10·57	=	99·21
d.	23·55	16·46	14·33	32·78	1·60	0·46	10·48	=	99·66
e.	23·21	15·59	13·89	34·58	2·62	0·49	10·59	=	100·97

These analyses lead to the formula $2(2FeO.SiO^2).(Al^2O^3;Fe^2O^3)^2SiO^2.4H^2O$.

THYME, OIL OF. The herb of garden thyme (*Thymus vulgaris*, L.) yields, by distillation with water, a volatile oil, which in the fresh state is colourless or yellowish, and mobile; the oil commonly occurring in commerce, however, is red-brown or brownish-red, and becomes thicker and darker by age. It has a pleasant pungent odour of thyme, and an aromatic camphorous taste. Its specific gravity is between 0·87 and 0·90. It dissolves sparingly in *water*, in about its own bulk of *alcohol* of specific gravity 0·85, and easily in *ether*. *Iodine* acts but slightly on oil of thyme; *alcoholic potash* dissolves it. It turns the plane of polarisation to the left, a column 100 millimetres long producing a deviation of $-8°$ to $-9°$.

Oil of thyme is a mixture of at least two hydrocarbons, namely thymene, $C^{10}H^{16}$, and cymene, $C^{10}H^{14}$, together with an oxygenated camphor or stearoptene, called thymol, $C^{10}H^{14}O$ (which is said to constitute about half of the crude oil), and perhaps other oxidised products of the hydrocarbons.

On submitting the crude oil to fractional distillation, the thymene passes over between 160° and 165°, and the cymene between 170° and 180°. This latter hydrocarbon may also be separated from the thymene by treating the mixture with strong sulphuric acid, washing the undissolved portion with water, and rectifying. The hydrocarbon thus obtained has the composition $C^{10}H^{14}$, and appears to be identical in every respect with cymene obtained from Roman cumin-oil.

On continuing the distillation of the thyme-oil, there passes over, between 185° and 225°, a mixture of thymene (and cymene) with about $\frac{1}{3}$ pt. of thymol, and between 225° and 335°, pure thymol, which may be separated from the remaining portions of hydrocarbon by solution in potash-ley. (Lallemand, Ann. Ch. Pharm. ci. 119; cii. 119.)

A pound of thyme yields, according to different statements, from 20 to 90 grains of oil, the quantity, doubtless, varying with the locality in which the plant is grown.

Wild thyme (*Thymus serpyllum*) yields, by distillation with water, from 0·08 to 0·09 per cent. of a yellow oil, having an agreeable odour of lemons and thyme, and an aromatic bitter taste. Alcohol of specific gravity 0·85 dissolves it in all proportions. (Herberger, Repert. Pharm. xxxiv. 41; Zeller, *Studien über ätherische Oele*, Landau, 1850.)

THYMEID. See under THYMOÏL (p. 793).

THYMENE. $C^{10}H^{16}$. (Lallemand, Ann. Ch. Phys. [3], xlix. 155.)—A hydrocarbon belonging to the camphene-group, and constituting the most volatile portion of the oil of garden thyme, distilling between 160° and 185° (p. 791). It may be purified by agitation with potash-ley, and repeated fractional distillation over potassium-hydrate; after this treatment, however, it usually still retains a small quantity of cymene, which may be removed by fractional distillation.

Thymene is a colourless oil, having an agreeable odour of thyme, boiling at 160°—165°, and of specific gravity 0·868 at 20°. It deflects the plane of polarisation to the left, but less strongly after repeated rectification over caustic potash (Lallemand). It dissolves in *oil of vitriol*, with rise of temperature, and yields by distillation the same products as oil of turpentine.—It absorbs *hydrochloric acid gas*, with slight rise of temperature, and forms a compound which remains liquid at −20°, and, after purification with chalk and animal charcoal, contains 20 per cent. chlorine. (Lallemand.)

From the volatile oil of the seeds of *Ptychotis Ajowan*, Stenhouse obtained, by fractional distillation, dehydration with chloride of calcium of the portion which passed over below 176°, distillation over caustic potash, treatment with sodium, and rectification, a colourless, strongly refracting oil, having a pungent aromatic odour, different from that of oil of thyme, of specific gravity 0·854 at 12°, and boiling at 172°. It formed with hydrochloric acid gas a brown thin liquid. It contains 88·24 per cent. C and 11·5 H, and is therefore $C^{10}H^{16}$, and perhaps identical with Lallemand's thymene. According to Haines (Ann. Ch. Pharm. xcviii. 315), it consists of cymene, $C^{10}H^{14}$.

THYMICIC ACID. Syn. with THYMOTIC ACID (p. 795).

THYMINE. This name was applied by Gorup-Besanez to a crystallisable, slightly basic substance, obtained from the thymus-gland, which, however, he afterwards found to be identical with leucine.

THYMOÏL. $C^{12}H^{16}O^2$. (Lallemand, Ann. Ch. Phys. xlix. 160; Ann. Ch. Pharm. cii. 119.)—A product of the oxidation of thymol. It is obtained by dissolving thymol in excess of sulphuric acid, diluting the liquid with five or six times its volume of water, and gradually mixing it in a retort with manganic peroxide or potassic dichromate; great heat is then evolved, and on distilling the liquid, water passes over, together with formic acid, and a yellow oil which soon solidifies. This substance, which is thymoïl, may be purified by recrystallisation from ether-alcohol.

Thymoïl forms reddish-yellow, four-sided, shining, crystalline laminæ, having an aromatic odour, recalling at the same time that of iodine and that of chamomile. It is heavier than *water*, only slightly soluble therein, sparingly soluble also in *alcohol*, easily in *ether*. It melts at 48°, gives off copious vapours at 100°, sublimes at a stronger heat, and boils with partial decomposition at about 235°, leaving in the retort a dark-red oily residue, which solidifies on cooling to a violet metallically lustrous mass.

Thymoïl is easily altered by light; when exposed to sunshine for some days in a sealed tube, it becomes quite black, and is converted into a mixture of several compounds, from which alcohol extracts thymoïlol and thymeid, together with other substances, and leaves a small quantity of a yellowish powder, consisting of oxythymoïl, $C^{12}H^{16}O^3$. This body is insoluble in water and in alcohol, sparingly soluble in ether, melts without decomposition at 100°, is insoluble in alkalis, and is, on the whole, a very indifferent substance.

Thymoïl dissolves in strong sulphuric or nitric acid at ordinary temperatures, and is separated therefrom unaltered by water. If the action of the acids be long continued, or assisted by heat, decomposition takes place, but the products have not been examined.

Chlorine acts slowly on thymoïl, and only when assisted by heat, forming chlorinated substitution-products.

Fused thymoïl slowly absorbs dry *ammonia-gas*, forming thymoïlamide, $N.H^2.C^{12}H^{15}O$, a dark-red, uncrystallisable, hard, brittle mass, which softens at 100°, so that it may be drawn into threads, and is soluble in alcohol.

In contact with *potash-ley*, thymoïl quickly absorbs oxygen from the air, and dissolves to a brown-red liquid, containing the potassium-salt of thymoïlic acid:

$$\underset{\text{Thymoïl.}}{4C^{12}H^{16}O^2} + O^{12} = \underset{\substack{\text{Thymoïlic}\\\text{acid.}}}{C^{48}H^{62}O^{19}} + H^2O;$$

The thymoïlate of potassium may be obtained by saturating the liquid with carbonic acid, evaporating to dryness, and exhausting the residue with alcohol; and on decomposing the solution of this salt with hydrochloric acid, thymoïlic acid is obtained, in yellow uncrystallisable flocks, sparingly soluble in water. All the thymoïlates, except the silver- and lead-salts, are soluble in water. The lead-salt has the composition $C^{48}H^{62}\overset{\prime\prime}{Pb}{}^{3}O^{13}$, showing that the acid is tribasic.

Thymoïl, under the influence of *reducing agents* (such as nascent hydrogen, sulphurous acid, ferrous sulphate, and stannous chloride), takes up 2 at. hydrogen, and is converted into thymoïlol, $C^{12}H^{18}O^2$, a compound homologous with colourless hydroquinone (iii. 213).

Strong aqueous sulphurous acid colours thymoïl dark-violet at first, but this colour disappears again, and after a few days the thymoïl is found to be converted into white flocculent thymoïlol, which may also be obtained, in a similar manner, by treating thymoïl with stannous chloride, &c. By recrystallisation from alcohol, it is obtained in small, colourless, four-sided prisms, which are inodorous and tasteless, dissolve sparingly in water, easily in alcohol and ether, melt at 145°, and distils without decomposition at 290°.

By the action of *oxidising agents*, thymoïlol is reconverted into thymoïl, this transformation being produced almost instantly by nitric acid, chlorine-water, ferric chloride, silver-nitrate, or potassic dichromate. In the oxidation of thymoïlol, however, as well as in the action of reducing agents upon thymoïl, a transient violet coloration is produced, indicating the formation of a body intermediate between thymoïl and thymoïlol. This body, thymeïd, $C^{24}H^{34}O^4 = C^{12}H^{16}O^2$ (thymoïl) + $C^{12}H^{18}O^2$ (thymoïlol), is obtained pure by mixing equal weights of thymoïl and thymoïlol in alcoholic or ethereal solution. The liquid then immediately assumes a blood-red colour, and yields, on evaporation, violet crystals, which exhibit by reflected light a greenish metallic lustre, like that of the wing-cases of many insects.

From these relations, thymoïl may be regarded as homologous with quinone, thymoïlol with colourless hydroquinone, and thymeïd with green hydroquinone or quinhydrone; thus,—

$$\underset{\text{Thymoïl.}}{C^{12}H^{16}O^2} + \underset{\text{Thymoïlol.}}{C^{12}H^{18}O^2} = \underset{\text{Thymeïd.}}{C^{24}H^{34}O^4}.$$

$$\underset{\text{Quinone.}}{C^{6}H^{4}O^2} + \underset{\text{Hydroquinone.}}{C^{6}H^{6}O^2} = \underset{\text{Quinhydrone.}}{C^{12}H^{10}O^4}.$$

THYMOÏLAMIDE.
THYMOÏLIC ACID. } See under THYMOÏL.
THYMOÏLOL.

THYMOL. $C^{10}H^{14}O = \left.\begin{matrix}C^{10}H^{13}\\ H\end{matrix}\right\}O$. *Thymylic Hydrate. Thymylic Alcohol. Thymylic Acid. Camphor* or *Stearoptene of Thyme-oil.*—This compound, the oxygenated constituent of thyme-oil (p. 791), is isomeric with cymylic alcohol (ii. 298), and homologous with phenol. It was first obtained from thyme-oil by Doveri (Ann. Ch. Pharm. lxiv. 374), and afterwards examined more particularly by Lallemand (Ann. Ch. Phys. [3], xlix. 148; Ann. Ch. Pharm. cii. 119); it appears to be identical with the stearoptene of the volatile oil of horsemint (*Monarda punctata*, L.), which was examined by Arppe (Ann. Ch. Pharm. lviii. 42), and with that of the oil of *Ptychotis Ajowan*, an East Indian umbelliferous plant, examined by Stenhouse and by Haines (iv. 746).

Preparation.—Thymol is obtained from thyme-oil, of which it forms about one-half, by fractional distillation, passing over chiefly between 225° and 235°. The more volatile portion, however (chiefly consisting of thymene and cymene, p. 791), likewise contains considerable quantities of thymol, which may be obtained by agitating the liquid with soda-ley, separating the undissolved oil, diluting the alkaline solution with water, and supersaturating it with hydrochloric acid. Part of the thymol sometimes crystallises spontaneously from the thyme-oil on cooling. Thymol is purified by crystallisation from alcohol.

Thymol is likewise obtained from the volatile oil of horsemint, and from that of *Ptychotis Ajowan* by fractional distillation and recrystallisation.

Properties.—Thymol crystallises in transparent rhomboïdal plates, with angles of 97° 30′, striated parallel to the lateral faces, and often aggregated into irregular six-sided tables (Arppe). From the oil of *Ptychotis Ajowan*, it crystallises (according to W. H. Miller) in rhombohedral crystals; from alcoholic solution in very thin plates, which appear monoclinic in consequence of the great development of two parallel rhombohedral faces. (For the angular measurements, see *Gmelin's Handbook*, xiv. 410.)

Thymol has a mild odour, which (according to Lallemand) is quite distinct from that of thyme-oil, and an aromatic peppery taste. In the solid state, it is somewhat heavier than water; specific gravity = 1·0285; in the liquid state rather lighter. It does not act on polarised light. Its melting-point is variously stated. According to Lallemand, it melts at 44° to a colourless liquid, and remains fluid for a long time after cooling; but if pure, it solidifies immediately when touched by a solid body. According to Arppe, it melts at 48°, and does not solidify till cooled to 27°. Thymol from the oil of *Ptychotis Ajowan* melts, according to Haines, at 53°; according to Stenhouse, at 44°. Thymol boils at 230° (Doveri; Lallemand), at 231° (Haines), at 222° (Stenhouse), and distils without decomposition. Vapour-density, obs. = 5·4; calc. = 5·2.

Thymol dissolves in about 300 pts. of *water*, easily in *alcohol*, *ether*, and *strong acetic acid*, and is not precipitated from the alcoholic solution by water. It is not altered by aqueous *ammonia*, but takes up a large quantity of *gaseous ammonia*, becoming liquid, but resolidifying after the ammonia has escaped. It dissolves in aqueous *potash* and *soda*, forming compounds which are soluble in water and in alcohol; but are very unstable, being decomposed by acids, even by the carbonic acid of the air, with separation of thymol.

When thymol-vapour is passed over *soda-lime* heated to dull redness, no gas is evolved, but a crystallisable thymolate of sodium, $C^{10}H^{13}NaO$, is formed, which melts when heated, and when dissolved in water forms precipitates with mercuric chloride and silver-nitrate. The mercury-compound, which is a basic salt, $C^{20}H^{26}Hg''O^2.Hg''O$, has a greyish-violet colour, is not decomposed at ordinary temperatures by dilute sulphuric or nitric acid, but is decomposed by hydrochloric acid, with separation of thymol. Alcoholic thymol does not precipitate the alcoholic solution of neutral lead-acetate; neither does it precipitate silver-nitrate, even after addition of ammonia.

Decompositions of Thymol.—1. Thymol is somewhat altered by repeated distillation, the liquid which passes over containing less carbon than the original substance (Stenhouse).—2. It is decomposed by *phosphoric anhydride*, but the products have not been obtained in very definite form.—3. Strong *sulphuric acid*, at 50°—60°, converts it into thymylsulphuric acid $C^{10}H^{14}SO^4$; but when heated with excess of sulphuric acid to 240°, it yields sulphodraconic acid (p. 521).—4. It dissolves in *glacial acetic acid*, and subsequent addition of sulphuric acid forms acetothymylsulphuric acid, $C^{12}H^{16}SO^5 = (C^2H^3O)(C^{10}H^{13})SO^4$ (Lallemand).—5. Thymol is easily oxidised by *chromic acid*, or by a mixture of sulphuric acid and manganic peroxide, yielding a distillate containing formic acid and thymoïl, $C^{12}H^{16}O^2$ (p. 792), and a residue consisting of a brown acid, solid and friable at ordinary temperatures, and dissolving with dark-red colour in alcohol.—6. *Nitric acid*, whether dilute or concentrated, acts violently on thymol, giving off nitrous and carbonic anhydrides, and forming a number of products, chiefly resinous bodies, and a large quantity of oxalic acid.—7. *Chlorine* in diffused daylight acts with great violence on thymol, with rise of temperature, and elimination of hydrochloric acid gas, the thymol remaining liquid, and assuming a wine-red colour at the beginning of the action. If too great heat be avoided, the product consists of trichlorothymol; then, if the passage of the chlorine be continued in bright daylight, a very viscid oil is formed, from which pentachlorothymol gradually crystallises (Lallemand).—8. *Oil of thyme*, distilled with 8 pts. chloride of lime and 24 pts. water, yields chloroform (Chautard, Compt. rend. xxxiv. 485).—9. *Bromine*, in sunshine, converts thymol into pentabromothymol (Lallemand).—10. Thymol is not altered by *hydrochloric acid* (Stenhouse). When hydrochloric acid gas is passed over thymol, it quickly assumes a brown, and, after removal of the excess of hydrochloric acid, a purple-brown colour, but does not increase in weight by more than 2 to 3 per cent., even when heated; on distilling the product, unaltered thymol is first obtained, then a red substance (Arppe).—11. Thymol gently heated with *sodium* in a stream of *carbonic anhydride*, takes up the elements of the latter, forming thymyl-carbonic acid, $C^{11}H^{14}O^3 = C^{10}H^{14}O.CO^2$, together with thymotic acid, an acid isomeric therewith. (Kolbe and Lautemann, p. 795.)

Derivatives of Thymol.

Pentabromothymol, $C^{10}H^9Br^5O$.—Thymol subjected to the action of bromine, ultimately in sunshine, is completely converted into a solid, white, earthy mass of pentabromothymol, which may be recrystallised from ether, melts at a rather high temperature, with incipient decomposition and evolution of hydrobromic acid, but apparently without simultaneous formation of hydrocarbon. (Lallemand.)

Chlorothymols.—*a. Trichlorothymol*, $C^{10}H^{11}Cl^3O$, is obtained by passing chlorine-gas into thymol in diffused daylight (taking care to avoid too much heating), till the thymol has absorbed a quantity of chlorine equal to two-thirds of its weight. On leaving the product to stand, long yellow needles are formed, which ultimately cause it to solidify: they may be purified by expressing the remaining liquid, and recrystallising from ether-alcohol.

Trichlorothymol crystallises in lemon-yellow, oblique rhombic prisms, which melt at 61°, and have an intoxicating odour. It decomposes at 180°.—Heated with *oil of vitriol* to 100°, it is converted into a colourless liquid, which floats on the oil of vitriol, solidifies on cooling, and, after solution in aqueous potash, precipitation with hydrochloric acid, and drying, forms silky talc-like flocks. This substance has at first an agreeable odour of benzoin, melts at 45°, and distils without decomposition at 250°; it dissolves in ammonia, and forms a salt crystallising in slender needles,—whence it is probably trichlorophenol, with which it appears to agree in composition.

β. *Pentachlorothymol*, $C^{10}H^{9}Cl^{5}O$. (Lallemand, *loc. cit.*)—When thymol is exposed for a considerable time to the action of dry chlorine-gas in bright daylight, a reddish-yellow glutinous oil is formed, in which, after a while, crystals of pentachlorothymol appear: they may be purified by recrystallisation from ether.

This compound forms colourless, very hard crystals, having the form of trichlorothymol (according to another statement of Lallemand, it has the form of thymol), melting at 98°. It decomposes at 200°, giving off hydrochloric acid gas and tritylene-gas, $C^{3}H^{6}$, while a solid product (trichlorotoluenol, $C^{7}H^{5}Cl^{3}O$) collects in the neck of the retort, and charcoal remains behind:

$$2C^{10}H^{9}Cl^{5}O \;=\; C^{7}H^{5}Cl^{3}O \;+\; C^{3}H^{6} \;+\; 7HCl \;+\; CO \;+\; C^{9}.$$

In one experiment, in which very pure pentachlorothymol was heated, the carbonic oxide evolved towards the end of the process was mixed with marsh-gas, and the solid distillate, melting at 150°, and crystallising from alcohol in needles, had the composition of tetrachlorotoluenol:

$$4C^{10}H^{9}Cl^{5}O \;=\; 2C^{7}H^{4}Cl^{4}O \;+\; 2C^{3}H^{6} \;+\; 12HCl \;+\; CH^{4} \;+\; 2CO \;+\; C^{17}.$$

Impure pentachlorothymol yielded also, by distillation, a large quantity of liquid product, which, after the solid products had been removed by weak potash-ley, boiled at 265° (or, according to Lallemand's first statement, at 365°), and had the composition of dichlorocumene, $C^{9}H^{10}Cl^{2}$.

Nitrothymols.—These compounds, which possess acid properties, are probably formed by the direct action of nitric acid upon thymol, but they are more easily prepared from thymylsulphuric acid. (Lallemand, Ann. Ch. Phys. [3], xlix. 152.)

α. *Dinitrothymol*, or *Dinitrothymic Acid*, $C^{10}H^{12}(NO^{2})^{2}O$.—When nitric acid is slowly dropped into thymylsulphuric acid, or into the solution of a thymylsulphate, the liquid becomes slightly warm, and deposits dinitrothymol as a reddish oil, which soon solidifies in crystals. This compound melts at 55°, is sparingly soluble in water, and dissolves in all proportions of alcohol and ether. It is converted, by a mixture of nitric and sulphuric acid, into trinitrothymol, and by alcohol and sulphuric acid, into ethylic dinitrothymolate.—With bases it forms salts, which crystallise in silky needles, detonate at 150°, and dissolve sparingly in water, to which however they impart a strong colour.—The *potassium-salt* is orange-yellow in the anhydrous, red in the hydrated state, very slightly soluble in water.—The *lead-salt*, $C^{20}H^{22}Pb''(NO^{2})$, is very sparingly soluble in water; so likewise is the *silver-salt*.

β. *Trinitrothymol*, or *Trinitrothymic Acid*, $C^{10}H^{11}(NO^{2})^{3}O$.—To prepare this compound, dinitrothymol is dissolved in sulphuric acid, and a small quantity of nitric acid is gradually added, without allowing the mixture to get hot. On diluting with water, yellowish flocks of trinitrothymol are precipitated, which may be recrystallised from boiling water. It forms beautiful yellow needles, which melt at 100°, and decompose suddenly at a higher temperature; dissolves sparingly in cold *water*, easily in *alcohol* and in *ether*.—A mixture of *oil of vitriol* and *alcohol* readily converts it into solid trinitrothymic ether.

It unites with *bases*, forming yellow or orange-yellow salts, which detonate at 150°, and dissolve in water more readily than the dinitrothymates. The aqueous solution of trinitrothymate of potassium precipitates the salts of the heavy metals.—*Trinitrothymate of lead* contains 28·83 per cent. lead-oxide, and is therefore $C^{20}H^{20}Pb''(NO^{2})^{6}O^{2}$.

THYMOTIC ACID. $C^{11}H^{14}O^{3} = C^{10}H^{14}O.CO^{2}$. (Kolbe and Lautemann, Ann. Ch. Pharm. cxv. 205.)—This acid, isomeric with thymyl-carbonic acid, $C^{10}H^{13}.H.CO^{3}$, is prepared by gently heating thymol with sodium in a flask through which a rapid current of carbonic anhydride is passed. A viscid yellowish-brown mass is thereby formed, containing thymyl-carbonate and thymotate of sodium; and by decomposing this mass with hydrochloric acid, agitating the liquid with excess of ammonium-carbonate, and boiling down the liquid separated from the thymol till it exhibits a faint acid reaction, a clear solution of sodic thymotate is obtained, from which, on addition of hydrochloric acid, thymotic acid separates in colourless flocks, containing a little resin. It is purified by distillation with water, partly going over with the water, and partly remaining as a crystalline deposit in the condensing tube.

Thymotic acid thus prepared is a white, loosely coherent, crystalline mass, having a silky lustre. It is nearly insoluble in cold, and only slightly soluble in boiling water; from the boiling saturated solution it crystallises, by slow cooling, in long slender needles; when boiled with water, it gives off pungent irritating vapours. It melts at 120°, expands in solidifying, and may be sublimed without alteration.

Thymotic acid, left in contact with a warm solution of *ferric chloride*, dissolves with fine blue colour; the neutral solution of the ammonium-salt is immediately coloured deep blue by ferric chloride.—Thymotic acid heated with *caustic baryta* is resolved into thymol and carbonic anhydride. (Kolbe and Lautemann.)

By *pentachloride of phosphorus*, it is converted into thymotide (Naquet):

$$\underset{\text{Thymotic acid.}}{C^{11}H^{14}O^{3}} + PCl^{5} = PCl^{3}O + 2HCl + \underset{\text{Thymotide.}}{C^{11}H^{12}O^{2}}.$$

The thymotates of the *alkali-metals* are soluble in water.—The *barium-salt* is obtained in large tables or laminæ, by dissolving the acid in baryta-water, and separating the excess of baryta with carbonic acid, or by mixing thymotate of ammonium with chloride of barium, and evaporating. The lead-, copper-, and silver-salts are flocculent precipitates.

THYMOTIDE. $C^{11}H^{12}O^{2}$. (Naquet, Bull. Soc. Chim. [1865], ii. 92.)—A body produced by the action of pentachloride of phosphorus on thymotic acid (*supra*), or by heating the latter to 200° with phosphoric anhydride. To prepare it, 1 at. sodic thymotate is heated with 2 at. phosphoric pentachloride (the action begins, however, in the cold), the heat being ultimately raised to 200°. Hydrochloric acid and phosphoric oxychloride are then given off, and a pasty mass remains, which, when freed from the oxychloride by water, dissolves completely in ether. The ethereal solution leaves, on evaporation, a gummy residue free from chlorine, which gives up to boiling water an acid, forming a white precipitate with ferric salts (probably thymyl-phosphoric acid); from the residue, dilute potash extracts thymotic acid. The portion then remaining undissolved consists of thymotide and a yellowish resin having nearly the same composition.

Thymotide crystallises from alcohol in white, mostly microscopic needles, which melt at 187°, are not altered by hot potash-ley or by heating to 200° with water, but by fusion with potassium-hydrate are converted, without evolution of gas, into thymotic acid.

THYMUS. See Thyme, Oil of (p. 791).

THYMUS-GLAND. (Gorup-Besanez, Ann. Ch. Pharm. lxxxix. 115; xcviii. 1.—Städeler and Frerichs, Müller's Archiv. [1854], p. 383; Wiener med. Wochenschr. [1854], No. 30; Verhandl. d. naturforsch. Gesellsch. z. Zürich, Bd. iii. u. iv.; J. pr. Chem. lxxii. 48.—Scherer, Ann. Ch. Pharm. cvii. 314.—Friedleben, *Die Physiologie der Thymusdruse*, Frankfurt, 1858.)—This gland, called "sweetbread" in the calf and lamb, is an organ situated in front of the pericardium and the large vessels arising from the base of the heart. In the embryo and the infant, it has, in proportion to the rest of the body, a very considerable size, but in after-life it becomes comparatively smaller, and at last nearly disappears. It has been found to contain, besides water and the chemical constituents of its solid tissue, the following organic compounds:—soluble albumin, leucine, sarcine, xanthine, volatile fatty acids (including formic and acetic acids), also lactic acid, succinic acid, sugar, and extractive matters. The inorganic constituents are potash, soda, magnesia, lime, phosphoric acid, sulphuric acid, chlorine, and ammoniacal salts. Gorup-Besanez found in the thymus-gland of the calf, a crystallisable, slightly basic substance, which he at first regarded as a peculiar compound, and designated as thymine, but he afterwards found that it was identical with leucine. The juice of the fresh gland mostly has a slight acid reaction, rarely alkaline or neutral.

According to Friedleben, the quantity of fat in the gland increases considerably with the age of the animal, whereas the amounts of gluten and albumin exhibit but small differences at different ages. The proportion of earthy phosphates gradually increases, with the growth of the animal, up to a certain point, and afterwards diminishes. The amount of potash exceeds that of soda. Friedleben found the quantity of potash at all periods of life to be nearly constant, varying only from 31·8 to 32·8 per cent., whereas the soda in a calf of ten days to three weeks old, amounted to only 16 per cent., while in young oxen of twelve to eighteen months it was from 23 to 24 per cent. The aqueous extract of the thymus-gland of the calf leaves an ash almost wholly soluble in water, and containing potash in large quantity, pyrophosphoric acid, and chloride of sodium, together with small quantities of magnesia and sulphuric acid. Gorup-Besanez found the proportion of potash to soda in one case to be 2·18 : 0·60; in another, 9·95 : 3·21. The quantity of phosphoric acid (anhydride ?) to that of chlorine was, in one experiment, as 23·25 : 14·34. According to Friedleben, the quantity of lime in the thymus exceeds that of magnesia; Gorup-Besanez, however, found the contrary proportion. (Handw. d. Chem. viii. 836.)

THYMYL. $C^{10}H^{13}$.—The radicle of thymol and its derivatives.

THYMYL, HYDRIDE OF. $C^{10}H^{13}.H$.—Cymene (ii. 295) may be supposed to be thus constituted.

THYMYLSULPHURIC ACID. $C^{10}H^{14}SO^4 = (C^{10}H^{13})HSO^4 = \left.\begin{matrix}(SO^2)''\\ C^{10}H^{13}\\ H\end{matrix}\right\}O^2$. *Sulphothymic Acid.* (Lallemand, Ann. Ch. Phys. [3], xlix. 150.)—Thymol dissolves abundantly in oil of vitriol at 50°—60°, and solidifies on cooling to a crystalline mass, having only a faint red colour. By dissolving this mass in water, and saturating the solution with carbonate of barium or carbonate of lead, sulphothymate of barium or lead is obtained, from which the sulphothymic acid may be separated, and crystallised by evaporating its aqueous solution in a vacuum. It crystallises in translucent pearly tables or prisms, which contain $C^{10}H^{14}SO^4.H^2O$, and do not deliquesce on exposure to the air, but are very soluble in water.

Its aqueous solution, treated with *nitric acid*, forms dinitrothymol; with sulphuric acid and *peroxide of manganese*, or *dichromate of potassium*, it forms thymoïl (p. 792).

With bases it forms the thymyl-sulphates, $C^{10}H^{13}MSO^4$, which crystallise in forms of the monoclinic system. They decompose at 120°, with violet-red colouring, and volatilisation of thymol.—The *ammonium-salt*, which separates from its aqueous solution in well-developed crystals, also the *potassium-* and *sodium-salts*, leave, when thus treated, anhydrosulphates.* The sulphothymates dissolve very easily in water and in absolute alcohol, somewhat less in ether.

Acetothymylsulphuric Acid, $C^{12}H^{6}SO^5 = \left.\begin{matrix}C^{10}H^{12}(C^2H^3O)\\ H\end{matrix}\right\}SO^4$. *Sulphacetothymic Acid.* (Lallemand, *loc. cit.*)—When thymol is dissolved in glacial acetic acid, and oil of vitriol containing a little anhydrous sulphuric acid is added to the mixture, combination takes place at a gentle heat; and the liquid, on cooling, deposits a crystalline mass, which must be dried on porous earthenware, and freed from excess of acetic acid, by leaving it over quicklime in a vacuum.

The acid is soluble in *water*. With bases it forms crystallisable salts, which become anhydrous without decomposition at 110°, but are decomposed, with liberation of acetic acid, when their aqueous solutions are boiled or quickly evaporated. The salts are soluble in water and in alcohol.

Sulphacetothymate of Barium, $C^{24}H^{30}Ba''S^2O^{10}$, is obtained by saturating the acid with carbonate of barium.

THYMYLSULPHUROUS ACID. $C^{10}H^{14}SO^3$. Syn. with CYMYLSULPHUROUS ACID (ii. 299).

TICUNAS POISON. An arrow-poison, used by the Tecunas (or Ticunas) and other Indian tribes dwelling near the Amazon. When given to animals, it produces strong convulsions, lasting for hours. It probably contains picrotoxin, like other South-American arrow-poisons; but it has not been accurately investigated.

TILE ORE. The earthy variety of native cuprous oxide (ii. 70).

TILKERODITE. Selenide of lead and cobalt (iii. 557).

TILLANDSIA. A genus of monocotyledonous plants, belonging to the natural order *Bromeliaceæ*. *T. usneoïdes* (called *Barbe de vieillard* by the French, *Barba de Pao* by the Portuguese) is a parasitical plant, growing on trees in Carolina and the West Indies, and having long, wiry, contorted stems, which creep along the trunks and branches of old trees, and sometimes hang down in a bunch, like the hairs of a horse's tail. These stems, when stripped of their leaves and bark, are used as packing material instead of horsehair. *Tillandsia recurvata*, growing in Peru, is also used for the same purpose.

According to Avequin (J. Pharm. [3], xxxv. 95), 100 pts. of the dried plant of *T. usneoïdes* [at what temperature ?] yield 3·23 per cent. ash, containing, in 100 pts., 35·4 carbonate, phosphate, sulphate, and chloride of potassium, 18·5 lime and carbonate of calcium, 28·6 phosphates of calcium and magnesium, and 17·4 silica, with traces of lime and magnesia.

---

* Unless the salts contain water of crystallisation, it is not easy to understand how thymol can be formed from their decomposition, inasmuch as it contains 14 at. hydrogen, whereas the anhydrous sulphothymates contain only 13 at.: $2C^{10}H^{13}MSO^4 = (2C^{10}H^{14}O - H^2O) + M^2SO^4.SO^3$.

Tillandsia dianthoïdea (L.), an air-plant, which does not grow in immediate contact with the soil, nevertheless contains from 6 to 8 per cent. ash, consisting chiefly of silica, together with lime and magnesia, and traces of alkalis, phosphoric acid, manganese, iron, sulphuric acid, chlorine, &c. (De Luca, Compt. rend. li. 176.)

TIMA. A medicinal preparation, introduced of late years as a remedy for phthisis. It is imported from Tampico, and is said to be prepared as a syrup, by boiling the fruits of *Crescentia edulis* with sugar, and mixing the product with almond-oil. (Arch. Pharm. [3], cvii. 375; Handw. d. Chem. viii. 840.)

TIMAZITE. Breithaupt's name for a rock, occurring in Eastern Servia, formerly regarded as belonging to the trachytes. It is porphyritic, and related to diorite, or to the so-called greenstones.

TIN. *Étain. Zinn. Stannum.—Atomic weight*, 118; *Symbol*, Sn.—This metal has been known from the earliest times: it is mentioned by Moses (Numbers xxxi. 22). The Phœnicians, long before the Christian era, fetched the metal **Κασσίτερος** from the British Isles, anciently called the Cassiterides. The word **Κασσίτερος** appears, however to have been applied in very ancient times, and the Latin word *stannum* somewhat later, not so much to tin as to certain white metallic alloys; at all events, tin and lead were regarded as similar metals, and were often confounded. Even Pliny sometimes does not use the word *stannum* for tin, but designates this metal as *Plumbum album*, s. *candidum*, in contradistinction to lead, or *Plumbum nigrum*. It was not till the fourth century of the Christian era that *stannum* was applied to the metal now called tin (Kopp's *Geschichte*), which was afterwards named Jupiter by the alchemists, and represented graphically by the symbol of that planet, ♃.

Occurrence and Distribution.—Tin occurs much less frequently than many other metals, as iron, copper, lead, zinc, &c., as the commercial supplies of it are drawn from comparatively few localities, Devonshire and Cornwall yielding by far the largest quantity. The stream-works of the peninsula of Malacca and the Dutch island of Banca probably rank next in importance. The exports from Bolivia are now very considerable, and large quantities have of late years been extracted from the mines of Saxony and Bohemia. A valuable addition of the metal has been obtained from Australia, shipped almost entirely from the port of Melbourne. The Australian tin contains, at times, so large an amount of gold, that the latter can be profitably extracted. No other deposits, of sufficient magnitude to be the object of mining explorations on any considerable scale, are at present known; but oxide of tin (*Cassiterite*) has been found in small quantities in the Isle of Man, Ireland, Greenland, France, Gallicia, Spain, Silesia, in the Fichtel and Riesengebirge in Germany, in Russia, the United States, Mexico, and Brazil. No mines are worked in Peru, but the name Peruvian tin has originated from the produce of the mines of Oruro and Carabuco, in Bolivia, being exported from Arica, a seaport on the Peruvian coast.

Tin occurs in the metallic state, somewhat more frequently as disulphide, in tin-pyrites, but most abundantly as dioxide or stannic oxide, forming the ore called tinstone, or cassiterite.

Native Tin (metallic tin) has been described by Hermann as occurring in the gold-sands of Siberia, and by Forbes in the auriferous drift of Tipuani in Bolivia; but as both these specimens contain lead, a metal seldom present together with tin-ores, it may be doubted whether the tin so found may not have been derived from artificial sources. Native tin has also been reported from Oruro, in Bolivia. (Forbes, Phil. Mag. [4], xxix. 133.)

Tin-pyrites (stannine, bell-metal ore, *Zinnkies*) is found in small quantities in the tin-veins of Cornwall, Saxony, and Oruro (Bolivia). It has the composition of a cuproso-ferrous sulphostannate, $\left.\begin{matrix}Cu^2S\\Fe''S\end{matrix}\right\}SnS^2$, the iron being generally more or less replaced by zinc; it contains from 14 to 30 per cent. of tin.

Cassiterite (tinstone, stream-tin, wood-tin), the dioxide or bioxide of the metal, SnO^2, may be regarded as the only ore of tin found in sufficient quantity to be the subject of mineral exploration; it is found both in veins and in alluvial drift-deposits, accompanied in many cases by tungsten, generally as wolfram, as in Cornwall, France, Saxony, Bohemia, Bolivia, &c. In the alluvial deposits, native gold is generally, if not invariably, found to accompany cassiterite, as is the case in Cornwall, Ireland, Virginia, Bolivia, Australia, &c. Although tin seldom enters into the composition of other minerals, it seems to be characteristic, though occurring only in very minute quantities, in some of the compounds of niobic or columbic, tantalic, and thus it has been observed in columbite, pyrochlore, tyrite, tantalite, fergusonite, aeschynite, polymignite, &c. Traces of tin have been ur in meteorites, and also in a variety of iron-pyrites from Spain.

Cassiterite is found in Cornwall, in veins or small strata, which traverse primitive rocks, mixed with other metals, such as copper, zinc, arsenic, and tungsten; the veins are of varying thickness. It is sometimes also found in numerous ramifications of small veins or "Stockwerke," which occur in felspar, porphyry, or in a granite which frequently has its felspar disintegrated into *kaolin*, or china-clay. These little veins seldom exceed six inches in width, and are frequently not nearly so wide; they run generally east and west, with a dip almost vertical; this description of ore is the common "tinstone."

The lodes in Cornwall are grouped into three districts, namely: first, in the south-west of the county, beyond Truro, near Helston; secondly, in the neighbourhood of St. Austell; and thirdly, in the vicinity of Tavistock, in Devonshire.

Many of the lodes traversing granite are worked profitably, as the rock in which they occur is generally softened by decomposition. As a general rule, the veins having an easterly or westerly direction are those which have the ore in profitable abundance, while those ranging northerly and southerly often contain other metals.

Although there are numerons exceptions, yet, as a whole, the distribution of this ore is somewhat marked. Certain combinations of rocks appear to be the conditions which may have assisted in rendering the ores of one metal more abundant than those of another in the range of parts of the same mineral lode. For instance, it is often found that a lode is cupriferous amid the slate-country, and chiefly stanniferous towards the granite. Some of the copper-veins in Cornwall have been worked for tin upon their *backs*, as the upper part of mineral veins are often termed in the mining districts, and have been abandoned when copper-ore was obtained beneath. In other places, copper has been found between tin; at Dalcoath mine, Camborne, tin occurred in profitable quantities in the *depth*, after the vein had been worked chiefly for copper, the *higher* portions having formerly furnished tin as the principal ore.

If tin be discovered first, it sometimes disappears, after sinking a certain depth, and is succeeded by copper; in others, tin is found to the depth of more than 300 fathoms beneath the surface. If a copper lode meets one of tin, it usually passes through it, and heaves it out of its course.

Metallurgy of Tin.—Tin, as above stated, is entirely extracted from the dioxide, The *vein*-tin requires much care in dressing, to separate mechanically the various foreign substances which it contains. The preliminary operations are:—

1. Cleansing the rough ore as it comes from the mine. This is sometimes done by placing the ore on a grating, allowing water to fall over it from some elevation, or by agitating it with a stream of water.

2. Sorting the cleansed ore into four qualities:

I. That which is rich in tin.
II. That containing tin and other metals.
III. That containing copper-ore.
IV. Stony gangue, or useless ingredients.

3. Stampingor rolling the ores No. I. into a certain fineness, according to its quality, which is of so much importance that it is regulated by a copper plate pierced with a certain number of holes in the square inch, placed in front of the stamp-box, through which everything from the stamping-mill is made to run off, with a constant stream of water introduced for the purpose. The stamps are of the usual description: the bars are of wood, between five and six inches square, fastened by a tail to a cast-iron head, of about 280 lbs. weight. The stamp-chest is open behind, so that, as the ore is pounded, it slips away from under the stamp-heads by its own gravity, along an inclined plane with a stream of water. The rolls are similar to those for other ores; generally, they consist of two pairs of smooth cylinders, turning simultaneously in opposite directions. Above the upper pair is a hopper, which discharges down between them, by means of a particular mechanical contrivance, the ore which is brought to it by waggons; these waggons advance upon a railway, and empty their contents into the hopper through a trap-hole. Below the hopper is a small iron bucket, which receives the ore, is shaken, and throws it continually upon the rolls by the constant jolts given to it by a crank-rod. This bucket is so contrived, that too much ore can never fall upon the rolls and obstruct their even movement. A small stream of water is often led into the bucket, spreading over the rolls and preventing them from heating. After the ore is reduced to powder, it next undergoes the very important operation of washing.

This operation is carried on under very advantageous circumstances compared with the similar operation with most other metals, in consequence of the high specific gravity of the cassiterite, which enables the washing to be profitably applied, even when the ore contains only 0·5 to 1·0 per cent. of tin. The ore is washed either in a *buddle* and *tossing-tub* or *dolly* (in the German *chest* or *rack*), or in the *trunking-box*, which are employed according to the different conditions of the pulverised ore. As the process of washing does not differ materially from that adopted for the ores of other metals, it is unnecessary to enter into a description of the various machines employed in Cornwall. The rich products of the washings consist principally of stannic oxide and the heavy metalliferous ores, such as arsenides, disulphides of iron, and wolfram mixed with sands and slimes. The sands from several of the tin-mines, after washing, have a white metallic colour, arising from the presence of arsenical pyrites (*mispickel*); the workmen call them *tin-white*. After the ores are washed, they are removed to the *burning-house*, to be calcined in a reverberatory calciner, which differs but slightly from that employed for copper-ores, excepting that it is smaller, and has only one door. The chimney generally leads to flues, in which the arsenious acid is condensed. At Par Consols the calciners have the following dimensions:—

The bottom, from the bridge to the front-door, is 7 ft. 4 in. long, 5 in the centre, 18 in. wide at the front-door, 8 in. high over the bridge, 16 in. in the centre, and 10 in. high at the sides. The ores are charged in the usual manner from a bin or hopper, the calcine-man extending them first over the surface near the bridge. They are rabbled every 20 or 30 minutes, according to the nature of the ores; and are divided into three heaps across the furnace, to expose their sides to the direct action of the heat. When some bright points are seen on the surface of the ores, and there is no longer any escape of white fumes, the work is finished. At the commencement of the calcination, only a moderate heat is applied, which is gradually increased until the sulphur (from the sulphides of iron, &c.) is nearly expelled. When the operation is conducted carelessly, and the heat applied too rapidly, a fusible sulphide of tin is formed, and the mass agglutinates, which is termed kerming: if this accident should happen, it is necessary to grind the ores over again.

When the charge is sufficiently calcined, it is removed from the calciner, and exposed in small heaps to the action of the atmosphere for a few days, to promote the oxidation of any remaining sulphides into sulphates. When thus oxidised, it is thrown into a large tub filled with water, stirred with a wooden rake, and left to settle, by which means the sulphates of iron and copper are dissolved. The water is afterwards transferred into a large tank, and the copper which may be in the solution is recovered by precipitation with metallic iron. The ore thus calcined, oxidised, and lixiviated, is washed once more on the rack-table, and the lighter parts removed. The heaviest parts necessarily contain the most metal, and are sold to the smelters under the name of black tin. That which remains in the middle of the table, being much mixed with wolfram, is called mock-lead, and sent once more to the stamps to be crushed and washed, after which it is sold as black tin.

The rotary calciners calcine well, and do much work; but they must be put in motion either by water or steam-power, and the cost of their erection is much greater than that of the ordinary reverberatory calciner, which can be put up for about £30.

The usual cost of calcining, per ton of black tin, is:

	s.	*d.*
For labour	4	0½
1714 lbs. of coal, at 13*s.* per ton . .	9	6
	13	6½:

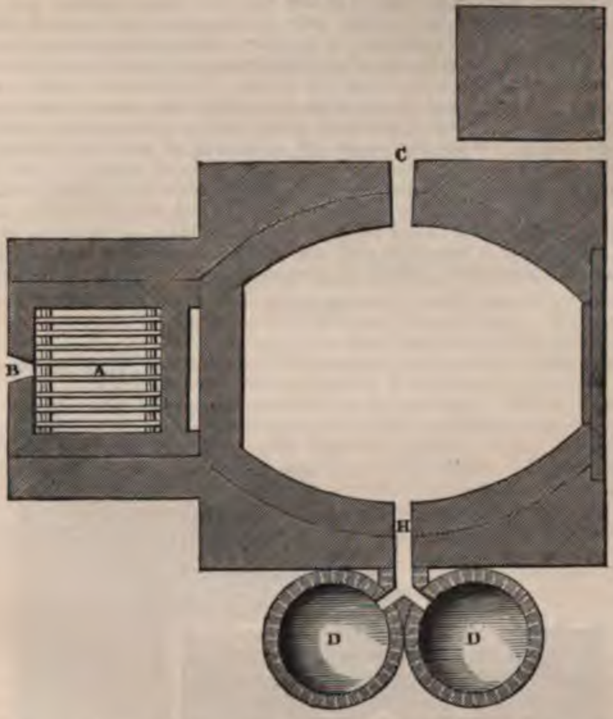
to which must be added the wear-and-tear of utensils, &c. Some calculate that the average cost is greater, amounting to 20*s.* per ton: from this is to be deducted, however, the value of a large quantity of arsenious acid obtained. The mean yield of tin-ores prepared in Cornwall may be estimated at 2 per cent.—that is to say, 50 tons of ore will give 1 ton of black tin. The cost of the mechanical preparation of the ores varies greatly in proportion to their yield, the hardness of the gangue, &c., but those of the usual produce and hardness may be reckoned at 4*s.* 10*d.* per ton of ores, or about £12 per ton on black tin. There are, however, many ores which do not contain more than 0·5 per cent. of metal, but they are easily dressed, as the grain is large and pure, and they require no calcining: their cost of calcination may be calculated as follows:

	s.	*d.*
Rugging and spalling	1	0
Stamping	0	4
Washing	1	0
	2	4 per ton of ore,

equal to £23 6*s.* 8*d.* per ton of black tin. This estimate does not take account of the loss in washing, which is supposed to average fully 20 per cent., and in the assay, which is less than the actual product.

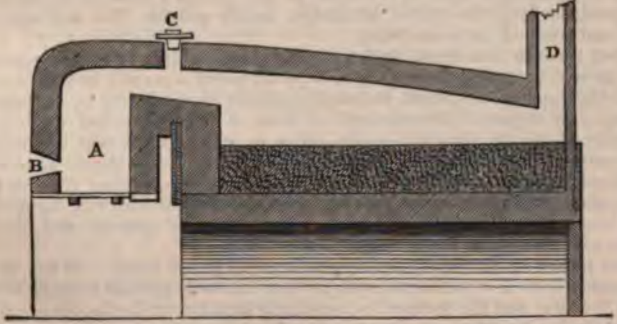
The smelting of the black tin is effected in reverberatory furnaces. When only an impure metal is required, it undergoes two different processes—first, in a reduction furnace, and then in a refining furnace. When a very pure tin is wanted, called *grain-tin*, the stream-tin is fused in a blast-furnace supplied with charcoal. It will be seen (by *figs.* 817, 818, and 819), that the reverberatory furnaces employed, are not essentially different from those for copper, except in the addition of the two round basins (*fig.* 817), D D, into which the melted tin is drawn off and ladled into moulds.

Fig. 817.



When the furnace is properly heated, it is charged with about a ton of calcined ore, which is intimately mixed with fine charcoal or anthracite-coal, to the amount of about 20 per cent. of its weight; also with some slaked lime or fluor-spar as a flux. When the charge is let down, the aperture C (*fig.* 818) in the roof of the bridge is opened, which permits the escape of fumes. The heat of the furnace is at first gently raised, for if it were too great, the tin-oxide would unite with the quartz of the gangue, and form a very difficultly decomposible silicate. The charge is allowed to heat for

Fig. 818.

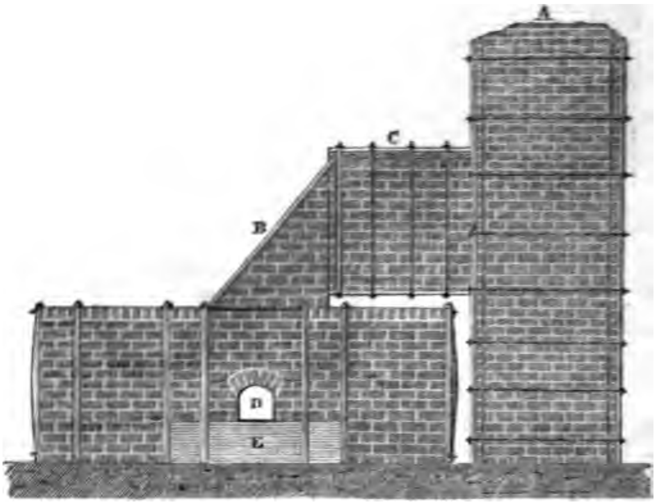


six or eight hours, when the door is opened, and it is thoroughly stirred with an iron rabble, to effect the separation of the metal and the slag. After waiting a short time to allow the metal to subside, the slag or scoria which floats on the surface is skimmed off with a skimming rabble and preserved; the upper part of the slag is poor in metal, but the lower is rich; it is therefore re-smelted. When the metal is perfectly skimmed, the tap-hole, which is stopped with a plug of dry wood at the side of the furnace, is opened, and the tin allowed to flow into the circular basins.

The tin thus reduced is by no means pure; it is necessary that it should undergo the refining process, which is performed by liquation and refining proper (lixiviation). Liquation is accomplished in a reverberatory furnace very similar to that in which the smelting is effected; but it is provided with a more sloping bottom, similar to that for refining copper. The pigs of tin are piled up in the [illegible] close to the bridge, and the tin, when moderately heated, gradually melts, and flows down into the refining-basin made in the bottom. When the blocks are exhausted of pure tin, skeletons of the pigs remain as a refractory residuum, consisting chiefly of oxides of iron and other foreign metals. More pigs are placed over the remains of the first, and the metal is then run from the furnace into a large iron pan or kettle, which holds about five tons.

The next process is *refining proper, or lixiviation*.—The kettle or refining-basin is placed over a fire-grate, and heated so as to preserve the metal in a fluid state. Into this metal bath, billets of greenwood are plunged, and set in a rotary motion by a machine called a *gibbet*, placed over the kettle: the disengagement of gas from the wood causes a constant ebullition in the tin, and a froth on the surface, which is composed chiefly of the oxides of foreign metals and tin; this is skimmed off the surface, and reserved for re-smelting.

Fig. 813.



In about three or four hours, the boiling is finished: the greenwood is removed, and the tin allowed to settle. On cooling slowly, the metal separates into different strata, of which the upper is the purest, the middle slightly charged with foreign metals, and the lowest very impure. After a couple of hours, it is gently ladled out into moulds. The quality of the tin depends on the order in which it has been ladled; the first blocks contain, of course, the purest metal, and the last are so impure as to require to be again subjected to liquation and refining. The whole operation requires from five to six hours, including from one to two hours for the subsidence of the metal. The moulds into which the tin is cast are generally made of granite, and are of a size sufficient to contain three hundredweight of black tin.

Tin-ore melted in the blast-furnace produces the purest metal. When the furnace is thoroughly heated, it is charged with ore and charcoal, damped to cause an adheison between the two, and the furnace is constantly kept full while the operation is going on. The tin is allowed to run into the first basin, and then into the second, where it is left to settle for some time. The tin in the metallic bath falls into strata similar to the refining furnace, the impure part settling to the bottom, which is again

Grain-tin is formed from the finest blocks; these are heated to nearly melting-point, when they become brittle; they are then dropped from a considerable height; the metal is thus broken, and forms elongated grains or tears.

The reverberatory furnace consumes about two tons of coal for one ton of metal; the blast-furnace about thirty-one hundredweight of charcoal for one ton of metal.

It is very difficult to find out the exact loss of metallic tin in smelting by the reverberatory and blast-furnaces. It has, however, been found that black tin, which gave 73 per cent. of tin by assay, yielded 66·5 per cent. of pure tin when smelted and refined, leaving a large quantity in the state of silicate, most of which, no doubt, could be recovered. In the blast-furnace the loss is considered to be about 15 per cent.

Properties of Tin.—The tin of commerce is never pure; the metal from Banca contains, perhaps, the smallest amount of impurity. Tin is generally associated with small quantities of arsenic, lead, iron, copper, and occasionally tungsten, manganese, antimony, zinc, bismuth, and molybdenum. To obtain it chemically pure, the tin of commerce is granulated and dissolved in strong hydrochloric acid; a small quantity of water is cautiously poured into the solution, so as to form two strata; and a plate of tin is then introduced, traversing the two liquids. After some time, crystals of pure tin are deposited upon the plate, owing to the feeble galvanic current which is excited. Or tin may be digested in nitric acid, the white insoluble residue (metastannic acid) digested in dilute hydrochloric acid, and the resulting powder reduced by charcoal.

Tin is a white metal, having however a peculiar yellowish tinge. When warm, it emits a characteristic smell, and a bar, when bent, gives a singular crackling sound (*cri d'étain*), owing to the interior crystals breaking against each other. It is soon tarnished by the air of large towns, owing probably to a film of sulphide, as it is not sensibly affected by the combined presence of air and moisture. Tin, with the exception of lead and thallium, is the least tenacious of the well-known metals. A wire $\frac{1}{15}$ of an inch in diameter will support only about 31 pounds: a bar, a quarter of an inch in diameter, will not support more than 294 pounds weight. The malleability of tin is very considerable; it is expanded, by combined hammering and heating, into sheets or leaves called **tinfoil**, barely $\frac{1}{1000}$th part of an inch in thickness. It is tinfoil that is laid upon the back of glass mirrors, and there amalgamated with mercury, forming what is called the **silvering**.

Tin can be easily obtained in crystals, in the same manner as bismuth. The best method is to fuse some pounds of the metal, and, when it is nearly solidified, to pierce the centre of the mass with a stick of incandescent charcoal, and pour off the portion which still remains liquid; fine crystals of tin are then found upon the sides of the interior. Tin, indeed, has a remarkable tendency to crystallise, as may easily be shown by washing the surface of the metal with warm, diluted, nitro-hydrochloric acid, when it becomes covered with a mass of crystalline forms, having a very beautiful appearance something like watered silk, and formerly much used, under the name of *moirée metallique*, for the manufacture of workboxes, tea-caddies, &c. The appearance is caused by the unequal reflection of light by the facets of the crystals exposed to the action of the acid. Louis Vallet, in 1817, obtained a patent for the production of these crystals, or, as he expressed it, for the manufacture of a new ornamental surface of metal or metallic composition. The surfaces of tin, or of metals coated with tin, are washed with a mixture of 10 pts. of sulphuric acid diluted with five times its bulk of water, together with 1 pt. of nitric acid diluted with its own weight of water. In the following year (1818), Mr. M. Isambard Brunel obtained a patent for a somewhat similar application of acids on the surface of tin. The process is thus described: "A new species of tinfoil, capable of being crystallised in large, varied, and beautiful crystallisation." A sheet of tin or tinfoil is laid evenly upon a flat plat of metallic or vitreous substance, which may be heated from below by a bath of melted alloy, as of two-thirds of tin and one-third of lead: heat is then applied, by means of common gas-jets and flexible tubes, to those parts to which it is desired to give an ornamental crystalline conformation. Sulphuric acid diluted with 5 pts. of water, and nitrous (?) acid diluted with 1 pt. of water, are mixed in the proportion of 10 pts. of the former to 1 pt. of the latter, and applied by a brush to the surface of the tin; it is then washed, and may be varnished or japanned in the usual way.

The specific gravity of tin is 7·29, and is not sensibly increased by rolling. That of the crystals was found by **Miller** to be 7·177: according to **Deville**, the specific gravity of slowly-cooled tin is 7·373; that of tin rapidly cooled, by pouring into water, 7·239. Its cubical expansion for 1° C. (between 9° and 72°) is 0·000070. (**Kopp.**)

Tin melts at 222° (**Crichton** and **Rudberg**), at 230° (**Kuppfer**), at 237·2° (**Person**). Its specific heat in the solid state is 0·0562, in the liquid state 0·0637; its latent heat of fusion, between 250° and 350°, is 14·252 (**Person**). It boils at a white heat. It has but a small heat-conducting power (according to Calvert = 422, that of silver being 1000). It takes a fine polish, and has then but little radiating power: hence vessels of polished tin are well adapted for keeping liquids warm.

Tin does not oxidise at ordinary temperatures in the air, even when moist, and but very slightly in water, retaining its metallic lustre for a long time: hence iron which is to be exposed to the air is often tinned, to prevent it from rusting. When tin is fused in the air, its surface becomes covered with a thin grey film, containing both protoxide and dioxide of tin. If the film be removed, it is again formed, and if this grey powder be continuously heated, it becomes white. It is used for polishing plate in the same way as *putty-powder*, which is obtained by the action of nitric acid upon the metal.

If tin be kept at an ordinary red heat, it gives out vapours, but they have little tension, and there is but small loss of weight; at a strong white heat, it burns in the air with a bright flame. At a full red heat it will decompose steam, with evolution of hydrogen.

Strong *nitric acid* of specific gravity 1·5 does not act upon tin, the metal even preserving its characteristic brilliancy; but if the acid is diluted, it attacks the metal with extreme violence, the tin being entirely converted into metastannic acid.

Tin dissolves slowly in dilute or cold *hydrochloric acid*, but rapidly when the latter is hot and concentrated, evolving hydrogen-gas, and yielding dichloride of tin. Dilute *sulphuric acid*, when heated, attacks tin slowly, with emission of hydrogen, but the hot concentrated acid acts more energetically, with production of sulphurous acid. Fused *nitre* and the *hydrate of potassium* and *sodium*, at high temperatures, act upon tin. It combines directly with *sulphur*, *phosphorus*, *chlorine*, *iodine*, &c., and forms alloys with many *metals*, particularly with *copper*, to which it gives a hardness approaching to that of steel.

Tin in a state of fine division is violently acted upon by *chloride of sulphur*, the heat evolved being so great that the sulphur-compound (which must be returned) passes over with the tetrachloride of tin. (Wöhler, Ann. Ch. Pharm. lxxiii. 374.)

Compounds of Tin.—Tin forms chiefly two classes of compounds: namely, the stannous compounds, in which it is diatomic—*e.g.*, $SnCl^2$, SnO. SnS, $Sn(SO^4)$, &c.; and the stannic compounds, in which it is tetratomic—*e.g.*, $SnCl^4$, SnO^2, SnS^2, $Sn(SO^4)^2$, &c. There are also a sesquioxide, Sn^2O^3, a sesquisulphide, Sn^2S^3, and several compounds of tin with alcohol-radicles, in which it is triatomic. F. F.

TIN, ALLOYS OF. Tin unites with most other metals, forming, in many cases, hard ductile alloys. Small quantities of tin are often sufficient to impart peculiar properties to an alloy.

Many of the alloys of tin have been already described in connection with the other metals. For Matthiessen's determinations of the specific gravities of tin-alloys, see Pogg. Ann. cx. 21; Jahresb. 1860, p. 111; also the article METALS in this Dictionary (iii. 943).

Tin and Antimony (i. 317).—According to Chaudet, 10 pts. tin and 1 pt. antimony form a perfectly ductile alloy.

Tin and Arsenic unite easily when heated together, forming a hard, brittle, laminar mass, less fusible than tin. When the proportion of arsenic is large, the alloy is insoluble in hydrochloric acid; with a smaller amount, it dissolves, with evolution of arseniotted hydrogen, leaving an alloy richer in arsenic. (Soubeiran.)

Tin and Bismuth.—An alloy of 177 pts. (3 at.) of tin and 213 pts. (2 at.) of bismuth, when cooled from a state of fusion, exhibits but one solidifying-point; inasmuch as it first cools regularly down to 143°, and then remains at that temperature for a considerable time, till the latent heat, set free in the solidification of the alloy, has had time to escape. But all other alloys of these metals likewise exhibit a higher solidifying-point, the excess of one or the other metal, or, rather, another definite alloy containing an excess of one of the two metals, solidifying first, and afterwards at 143°, the hitherto fluid alloy containing Sn^3Bi^2. The higher solidifying-point, or point of separation, is 190° for Sn^4Bi, 160° for Sn^2Bi, 150° for $SnBi$, 170° for Sn^2Bi^3, and 190° for $SnBi^2$. (Rudberg, Pogg. Ann. xviii. 240.)

a. 40 pts. tin to 1 pt. bismuth: perfectly ductile; the addition of 1 pt. of lead diminishes its extensibility.—*b.* 25 pts. tin to 1 pt. bismuth: slightly ductile (Chaudet).—*c.* 8 pts. tin to 1 pt. bismuth: melts at 199° (Lewis).—*d.* 3 pts. tin to 1 pt. bismuth: pulverisable; of dull grey fracture, and specific gravity 7·776; gives up all its tin, with a small quantity of bismuth, to heated hydrochloric acid (Chaudet).—*e.* 2 pts. tin to 1 pt. bismuth: melts at 166° (Lewis).—*f.* 236 pts. (2 at.) tin to 213 pts. (1 at.) bismuth: specific gravity = 8·085 (Regnault).—*g.* 1 pt. tin to 1 pt. bismuth: perfectly brittle; pulverisable; of fine-grained fracture; [illegible] gravity = 8·345 (Chaudet). Melts at 138° (Lewis). Expands stro[illegible]ifying (Marx). With hydrochloric acid it behaves like *d* (Chaudet, A[illegible][2], v. 142).—

h. 177 pts. (3 at.) tin to 213 pts. (2 at.) bismuth: melts between 131° and 137° (Döbereiner, Kastn. Arch. iii. 90).—*i.* 118 pts. (1 at.) tin to 213 pts. (1 at.) bismuth: specific gravity = 8·759. (Regnault.)

236 pts. (2 at.) tin to 213 pts. (1 at.) bismuth, and 129 pts. (1 at.) antimony, form an alloy of specific gravity 7·883 at 20°. (Regnault, Ann. Ch. Phys. [2], lxxvi. 136.)

Respecting the alloys of tin, bismuth, and lead, see i. 591, and iii. 536.

Tin and Cadmium.—The alloy Sn^2Cd melts at 173·8°. (Rudberg.)

Tin and Cobalt form a somewhat malleable alloy.

Tin and Copper (see COPPER, ii. 43). Rieffel (Compt. rend. xxxvii. 454; Jahresb. 1853, p. 376) gives the following list of alloys, which he regards as chemical compounds of copper and tin:—

	Cu.	Sn.	Colour.
$CuSn^{48}$	1·11	98·89	White, more or less approaching to that of tin.
$CuSn^{24}$	2·19	97·81	
$CuSn$	34·98	65·02	Iron-grey.
$SnCu^{24}$	92·81	7·19	Golden-yellow.
$SnCu^{48}$	96·27	3·73	Orange-yellow.
$SnCu^{72}$	97·48	2·52	Yellowish-rose.
$SnCu^{96}$	98·10	1·90	Rose.

In the alloy SnCu, which crystallises in large steel-grey laminæ, hard, bulky, and melting at about 400°, the properties of both the constituent metals are said to be nearly masked; the other alloys exhibit the characteristics of the predominant metal. The formation of all these compounds is attended with condensation.

The alloy $CuSn^2$ (21·3 pts. copper and 77·6 pts. tin) has been found, as a furnace-product, in white six-sided prisms, of specific gravity 7·53 (Miller, Pogg. Ann. cxx. 55).—Another furnace-product, from Schlackenwald, Cu^3Sn^7 (18·9. pts. copper and 80·8 pts. tin), forms semi-malleable six-sided prisms, of specific gravity 6·994, having a white colour, with golden-yellow tarnish. (Rammelsberg, *ibid.* cxx. 54.)

According to Calvert and Johnson (Jahresb. 1858, p. 111), the heat-conducting power of Sn^5Cu = 396; of SnCu = 415 (silver = 1000).

Calvert, Johnson, and Lowe (Jahresb. 1861, p. 1) have determined the relative expansions of several alloys of copper and tin to be as follows: SnCu = 138·1; SnCu = 118·1; $SnCu^4$ = 111·8; $SnCu^{15}$ = 98·3; $SnCu^{25}$ = 105·0.

Alloys of tin with copper and antimony constitute several varieties of Britannia-metal, also Deurance's alloy for fractional bearings (ii. 46).

Tin and Gold.—Tin considerably diminishes the extensibility of gold. The alloy of 11 pts. gold and 1 pt. tin is pale-yellow, fine-grained, only slightly malleable, and has a specific gravity of 17·307 (Hatchett). Alloys of tin and gold are, for the most part, easily crystallisable. The compounds SnAu and Sn^3Au^2 do not, however, appear to crystallise; but on addition of more tin, in such proportion as to form the compound Sn^2Au, the fused mass separates into a less fusible portion, having a vitreous fracture, and an easily fusible crystalline mass. (Matthiessen and v. Bose, Phil. Trans. 1860, p. 170.)

Iridium melts with 4 pts. of tin, at a bright-red heat, to a dull-white, hard, crystallisable alloy (Berzelius). The alloy $IrSn^2$ (45·4 pts. iridium and 54·6 pts. tin) crystallises in cubes, which are not altered by nitromuriatic acid.

Respecting the alloys of tin with iron, lead, and mercury, see iii. 370, 534, 870; with palladium and platinum, iv. 327, 667.

Tin and Nickel form a hard brittle alloy.

Tin and Potassium melt easily together. Stanniferous potassium, obtained by igniting tin or stannic oxide with cream of tartar, is brittle, and decomposes water.

Tin and Rhodium form a black, shining, crystalline mass, containing RhSn. 47·3 pts. tin, 32·0 platinum, 12·5 iridium, and 1·9 rhodium, form a crystallisable alloy, $(PtIrRh)^2Sn^3$, which is not altered by hydrochloric acid.

Tin and Ruthenium.—When 1 pt. of ruthenium is fused with 10 to 15 pts. tin in a crucible lined with charcoal, and the cooled mass is treated with hydrochloric acid, a crystallisable alloy, $RuSn^3$, remains, containing 33 pts. ruthenium to 67 pts. tin.

Tin and Silver (p. 287).

Tin and Sodium may be alloyed together by direct fusion, or by igniting tin with soda-soap. The alloy resembles that of tin and potassium.

Tin and Zinc. See ZINC.

TIN, BROMIDES OF. *Stannous bromide*, $SnBr^2$, is formed by heating metallic tin in hydrobromic acid gas, or with mercuric bromide. It is a greyish-white, shining, crystalline mass. It dissolves in water, and the resulting solution, as well as that obtained by dissolving tin in aqueous hydrobromic acid, yields, on evaporation, [illegible] crystals. Stannous bromide melts, at a high temperature to [illegible] the air, it gives off stannic bromide and leaves stannic [illegible]

[illegible] $SnBr^4$, is produced, with incandescence, when tin or stannous [illegible] vapour. It is a white crystalline mass, of specific gravity [illegible] and sublimes in needles. It dissolves in water [illegible] temperature; melts under oil of vitriol without sensible [illegible] it to stannic hydrate, with separation of bromine.

[illegible] is formed by the action of bromine on stannous oxide.

[illegible] forming the compound $SnBr^4.(C^2H^5)^2O$, in deli[illegible] water before dissolving in it, and are easily disin[illegible] yielding hexagonal prisms of stannous bromide. [illegible]

TIN, BUTTER OF. [illegible].—An obsolete name for hydrated tetr[illegible] Gmelin's Handbook (v. 84), for the anhydrous di[illegible]

TIN, CHLORIDES OF. Three chlorides of tin are known, corresponding to [illegible] and $SnCl^4$.

Dichloride, or Stannous Chloride, $SnCl^2$, (commonly called *Protochloride of Tin*, and represented, according to the old atomic weight of tin, by the formula SnCl.) — [illegible] is prepared:—1. By gradually heating tin, or tin-amalgam, [illegible] or with at most 2 pts. of mercuric chloride, the mercury [illegible]. 2. By heating tin in hydrochloric acid gas, hydrogen being set free. — 3. By heating hydrated stannous chloride in close vessels, whereupon, when the heat is gradually raised to redness, and the receiver changed, the anhydrous chloride passes over after the water. Capitaine (J. Pharm. xxv. 552) gently heats [illegible] in a capacious crucible (to prevent frothing over), as long as it gives off water and sulphuric acid; pours the mass, as soon as it is [illegible] tranquil fusion, into a small crucible; then pounds it up coarsely, and distils it from a [illegible] glass retort. The first portions of stannous chloride which pass over are perfectly pure; the last portions contain a small quantity of iron, from which they may be freed by a second distillation.

Stannous chloride is translucent, almost pure white (frequently grey), with a fatty lustre and conchoidal fracture; soluble in water and in alcohol. It melts at 250° to an oily liquid, which penetrates the crucibles and makes them crack; boils at a heat near redness, but always with some degree of decomposition. When cooled after fusion, it remains liquid for a long time, but afterwards becomes syrupy and solidifies. When heated to bright redness, it gives off tetrachloride of tin, and afterwards unaltered dichloride, leaving a black shining mass, which dissolves in aqueous hydrochloric acid with evolution of hydrogen-gas, and forms a solution of stannous chloride (A. Vogel, Schw. J. xxiv. 66). When heated to the boiling-point, it passes over in company with tetrachloride of tin, and leaves yellow, earthy, stannous oxychloride, $SnCl^2.SnO$ (Capitaine).—When heated with sulphur, it yields tetrachloride and disulphide of tin: $2SnCl^2 + S^2 = SnCl^4 + SnS^2$ (Proust).—When heated in the air, or with nitre, chloride of potassium, or mercuric oxide, it gives off tetrachloride of tin, and leaves stannic oxide. At ordinary temperatures, it does not suffer much alteration by exposure to the air: in the course of three weeks, however, it becomes somewhat disintegrated, but still dissolves completely in water.

Stannous chloride absorbs dry *ammonia-gas*, and when heated with it, forms the compound $SnCl^2.NH^3$.

Hydrated stannous chloride, commonly called *tin-salt*, is obtained by dissolving the anhydrous chloride in water, or by the solution of metallic tin in hydrochloric acid.

The preparation on the large scale is performed in copper vessels, which, so long as any portion of tin remains undissolved, are not attacked by the acid. If granulated tin be covered with hydrochloric acid, then the acid poured off, and the tin exposed to the air—afterwards the acid poured on again, and so on alternately—the tin takes up oxygen from the air, whereby it becomes heated, and dissolves much more quickly than by the simple action of the acid (Berard). In the preparation of *tin-salt* on the large scale, Nöllner (Arch. Pharm. lxiii. 120) recommends that the hydrochloric acid, as it is evolved from the retorts, be made to act directly upon granulated tin contained in stoneware receivers adapted to the retorts, and that the concentrated solution of tin-salt thus formed be aft[illegible] tinned pans, with addition of granulated tin.

The solution, when e[illegible] rent, colourless prisms (monoclinic accor[illegible] metallic taste. According to Be[illegible] ording to Henry, they contain $SnCl^2.2H^2O$. The crystals, when heated, evolve water and hydrochloric acid containing a small quantity of tin, and leave stannous chloride and oxide. Cold oil of vitriol separates from them but a small quantity of hydrochloric acid; heated oil of vitriol separates hydrochloric acid—together with small quantities of stannous chloride, sulphurous acid, and sulphuretted hydrogen (the two latter substances partly decomposing each other, and yielding a precipitate of sulphur)—and forms stannic sulphate. (A. Vogel.)

The pure crystals of tin-salt dissolve completely in a certain quantity of deaërated water, a litre of the solution, saturated at 15°, having a specific gravity of 1·827, and containing 1,333 grms. of stannous chloride to 494 grms. of water (Michel and Kraft). A larger quantity of water produces partial decomposition, hydrochloric acid being dissolved, and a hydrated stannous oxychloride, $Sn^2OCl^2.2H^2O$, being deposited in the form of a milk-white powder:

$$2SnCl^2 + H^2O = Sn^2OCl^2 + 2HCl.$$

The clear neutral solution also becomes turbid on exposure to the air, likewise from formation of oxychloride, while stannic chloride remains in solution:

$$3Sn''Cl^2 + O = \overset{\text{iv}}{Sn}{}^2OCl^2 + Sn^{iv}Cl^4.$$

In either case the decomposition may be prevented, and the solution kept clear, by addition of hydrochloric or tartaric acid, or of sal-ammoniac, with which stannous chloride forms a double salt not decomposible by water or by exposure to the air. The crystals of tin-salt likewise decompose on exposure to the air in the manner above mentioned.

A *hydrated stannous chloride*, containing $SnCl^2.4H^2O$, is obtained in needle-shaped deliquescent crystals, melting at 50°, by dissolving stannous oxide in an equivalent quantity of stannic chloride, and evaporating, the mother-liquor then retaining stannic oxide dissolved in stannic chloride:

$$2SnO + 2SnCl^4 + 8H^2O = 2(SnCl^2.4H^2O) + SnO^2 + SnCl^4.$$

Stannous chloride is a powerful deoxidising agent, reducing *gold-*, *silver-*, and *mercury-salts* to the metallic state; converting *ferric*, *manganic*, and *cupric chlorides* into ferrous, manganous, and cuprous chlorides respectively; the *trioxide of chromium* (chromic anhydride) into sesquioxide; *tungstic* and *molybdic anhydrides* into the corresponding blue oxides; the higher oxides of *lead*, *bismuth*, &c., into lower oxides, and *indigo-blue* into indigo-white.—*Arsenic acid* forms with stannous chloride a precipitate consisting, according to Schiff, of stannic arsenite, $2SnO^2.As^2O^3$; an excess of stannous chloride, however, reduces the arsenic acid to metallic arsenic. Stannous chloride also reduces *nitric acid* to nitric or nitrous oxide, *hypochlorous acid* to chlorine, &c. With *sulphurous acid* in presence of hydrochloric acid, it forms stannic sulphide together with stannic chloride, a reaction which may be used for the detection of sulphurous acid (p. 541):

$$6SnCl^2 + 8HCl + 2H^2SO^3 = SnS^2 + 5SnCl^4 + 6H^2O.$$

Stannous chloride is often used as a reagent in volumetric analysis for the estimation of indigo, &c. Tin-salt is extensively employed as a mordant in dyeing and calico-printing, sometimes also as an antichlore.

Stannous chloride forms crystallisable double salts with several other metallic chlorides.

Ammonio-stannous Chlorides.—α. The compound $2NH^4Cl.SnCl^2$ is formed by heating tin-filings with sal-ammoniac, more easily, however, by evaporating a mixed solution of the component chlorides; the crystals thus obtained are sometimes anhydrous, sometimes they contain 2 at. water (Graham). Apjohn obtained octahedral crystals, $2NH^4Cl.SnCl^2.H^2O$, which were permanent in the air, had an acid reaction, and dissolved in water, forming a solution which became cloudy on boiling. Rammelsberg obtained rhombic crystals having the same composition.—β. The salt $4NH^4Cl.SnCl^2.3H^2O$ forms tufts of needles permanent in the air, but decomposed by water. (Poggiale, Compt. rend. xx. 1180.)

The *barium-* and *strontium-salts* are represented by the formulæ $BaCl^2.SnCl^2.4H^2O$ and $SrCl^2.SnCl^2.4H^2O$.

Potassio-stannous Chlorides.—α. The salt $2KCl.SnCl^2$ is prepared like the corresponding ammonium-salt, and is said to form anhydrous crystals, as well as crystals with 1, 2, and 3 at. water. The monohydrate forms rhombic crystals. (Marignac, Compt. rend. lv. 650.—Rammelsberg, Krystall. Chemie, p. 211.)

A compound of *stannous chloride* with *potassio-stannous sulphate*, $SnCl^2.4SnK^2(SO^4)^2$, separates from a mixture of the hot concentrated solutions of stannous chloride and potassium-sulphate, in small, shining, hexagonal crystals, which may be recrystallised from water without decomposition.

Sesquichloride of Tin, or *Stannoso-stannic Chloride*, $Sn^2Cl^6 = SnCl^2.SnCl^4$.

—This compound, known only in solution, is produced by dissolving stannoso-stannic hydrate in hydrochloric acid, in a vessel from which the air is excluded. The solution reacts like a mixture of stannous and stannic chlorides.

Tetrachloride of Tin, or **Stannic Chloride**, $SnCl^4$.—This compound was known to the older chemists, having been mentioned by Libavius, in 1605, under the name of *Liquor s. Spiritus argenti vivi sublimati* (from the mode of preparation with mercuric chloride); afterwards it was commonly called *Spiritus fumans Libavii*, sometimes also *Fumigatorium perpetuum joviale*.—The anhydrous tetrachloride may be obtained by distilling stannic sulphate with sodium-chloride, or by distilling the hydrated tetrachloride with oil of vitriol. It is usually prepared by distilling a mixture of 1 pt. tin-filings with 4 or 5 pts. mercuric chloride, or by heating tin-filings or stannous chloride in dry chlorine-gas, the tetrachloride then collecting in the receiver, which must be kept cool. In preparing it by the last-mentioned method, the free chlorine must be removed by agitating the distillate with tin-filings, and then rectifying it.

Stannic chloride is a colourless mobile liquid, of specific gravity 2·267 at 0°. It fumes strongly in moist air; boils at 115° (at 120° according to Duma, at 112° according to Andrews). Vapour-density, according to Dumas' determination, = 9·20; by calculation = 9·01. Its specific heat for the unit of volume is 0·8639; for the unit of weight, 0·0939 (Regnault). It does not conduct electricity. It is highly caustic, decomposes alcohol, with formation of ether; in contact with oil of turpentine, it produces great heat, sometimes setting fire to the turpentine. It converts mercury into calomel. Strong nitric acid decomposes it, with formation of metastannic acid; heated in sulphydric acid gas, it is partially decomposed, with formation of stannic sulphide.

Hydrated Stannic Chloride.—The anhydrous tetrachloride absorbs water rapidly from the air, and forms crystals of a trihydrate, $SnCl^4.3H^2O$ (Casselmann). Mixed with one-third of its weight of water, it solidifies to a soft fusible mass, called *Butter of tin*, or *Butyrum stanni*, which dissolves in excess of water, the solution yielding, by evaporation, deliquescent crystals of a pentahydrate, $SnCl^4.5H^2O$, which give off 3 at. water over oil of vitriol (Lewy, Compt. rend. xxi. 369). A solution of stannic chloride may be prepared by dissolving ordinary stannic hydrate in hydrochloric acid, by treating a solution of stannous chloride with chlorine-gas, or by mixing stannous chloride with hydrochloric acid and treating it with nitric acid. The salt generally known in commerce as nitromuriate of tin, is prepared by dissolving tin in nitromuriatic acid, which must be kept cool, and must not contain too much nitric acid—otherwise metastannic acid is likely to be produced. This solution is used in dyeing for the brightening and fixing of red colours, and is sometimes designated by the old names, "composition, physic, or tin-solution." The same solution is obtained by dissolving tin to saturation in hydrochloric acid, then adding half as much hydrochloric acid as was required to dissolve the tin, together with a certain quantity of sulphuric acid and nitre. Stannic chloride may also be prepared by oxidising stannous chloride with chlorate of potassium; and on evaporating the liquid, or the solution of stannous chloride mixed with nitric acid, the trihydrate, $SnCl^4.3H^2O$, is obtained (which, when dried in a vacuum, leaves the dihydrate, $SnCl^4.2H^2O$), while the mother-liquor contains stannic hydrate dissolved in stannic chloride. (Scheurer-Kestner, Compt. rend. l. 50.)

The solution of stannic chloride exhibits all the reactions of ordinary stannic salts (p. 810). When evaporated, it first gives off water, then stannic chloride. The concentrated solution does not alter perceptibly; but the dilute solution gradually decomposes, yielding hydrochloric acid and metastannic hydrate (p. 817), which remains behind when the hydrochloric acid is evaporated. According to Casselmann, a solution diluted to a certain point deposits ordinary stannic hydrate as well as metastannic hydrate. When stannic chloride is heated with a small quantity of water in a sealed tube, pure amorphous stannic oxide separates. (Senarmont.)

Aqueous stannic chloride easily dissolves stannous oxide, forming stannous chloride which on evaporation crystallises as a tetrahydrate, $SnCl^2.4H^2O$ (p. 807), while the liquid retains stannic hydrate dissolved in stannic chloride. When an excess of stannous oxide is dissolved in stannic chloride, the mass solidifies to a pulp of stannic hydrate, and the liquid which runs off yields, on evaporation, the dihydrate of stannous chloride, $SnCl^2.2H^2O$. (Scheurer-Kestner.)

Compounds of Stannic Chloride.—Stannic chloride unites with a considerable number of bodies, both organic and inorganic. It dissolves crystallisable (not amorphous) *sulphur*, when heated with it; also ordinary *phosphorus*, *iodine*, and other bodies, in large quantity; it mixes in all proportions with *bromine* and *carbonic disulphide*, and like the latter is a solvent for many bodies. Sulphur crystallises from the hot saturated solution in rhombic prisms. (Girardin, Compt. rend. li. 1057.)

Anhydrous stannic chloride absorbs *ammonia-gas*, forming the compound

$SnCl^4.2NH^3$, which is a white powder, sublimable without decomposition, and perfectly soluble in water after sublimation. (H. Rose.)

Vapour of *sulphuric anhydride* is easily absorbed by stannic chloride, forming a solid mass. (Rose, Pogg. Ann. xliv. 320.)

Stannic chloride also quickly absorbs *sulphydric acid gas*, giving off hydrochloric acid, and forming a stannic sulphochloride, $SnS^2.2SnCl^4$:

$$3SnCl^4 + 2H^2S = SnS^2.2SnCl^4 + 4HCl.$$

The compound obtained by perfect saturation with sulphydric acid, is a yellowish or reddish liquid, heavier than water. When heated, it gives off tetrachloride of tin, and leaves the disulphide. (Dumas.)

A compound of stannic chloride with *tetrachloride of sulphur*, $SnCl^4.2SCl^4$, is produced by the action of chlorine-gas on sulphide of tin at ordinary temperatures:

$$SnS^2 + 6Cl^2 = SnCl^4.2SCl^4.$$

It forms large yellow crystals, which melt when heated, and sublime without decomposition; they fume in the air more strongly than tetrachloride of tin.

Tetrachloride of Tin with Pentachloride of Phosphorus, $SnCl^4.PCl^5$.—When a mixture of the last-described compound with trichloride of phosphorus is moderately heated in a stream of hydrochloric acid gas, a rapid action takes place, and this compound is formed, together with other products:

$$SnCl^4.2SCl^4 + 3PCl^3 = SnCl^4.PCl^5 + 2PCl^5 + S^2Cl^2.$$

If the retort in which the action takes place is connected with a receiver surrounded with ice, a pasty yellowish mass collects in the receiver, and an amorphous white body remains in the retort. On heating the yellowish mass between 100° and 120°, disulphide of chlorine escapes, and there remains a mixture of pentachloride of phosphorus with the double chloride, identical, in fact, with the amorphous white mass in the retort. On heating this mixture to a temperature between 140° and 160°, the pentachloride of phosphorus is also driven off, leaving the double chloride, which sublimes, between 200° and 220°, in highly lustrous colourless needles, which, however, soon crumble to an amorphous powder, even when kept in close vessels. The compound fumes strongly in air, and rapidly absorbs water, being thereby converted into transparent colourless crystals containing water of crystallisation. (Casselmann, Ann. Ch. Pharm. lxxxiii. 257.)

Tetrachloride of Tin with Oxychloride of Phosphorus, $SnCl^4.POCl^3$.—Obtained by the action of oxychloride of phosphorus on tetrachloride of tin: if an excess of either substance is present, the compound separates in large isolated crystals. It has a peculiar odour, melts at 66°, boils at 180°, and distils without alteration if kept from contact with moist air. It fumes in the air, and is decomposed by water. When oxychloride of phosphorus comes in contact in a close vessel with the compound $SnCl^4.2SCl^4$, the whole dissolves, forming a yellowish liquid, from which, after a while, the compound $SnCl^4.POCl^3$ crystallises; and above the crystals there remains a yellow liquid, probably SCl^4. (Casselmann.)

Tetrachloride of Tin with Phosphoretted Hydrogen, $3SnCl^4.2PH^3$.—The two bodies unite without production of hydrochloric acid; the compound is solid. (Rose.)

Nitric oxide is abundantly absorbed by tetrachloride of tin, forming a crystallisable compound, which may be distilled, but, in contact with water or with moist air, is resolved into nitric oxide and stannic chloride (Kuhlmann, Ann. Ch. Pharm. xxxix. 319). According to Hampe (*ibid.* cxxvi. 43), nitric oxide does not act on stannic chloride except in presence of oxygen; but nitric peroxide and nitrous anhydride are absorbed by stannic chloride, forming a yellow mass, which contains stannic oxide together with a crystalline sublimable compound, $3SnCl^4.4NO^2Cl$.

With *ethylic oxide*, stannic chloride forms the compound $SnCl^4.2(C^2H^5)^2O$, crystallising in shining rhombic plates, which melt at 80°, volatilise without decomposition, dissolve in ether, but are decomposed by water.—With *ethylic oxalate* it forms a crystallisable compound, $SnCl^4.C^6H^{10}O^4$, which is also decomposed by water (Lewy, Compt. rend. xxi. 371). It also forms crystallisable compounds with several nitriles, as with *acetonitrile, propionitrile, capronitrile, benzonitrile*, &c.

Double Salts.—Stannic chloride unites with the chloride of the alkali-metals and alkaline earth-metals, forming double salts, sometimes called chlorostannates: they are prepared by evaporating the mixed solutions of the component chlorides, and some of them form well-defined crystals.

The *ammonium-salt*, $2NH^4Cl.SnCl^4$, separates, on mixing the concentrated solutions of the constituent chlorides, as a crystalline powder: from less concentrated solutions, it separates, on evaporation, in regular octahedrons or cubo-octahedrons of larger size and permanent in the air. This salt is also formed in the preparation of stannic sulphide, or mosaic gold, from tin, sulphur, and sal-ammoniac, in which case it sublimes in transparent octahedrons. The crystals dissolve in 3 pts. water at 14°. The concentrated solution is not decomposed by boiling; a more dilute solution decomposes at the boiling heat, with separation of stannic hydrate, which unites with any colouring-matter contained in the solution, so that the salt acts as a mordant. It is used in calico-printing, under the name of **pink salt**, for the production of red colours. The dry salt decomposes when strongly heated, giving off stannic chloride, and yielding a sublimate of white laminar crystals.

The *barium-*, *calcium-*, and *strontium-salts* are crystallisable, and their composition (according to Lewy) is represented by the formula $M''Cl^2.SnCl^4.5H^2O$.—The *magnesium-salt*, $MgCl^2.SnCl^4.5H^2O$, crystallises in rhombohedrons.

The *potassium-salt*, $2KCl.SnCl^4$, is prepared like the ammonium-salt, or by fusing 1 at. stannic oxide with 2 at. potassium-hydrate, and dissolving in hydrochloric acid. It crystallises in octahedrons, which are permanent in the air, soluble in water, and decomposed by heat (Bolley; Lewy).—The *sodium-salt*, prepared like the potassium-salt, crystallises in rhombic laminæ, permanent in cold, efflorescent in warm air (Bolley, Ann. Ch. Pharm. xxxix. 100). Wittstein (Repert. Pharm. lxiv. 7) obtained it in anhydrous deliquescent crystals.

TIN, CYANIDE OF. See CYANIDES (ii. 273).

TIN, DETECTION AND ESTIMATION OF. 1. *Blowpipe Reactions.*—All tin-compounds, when heated on charcoal with carbonate of sodium or cyanide of potassium, yield a malleable metallic globule, without any incrustation on the charcoal. This globule, when dissolved in hydrochloric acid, gives, with mercuric chloride, a white precipitate, becoming grey when heated.

2. *Reactions in Solution.*—*α. Stannous salts.*—Stannous oxide has no acid properties, tin being basylous in all stannous salts. These salts are obtained by dissolving stannous oxide in acids, the hydrate dissolving much more easily than the anhydrous oxide. They are colourless, and, in neutral solution, are partially decomposed by water, with precipitation of a basic salt. They absorb oxygen from the air, forming stannic oxide, which is precipitated if there is not enough free acid present to hold it in solution. The reactions of stannous salts are most readily studied in the solution of the chloride. They exert a powerful reducing action, converting ferric oxide into ferrous oxide, and precipitating silver and platinum in the metallic state from their solutions.—With *mercuric chloride* a white precipitate of mercurous chloride is formed, which, if the stannous salt is in excess, is further reduced to metallic mercury.—*Trichloride of gold* produces a purple precipitate in stannous salts, consisting probably of sesquioxide of tin in combination with protoxide of gold, a test by which stannous salts may always be distinguished.—*Sulphydric acid* produces, in neutral or acid solutions of stannous salts, a brown-black precipitate of stannous sulphide, which, when gently heated with a considerable quantity of sulphide of ammonium containing excess of sulphur, is converted into stannic sulphide and dissolved; acids added in excess to this solution, precipitate yellow stannic sulphide.—*Caustic alkalis* and *alkaline carbonates*, added to stannous salts, throw down a white precipitate of hydrated stannous oxide, soluble in caustic potash or soda, but not in ammonia.—*Ferrocyanide of potassium* produces a white precipitate, soluble in hydrochloric acid. Stannous salts, heated with *sulphurous acid*, yield yellow stannic sulphide and white stannic oxide.

β. Stannic salts.—Stannic oxide in the anhydrous state is insoluble in all acids, even in nitromuriatic acid. It forms two hydrates, distinguished as **stannic** and **metastannic hydrates**, the former of which is an amorphous gummy substance, soluble in hydrochloric, sulphuric, and nitric acids, and in caustic alkalis, whereas the latter, formed from by it the action of strong nitric acid, is distinguished by its insolubility in acids, especially in nitric acid and in concentrated hydrochloric acid.

The solution of **stannic hydrate** in hydrochloric acid is identical with the aqueous solution of stannic chloride. It is distinguished from stannous solutions by not exerting any reducing action.—*Metallic zinc* and *cadmium* immersed in stannic solutions throw down metallic tin in an arborescent form.—*Sulphydric acid* and *sulphide of ammonium* throw down the yellow disulphide, soluble in alkalis and in sulphide of ammonium.—*Ammonia* throws down a white bulky hydrate, soluble, with some turbidity, in a large excess of ammonia. The presence of tartaric acid prevents the precipitation.—*Potash* throws down a white bulky hydrate (probably containing potash), easily soluble in excess.—*Carbonate of potassium* gives a white precipitate, consisting (according to Frémy) of potassic stannate, which dissolves in excess of the reagent, but separates completely after a while.—*Dicarbonate of potassium* and *sesquicarbonate of ammonium* throw down the hydrated oxide, insoluble in excess of the reagent.—*Chloride of gold* gives no precipitate with stannic salts.

Metastannic hydrate, as already observed, does not dissolve in strong hydro-
forms with it a compound insoluble in acids, but soluble in pure water.

The resulting solution is precipitated by dilute sulphuric acid, also by nitric and strong hydrochloric acid.—*Potash* throws down metastannic hydrate, soluble in excess of the alkali, and reprecipitated by excess of acid, also by the chlorides of the alkali-metals, chloride of ammonium, and sulphate of potassium. The alkaline solution of metastannic hydrate solidifies to a transparent jelly on cooling.—*Ammonia* precipitates metastannic hydrate from its solution in very dilute acid; the precipitate is insoluble in excess of strong sulphuric acid, and in tartaric acid: hence metastannic hydrate is precipitated by ammonia even in presence of tartaric acid.—*Alkaline carbonates* precipitate the hydrochloric acid solution, the precipitate being insoluble in excess of the reagent.—*Nitrate of silver* forms a white precipitate, which dissolves but partially in ammonia, leaving metastannic hydrate.—*Tincture of galls* forms, after a while, a yellowish-white precipitate.—*Stannous chloride* forms a yellowish precipitate of stannous metastannate.—*Sulphydric acid* and *sulphide of ammonium* react with metastannic in the same way as stannic solutions.

Stannic and metastannic hydrates may be distinguished one from the other by their reaction with *ferrocyanide of potassium*, inasmuch as 1 at. stannic hydrate completely precipitates 1 at. ferrocyanide of potassium, whereas metastannic hydrate does not decompose that salt.

Both stannic and metastannic hydrates react as acids, forming definite salts with bases. The solutions both of stannates and metastannates, when decomposed by acids, yield precipitates consisting of the particular modification of stannic acid contained in them, which may then be distinguished by its behaviour with hydrochloric acid, &c.

Metastannic hydrate fused with a sufficient quantity of caustic alkali, forms a stannate from which acids precipitate ordinary stannic acid.

3. *Quantitative Estimation.*—Tin is estimated in the state of stannic oxide, SnO^2, which contains 78·62 per cent. of the metal. If the tin is united with other metals in the form of an alloy, the alloy must be treated with nitric acid of specific gravity about 1·3. The tin is then converted into insoluble metastannic hydrate, while the other metals (with the exception of antimony, gold, and the platinum-metals) are dissolved by the acid. The insoluble residue must then be thoroughly washed, afterwards dried, ignited, and weighed as stannic oxide. To insure complete oxidation, the alloy should be finely divided.

When the tin is in solution in hydrochloric acid (which is its usual solvent), it may be precipitated as a sulphide by sulphydric acid, and the sulphide then converted into stannic oxide by roasting in an open porcelain crucible, a small quantity of nitric acid being added to complete the oxidation.

From solutions of stannic salts, tin may be completely precipitated as stannic or metastannic acid by *dilute sulphuric acid*. The solution is first neutralised with ammonia, so as to cause a slight precipitate; hydrochloric acid is then cautiously added till the precipitate is redissolved, care being taken to avoid any great excess of acid. This solution is then mixed with sulphuric acid. If the liquid contains ordinary stannic acid (or the corresponding chloride), it must be largely diluted to insure complete precipitation; if, on the other hand, the tin is present as metastannic acid, it will be completely precipitated by sulphuric acid from less dilute solutions. In all cases the precipitate must be left to settle for some hours, the time required being longer as the quantity of free acid present is greater. It is then to be thoroughly washed, and ignited, to convert it into stannic oxide. To ascertain whether the precipitation is complete, it is advisable to test the wash-waters with sulphuretted hydrogen.

Sulphate of sodium and *nitrate of potassium* or *ammonium* are sometimes used, instead of sulphuric acid, to precipitate tin. Sulphate of sodium does not appear, however, to possess any advantage over sulphuric acid in this respect. The nitrates may be advantageously used when the solution contains bases which form soluble sulphates.

The mode of precipitation just described is very accurate, and affords a means of separating stannic from stannous salts, the whole of the latter remaining in solution after the precipitation of the stannic oxide by sulphate of sodium. (Löwenthal.)

Another method of determining the proportions of stannic and stannous salt in a mixed solution of the two, is to divide the solution into two equal parts, convert the whole of the one into stannic salt by treatment with chlorine or chromate of potassium, and precipitate with sulphuric acid, as above; this determines the total amount of tin present. The other portion is dropped into a solution of *mercuric chloride*, and the mercurous chloride thereby precipitated is collected on a weighed filter, washed, dried, and weighed. From its weight, the quantity of tin present as stannous salt may be calculated, 2 at. mercurous chloride (471) corresponding to 1 at. tin (118), present as stannous chloride, according to the equation:

$$2HgCl^2 + SnCl^2 = 2HgCl + SnCl^4.$$

Volumetric Estimation.—Tin may be estimated volumetrically by converting a stannous into a stannic salt with oxidising solutions of known strength. One at. stannous oxide, SnO, by taking up 1 at. oxygen, is converted into stannic oxide, SnO^2: consequently, 1 at. oxygen (16) is equivalent to 1 at. tin (118). The quantity of the oxidising solution required to effect the conversion is, however, materially affected by the greater or less dilution of the solution, the greater or smaller amount of free acid present, and the quantity of oxygen dissolved in the water. **Penny** (Chem. Soc. Qu. J. iv. 239; vii. 50), and afterwards **Streng** (Ann. Ch. Pharm. xc. 411), used a solution of acid potassic chromate for the titration of tin; **Schlagdenhauffen** (J. Pharm. [3] xxxi. 96) uses manganate of potassium.

Streng mixes the acid solution of stannic chloride with a little starch-paste containing iodide of potassium, and then adds a graduated solution of acid potassium-chromate, till a blue colour is developed by the separation of iodine. The reaction takes place as shown by the equation, $3SnO + Cr^2O^6 = 3SnO^2 + Cr^2O^3$, so that 1 at. tin (118) corresponds to $\frac{1}{3}$ at. acid potassium-chromate ($K^2Cr^2O^7 = 230{\cdot}6$). Streng and Penny found that 100 pts. tin required 83·2 pts of the acid chromate; the calculated quantity is 83·4. According to **Kessler** (Pogg. Ann. xcvi. 129), the titration by this method generally gives inaccurate results, for the reasons above mentioned. According to **Mulder**, the chromic acid solution ought to be titrated with pure tin, and the process conducted as far as possible under similar circumstances. According to **Löwenthal** (J. pr. Chem. lxxvi. 484; lxxviii. 384), stannous chloride in acid solution may be more exactly titrated after addition of ferric or cupric chloride. **Stromeyer** (Ann. Ch. Pharm. cxvii. 261) oxidises metallic tin, or stannous chloride, by dissolving it in excess of ferric chloride, whereby stannic and ferrous chlorides are produced:

$$Sn + 4FeCl^3 = SnCl^4 + 4FeCl^2,$$
$$\text{and } SnCl^2 + 2FeCl^3 = SnCl^4 + 2FeCl^2.$$

The quantity of ferrous salt thus formed is determined by titration with permanganate, the ferrous salt being less susceptible to the action of free oxygen than the stannous salt—and the quantity of tin is thence determined by calculation. In the first case, 4 at. iron (224 grms.), or 2 at. oxygen added (32 grms.) correspond to 1 at. tin (118); in the latter, 2 at. iron (112) or 1 at. oxygen (16), correspond to 1 at. tin (118) or 1 at. stannous chloride (189). If the tin is in the state of stannic oxide or chloride, it must first be reduced by introducing a plate of zinc into the solution, and the precipitated tin then dissolved in ferric chloride, with addition of hydrochloric acid. If it has been precipitated from an acid solution as sulphide, this precipitate is also to be dissolved in ferric chloride, a reaction which is attended with separation of sulphur:

$$SnS^2 + 4FeCl^3 = SnCl^4 + 4FeCl^2 + S^2.$$

The solution is then to be titrated as above, 4 at. iron corresponding to 1 at. tin. If the tin has been precipitated from an alkaline sulphostannate by an acid, the precipitate consists (according to **Kühn**), not of pure stannic sulphide, but of stannic sulphydrate $Sn^{iv}H^2S^3$. The decomposition by ferric chloride then takes place as shown by the equation:

$$SnH^2S^3 + 6FeCl^3 = SnCl^4 + 6FeCl^2 + 2HCl + S^2.$$

In this case 6 at. iron are equivalent to 1 at. tin.

Lenssen (Ann. Ch. Pharm. cxiv. 113) titrates stannic chloride with *iodine* in alkaline solution. The tin or stannous salt is dissolved in hydrochloric acid in an atmosphere of carbonic anhydride, and sodio-potassic tartrate (Rochelle salt), or acid sodic carbonate, is added in excess; the solution is then mixed with starch-paste, and a titrated solution of iodine in iodide of potassium is added, till a permanent blue colour is produced. Stannic iodochloride is then formed, according to the equation $Sn''Cl^2 + I^2 = Sn^{iv}Cl^2I^2$, so that 2 at. iodine (254) correspond to 1 at. tin (118).

To determine volumetrically the relative quantities of stannous and stannic salt existing together in a solution, the liquid is first titrated directly by either of the preceding methods, whereby the quantity of tin existing as stannous salt is determined; and, secondly, after the stannic salt has been reduced to stannous salt, which gives the total amount of tin.

4. *Separation of Tin from other Metals.*—In metallic alloys tin, as already observed, may be separated from most other metals except antimony, gold and the platinum-metals, by oxidising the alloy with *nitric acid*, whereby the tin is converted into insoluble metastannic acid, while silver, copper, lead, cadmium, iron, manganese, cobalt, nickel, and zinc—and likewise bismuth, if a sufficient quantity of dilute nitric acid is used—are dissolved. Tin, alloyed with metals which form volatile chlorides, may be separated by heating the finely-divided alloy in a current of *chlorine gas*; stannic chloride then

volatilises, and may be condensed in water. This method serves to separate tin from gold and the platinum-metals, which do not dissolve in nitric acid.

Precipitation with *sulphydric acid* serves to separate tin from all metals whose sulphides are not thrown down by that reagent from acid solutions. From bismuth, cadmium, copper, lead, mercury, palladium, and silver, which are precipitated in the same manner, it may be separated by digesting the precipitate in *sulphide of ammonium* containing excess of sulphur. Stannic sulphide then dissolves, and may be precipitated by hydrochloric acid.

Sulphide of ammonium also dissolves the sulphides of arsenic, antimony, gold, platinum, molybdenum, selenium, and tellurium. The methods of separating tin from antimony and arsenic have already been fully described (i. 322, 369). From a solution of stannic chloride containing also the chlorides of gold and platinum, the latter metals may be precipitated in the metallic state by *ferrous acetate*, the tin then remaining in solution. If tin is mixed with these metals in the form of oxide or other insoluble compound, the three metals may be reduced by igniting the compound in hydrogen-gas, and the reduced alloy heated in chlorine gas, as above described.

From molybdenum, selenium, and tellurium, and from all metals which form soluble sulphates, tin, after being brought to the state of stannic chloride by treatment with chlorine or chlorate of potassium, may be separated, by precipitation as stannic or metastannic acid, with *sulphuric acid*. From barium, strontium, or calcium, it may be separated, in like manner, by *nitrate of ammonium* or *potassium*.

5. *Atomic Weight of Tin.*—Berzelius (Gilb. Ann. x. 235) found that 100 pts. tin, oxidised by nitric acid and ignited, yielded 127·2 pts. stannic oxide, SnO^2: hence the atomic weight of tin should be 117·64. Mulder (Ann Ch. Pharm. lxxii. 212) obtained, in like manner, 127·56 pts. of stannic oxide, giving $Sn = 116·1$. Dumas (*ibid.* cv. 104; cxiii. 26), on repeating this experiment, obtained, as a mean, $Sn = 118·06$; and by determining the quantity of silver required for precipitating a known weight of stannic chloride, the same chemist obtained $Sn = 118·09$. The atomic weight of tin may therefore be taken at 118°.

TIN, FLUORIDES OF. Tin forms two fluorides—viz., a difluoride and a tetrafluoride.

The *Difluoride*, or *Stannous fluoride*, SnF^2, is obtained by evaporating the solution of stannous oxide in hydrofluoric acid, and crystallises in small, shining, opaque prisms, having a sweetish astringent taste. When heated in the air, it takes up oxygen, and forms stannic oxyfluoride, $Sn^{iv}OF^2$ or $SnO^2.SnF^4$.

Ammonio-stannous fluoride.—Stannous chloride yields, with fluoride of ammonium, a precipitate composed of metallically lustrous micaceous laminæ, soluble in potash. (Unverdorben.)

The *Tetrafluoride*, or *Stannic fluoride*, has not been obtained in the free state as a definite compound, but it forms crystallisable double salts with other metallic fluorides. A solution of stannic hydrate in aqueous hydrofluoric acid coagulates like albumin when heated, but does not yield any crystals by evaporation; when evaporated in contact with the air, it gives off hydrofluoric acid, and leaves the oxyfluoride above mentioned.

The fluostannates, $2MF.SnF^4$ and $M''F^2.SnF^4$, are analogous in composition to the stannates, $M^2O.SnO^2$, and isomorphous with the corresponding fluosilicates and fluotitanates. (Marignac, Ann. Min. [5], xv. 221; Jahresb. 1859, p. 110.)

The *ammonium-salt*, $2NH^4F.SnF^4$, is obtained by the action of hydrofluoric acid on stannate of ammonium, or, better, by double decomposition of the lead- or silver-salt with sulphate or chloride of ammonium. The crystals, which are seldom distinct, are rhombohedral combinations, united in twins, or complex aggregates.—When evaporated with fluoride of ammonium, it yields the salt $4NH^4F.SnF^4$, in distinct rhombic combinations.

The *barium-salt*, $Ba''F^2.SnF^4$, is obtained, as a sparingly soluble precipitate, by decomposing the zinc-salt with chloride of barium. By slowly cooling a slightly concentrated solution of this precipitate, or by spontaneous evaporation, a hydrate, $Ba''F^2.SnF^4.3H^2O$, is obtained in monoclinic crystalline laminæ, but on evaporating the solution near its boiling-point, the anhydrous salt separates in microscopic indistinct crystals.

The *cadmium-salt*, $Cd''F^2.SnF^4.6H^2O$, is isomorphous with the magnesium-salt.

The *calcium-* and *strontium-salts* form monoclinic crystals containing 2 at. water.

The *cupric salt*, $Cu''F^2.SnF^4.4H^2O$, forms blue monoclinic crystals, permanent in the air.

The *lead-salt*, $PbF^2.SnF^4.3H^2O$, crystallises with difficulty in thin nacreous laminæ, isomorphous with the trihydrated barium-salt. It has a great tendency to form supersaturated solutions, which ultimately solidify in nodular crystalline masses.

By recrystallisation from water the salt is decomposed, with separation of lead-fluoride.

The *lithium-salt*, $2LiF.SnF^4.2H^2O$, rarely forms distinct monoclinic crystals: generally only crystalline crusts, or indistinct microscopic crystals.

The *magnesium-salt*, $Mg''F^2.SnF^4.6H^2O$, crystallises in hexagonal combinations, permanent in the air.—The *manganese-salt*, $Mn''F^2.SnF^4.6H^2O$, forms pale-red shining crystals, isomorphous with the last, and gradually becoming dull on exposure to the air.—The *nickel-salt*, $NiF^2.SnF^4.6H^2O$, is likewise isomorphous with the magnesium-salt.

The *potassium-salt*, $2KF.SnF^4.H^2O$, is obtained by saturating a solution of potassic stannate with hydrofluoric acid, and evaporating, in laminar crystals, which dissolve in 2·3 pts. of boiling water, and in 15 to 16 pts. water at 18°. Sometimes, especially on recrystallising with addition of a drop of hydrofluoric acid, a salt, identical in composition with that just described, is obtained in granular crystals having the form of rhombic pyramids, soluble in 3 pts. boiling water and in 27 pts. water at 18°. The crystals of both kinds retain their water till heated above 100°, and melt at a red heat, with loss of hydrofluoric acid.—An *acid potassium-salt*, $2(2KF.SnF^4).(KF.HF)$, or $2K^2Sn^{iv}F^6.KHF^2$, crystallises in needle-shaped monoclinic combinations.

The *silver-salt*, $2AgF.SnF^4.4H^2O$, forms indistinct crystals, which melt below 100°, but do not give off their water till heated to a higher temperature, at which also hydrofluoric acid is given off.

The *sodium-salt*, $2NaF.SnF^4$, has not been obtained in distinct crystals: it dissolves in 18 to 19 pts. of water at 20°.

The *zinc-salt*, $ZnF^2.SnF^4.6H^2O$, is isomorphous with the magnesium-salt, and easily soluble in water.

TIN, IODIDES OF. There are two iodides of tin analogous to the protoxide and dioxide. The existence of a sesquioxide, Sn^4I^6, is doubtful. A solution of iodine in iodide of potassium (1 at. iodine to 2 at. KI) does not precipitate a solution of stannic chloride, but on evaporation a yellow powder is deposited, which may possibly be the sesqui-iodide. (Boullay.)

Di-iodide of Tin, or *Stannous Iodide.*—This compound is produced:—1. By heating 1 pt. of tin with 2 pts. of iodine till the iodine melts. A violent action then takes place, and a brown mass is formed, consisting of stannous and stannic iodides, the latter of which may be separated by sublimation, while the stannous iodide remains in the form of a red crystalline mass.—2. By adding iodide of potassium in slight excess to a warm concentrated solution of stannous chloride, the liquid, as it cools, depositing stannous iodide in yellowish-red needles.—3. By the action of hydriodic acid on tin or the dichloride. When moderately concentrated hydriodic acid is placed in contact with strips of tinfoil, or with tin-filings, in a long glass tube, and kept in gentle ebullition for several days, or heated in a sealed tube to 120°—150° for some hours, stannous iodide is formed, in shining yellowish-red prisms (Wöhler and Dünhaupt, Ann. Ch. Pharm. lxxxvi. 374). Tin, heated with iodide of amyl to 180°, in a sealed tube for some time, is converted, partly into yellowish-red quadratic octahedrons, partly into sulphur-yellow prisms, which quickly turn red in contact with the air: these compounds have not been analysed.

Stannous iodide, heated in a close vessel, melts to a dark-red crystalline mass, yielding a cinnabar-coloured powder. When heated in contact with the air, it is decomposed, stannic iodide subliming, and stannous oxide remaining. It is slightly soluble in cold, somewhat more soluble in hot water, and is not decomposed thereby. A solution of stannous iodide is likewise formed by heating tin with water and iodine. Stannous iodide dissolves also in aqueous stannous chloride.

Compounds of Stannous Iodide.—*a.* With stannous chloride.—An aqueous solution of stannous chloride mixed with iodine, deposits stannous iodide; and on evaporating the remaining liquid (which contains stannic chloride, stannous chloride, and stannous iodide), stannous chloriodide, SnClI or $SnCl^2.SnI^2$, separates in straw-yellow, non-volatile crystals, which are decomposed by water, with separation of stannous iodide. (Henry.)

β. With stannous oxide.—Stannous iodide is decomposed by a large excess of water, forming hydriodic acid which dissolves, and stannous oxide which unites with the undecomposed iodide, forming, according to Personne (Compt. rend. liv. 216), insoluble oxyiodides of variable composition, which are yellow, pulverulent, and are decomposed by a large quantity of water. Personne analysed four of these compounds, ing $Sn^3IO^2 = SnI^2.2SnO$; $Sn^2I^2O = SnI^2.SnO$; $Sn^3I^4O = 2SnI^2.SnO$; and $3SnI^2.SnO$.

ammonia.—100 pts. stannous iodide absorb 20 pts. ammonia-gas, form- compound, which in the pure state is probably $2NH^3.SnI^2$, or iodide of ium $(N^2H^6Sn'')I^2$. (Rammelsberg, Pogg. Ann. xlviii. 169.)

5. With other metallic iodides.—Stannous iodide unites with the iodides of the alkali-metals and alkaline earth-metals, forming double salts, which may be obtained either by direct mixture of the solutions of the constituent iodides, or by mixing a solution of stannous chloride with excess of a metallic iodide. They must be crystallised from alcohol, as they are decomposed by water, forming stannous oxyiodides, similar to those produced from stannous iodide and water.

The *ammonium-salt*, $2NH^4I.SnI^2$, forms greenish-yellow needles (Boullay). According to Personne, there is also a salt containing $NH^4I.SnI^2.\frac{3}{2}H^2O$.—The *potassium-salt*, $2KI.SnI^2$, forms yellowish silky needles, which, when heated in chlorine gas, yield stannic chloride, chloride of potassium, and free iodine (Boullay). Personne likewise obtained the hydrated salt, $KI.SnI^2.\frac{3}{2}H^2O$.—The *sodium-salt*, $NaI.SnI^2$, forms pale-yellow crystals.

Stannous iodide also forms crystallisable double salts with the iodides of *barium* and *strontium*.

Tetraiodide of Tin, or *Stannic Iodide*, SnI^4, is formed, together with stannous iodide, by heating tin-filings with iodine in a sealed tube, combination taking place with incandescence at 50°. It may be separated from the stannous iodide by its greater volatility. It is also produced by the action of iodine on stannous chloride, or by dissolving stannic hydrate in hydriodic acid. (Berzelius.)

Sublimed stannic iodide forms yellowish-red octahedrons, of specific gravity 4·696. It melts at 146°, solidifies at 142°, sublimes at 180°, and boils at 295°. It is decomposed by water, completely at the boiling heat, into hydriodic acid and stannic hydrate. It dissolves in alcohol, ether, and benzene.

Stannic iodide does not combine either with stannic hydrate, or with the iodides of the alkali-metals. It easily absorbs dry ammonia-gas, forming at first a yellow body, $3NH^3.SnI^4$, and by further assumption of ammonia, the two compounds, $4NH^3.SnI^4$ and $6NH^3.SnI^4$. (Personne.)

TIN, OXIDES OF. Tin forms three oxides: a protoxide, a sesquioxide, and a dioxide.

Protoxide of Tin, or **Stannous Oxide,** SnO.—This oxide is produced: 1. By heating stannous oxalate out of contact with air (Liebig).—2. By precipitating stannous chloride with carbonate of sodium, and heating the washed and dried precipitate of stannous hydrate in an atmosphere of hydrogen or carbonic anhydride, to a temperature not exceeding 80°; the anhydrous oxide is thus obtained as a brown or black powder (Berzelius). According to Otto, the hydrate sometimes changes to the black oxide on the filter, or on the sides of the precipitating vessel, where it is touched with a glass rod.—3. Stannous hydrate, boiled with a quantity of caustic potash or soda less than sufficient to dissolve it, is converted into small, black, shining crystals of the anhydrous oxide (Frémy, Berz. Jahresb. xxiv. 133; xxv. 172).—4. A solution of stannous chloride is evaporated in contact with metallic tin, till a residue of the fused chloride is obtained; this, after removal of the metallic tin, is heated with 1 at. or more of crystallised sodic carbonate till it turns black, and the stannous oxide thus produced is washed and dried. (Sandall, J. pr. Chem. xiv. 254.)

Stannous oxide is a black powder, of specific gravity 6·666 (Berzelius); bluish-black or slate-grey (Sandall). The crystals obtained by the third process are, according to Nordenskjöld, monometric, exhibiting the combination $\infty O \,.\, \infty O \infty$, have a specific gravity of 6·1, and yield a greenish-brown powder. When heated to 258°, they decrepitate, swell up, and are resolved into olive-green laminæ, soft to the touch (Frémy). This olive-green modification is likewise obtained by boiling stannous hydrate with excess of ammonia (Gay-Lussac). A third modification is obtained by evaporating a very dilute solution of sal-ammoniac in which hydrated stannous oxide is diffused, that compound being converted, as soon as the sal-ammoniac crystallises, into anhydrous stannous oxide having the form of a cinnabar-coloured powder (Frémy). The red modification is also produced by digesting thoroughly-washed hydrated stannous oxide, at a temperature of 133°, in a slightly acid solution of stannous acetate having a density of 1·06. The oxide is then obtained in heavy, hard, crystalline grains, which yield a greenish-brown powder by trituration, and blacken when exposed to sunshine. (Roth, Ann. Ch. Pharm. lx. 214.)

Stannous oxide is permanent in the air at ordinary temperatures, but easily oxidises to stannic oxide when heated. When dry, it may be set on fire by a glowing body, and then burns to stannic oxide. It is reduced at a red heat by *hydrogen* or *charcoal*, and when heated before the blowpipe with *carbonate of sodium* (best with addition of cyanide of potassium), it yields a button of metal.—Heated in *chlorine-gas* it is converted into stannic chloride and stannic oxide. When ignited with *sulphur*, it yields stannic sulphide and sulphurous anhydride. By boiling with caustic *potash* or *soda*, it is converted into a stannate of the alkali-metal, with separation of tin.—With *acids*, it forms the stannous salts.

Stannous Hydrate, $Sn^2H^2O^3 = 2SnO.H^2O$, is obtained, as a white precipitate, by decomposing a stannous salt with an alkaline carbonate. It dissolves in acids and in the fixed alkalis much more easily than the anhydrous oxide, but is insoluble in ammonia. When boiled with water or with aqueous alkalis, or when gently heated in the dry state, it is converted into the anhydrous oxide. When exposed to the air, it gradually takes up oxygen, and is converted into stannic hydrate. When boiled with strong potash-ley, it yields stannate of potassium and metallic tin.

Stannous hydrate acts as a deoxidising agent, like the corresponding chloride (p. 806), reducing some metallic oxides to metal, others to a lower state of oxidation. Its action on *cupric oxide* has been specially studied by Lenssen (J. pr. Chem. lxxxix. 90; Jahresb. 1860, p. 182). When a solution of stannous hydrate in alkaline carbonate is mixed with an alkaline cupric solution (prepared with cupric sulphate, tartaric acid, and sodic carbonate), a flesh-coloured precipitate is at first produced, consisting of cuprous and stannous oxides; and on adding more cupric sulphate, a red precipitate is formed, containing cuprous and stannic oxides. When solutions of stannous and cupric oxide in caustic alkali are mixed together, cuprous oxide is precipitated, together with stannic oxide.—With excess of the tin-solution, a yellowish liquid is produced, which, when heated, deposits a black powder, composed of $Cu^2O.3SnO.SnO^2.5H^2O$. This compound acquires a tinge of green in drying, gives off 2 at. water at 100°, and when heated in the air, oxidises with incandescence, and then contains cuprous and stannic oxides.—When a boiling solution of stannous oxide in caustic alkali is mixed with a small quantity of alkaline cupric solution, a heavy black powder is deposited, which acquires metallic lustre by burnishing; this body contains 79·1 per cent. copper to 14·8 tin; therefore 10 at. copper to 1 at. tin and 3 at. oxygen: hence it appears to be an alloy of copper and tin mixed with cuprous or stannous oxide.

Sesquioxide of Tin, Sn^2O^3.—This oxide was obtained by Fuchs, in combination with water, by diffusing recently precipitated ferric oxide in a solution of stannous chloride not containing any excess of acid, and afterwards boiling the mixture. Sesquioxide of tin is then precipitated, and ferrous chloride remains in solution:

$$2SnCl^2 + Fe^2O^3 = Sn^2O^3 + 2FeCl^2.$$

The sesquioxide thus obtained is a slimy grey matter, generally yellow from adhering oxide of iron. Ammonia dissolves it easily and without residue, a character which distinguishes this oxide from the protoxide of tin, the latter being insoluble, or nearly so, in ammonia. Sesquioxide of tin is dissolved by concentrated hydrochloric acid; the taste of the solution is not metallic. The solution is distinguished from that of a stannic salt, by producing the characteristic purple precipitate with chloride of gold. Sesquioxide of tin does not appear to form definite salts.

Dioxide of Tin, or **Stannic Oxide,** SnO^2.—This oxide occurs native as *Tinstone* or *Cassiterite*, being in fact the principal ore of tin (p. 798). It forms quadratic crystals, usually exhibiting the combination $P . \infty P . P\infty . \infty P\infty$ (*fig.* 322, vol. ii. p. 160). The prismatic faces are often but little developed, and $P\infty$ is often absent altogether. The combinations $P . \infty P . \infty P\frac{3}{2}$, and $P . \infty P . 3P\frac{3}{2}$, likewise occur. For P, the length of the principal axis is 0·6743. Angle P : P (terminal) = 121° 35′; P : P (lateral) = 87° 17′. Twins occur like *fig.* 323. The crystals cleave imperfectly parallel to ∞P and $\infty P\infty$, and in traces parallel to P. The mineral occurs also in imbedded and implanted crystals, and in botryoïdal or reniform shapes, with fibrous divergent structure, and composed of concentric coats, constituting the variety called *wood-tin*, or, when it occurs in small lumps, *toad's-eye-tin*; also massive, granular or impalpable. Hardness = 6 to 7. Specific gravity = 6·3 to 7·1. Lustre adamantine; crystals usually splendent. Colour brown or black, sometimes red grey, or yellow; rarely colourless. Streak white, greyish, or brownish. Nearly transparent—translucent. Fracture subconchoïdal, uneven. Brittle.

Analyses.—*a.* From Schlackenwald, in Bohemia (Klaproth, *Beiträge*, ii. 245).—*b.* Alternon, in Cornwall (Klaproth).—*c.* Finbo, near Fahlun, in Sweden (Berzelius, Schw. J. xvi. 256).—*d.* County of Wicklow, Ireland: brown grains from the sand: specific gravity = 6·753 (Mallet, Dublin Geol. Soc. J. iv. 272).—*e.* Xeres, in Mexico: dark-brown wood-tin, yielding a red powder: specific gravity = 6·862 (Bergemann, Leonh. Jahresb. 1857, p. 395).—*f*, *g*. From the sand of the Tipuani river in Bolivia, occurring with gold, metallic tin, and several other minerals: *f.* brownish, *g.* black; specific gravity = 7·021 (D. Forbes, Phil. Mag. [4], xxx. 139):

A colourless specimen from the last-mentioned locality, of specific gravity 6·843 (also after strong ignition), was found by Forbes to consist of nearly pure stannic oxide. A specimen from Carabuco, in Bolivia, occurring in prisms of specific gravity 6·4, was found by Kröber to contain 96·339 per cent. stannic oxide, 2·177 ferric oxide, 0·0115 silver, 0·20 tungstic anhydride, 0·250 lead, and 1·737 water (= 100·538). Chandler (Sill. Am. J. [2], xxxix. 340) found in a tinstone from Durango, in Mexico, about 95·9 per cent. stannic oxide, and 4·1 topaz, in crystals of various size.

Stannic oxide may be crystallised artificially:—1. By passing the vapour of stannic chloride mixed with aqueous vapour through an ignited porcelain tube; larger crystals are, however, obtained by diffusing the vapour of the stannic chloride through a stream of dry carbonic anhydride, instead of volatilising it by heat, and then passing it, mixed with steam, through the ignited tube. The crystals thus obtained are colourless, with an adamantine lustre, and a specific gravity of 6·72, and are hard enough to scratch glass: they are trimetric prisms, isomorphous with the variety of native titanic oxide called brookite, and therefore different from those of native tinstone, which are quadratic, and isomorphous with anatase. Stannic oxide is therefore dimorphous (Daubrée, Pharm. Centr. 1849, p. 821).—2. By igniting amorphous stannic oxide in a stream of hydrochloric acid gas, the crystals being larger with a rapid than with a slow current of the gas. These crystals are quadratic, like those of native tinstone (Deville, Compt. rend. liii. 161).—3. The formation of crystallised stannic oxide has been observed to take place in fusing the dross or slag collected on the hearth of a furnace used for casting gun-metal. The crystals thus produced were very hard, brittle, four-sided prisms, similar in form to those obtained by Daubrée. (Abel, Chem. Soc. Qu. J. x. 119.)

Amorphous stannic oxide is easily obtained by heating tin in contact with the air. A grey film is first formed, consisting of a mixture of stannic oxide and metallic tin, formerly called *Civis jovialis* (a name afterwards applied to stannic oxide itself); by further heating, it is converted into pure stannic oxide. Tin, when rapidly heated to its boiling-point, burns with a white flame, yielding flocks of stannic oxide, formerly called *Flores stanni*, s. *Fl. Jovis*. Stannic oxide is also formed by igniting the protoxide or sesquioxide, or the corresponding hydrates, in contact with the air. Stannous oxalate, heated in small quantities in contact with the air, yields very hard stannic oxide. (Vogel, Pharm. Centr. 1855, p. 413.)

Amorphous stannic oxide is a white or yellowish powder, assuming, when heated, a transient dark-yellow or brown colour. Its specific gravity is 6·6 to 6·9; its cubical expansion, between 0° and 100°, is 0·0016 (Kopp), 0·0017 (Joule and Playfair). It is hard, and is therefore used for polishing stone and glass, and for sharpening and polishing steel, &c. The oxide used for this purpose is called **putty-powder**; it is sometimes a mixture of the oxides of tin and lead.

Stannic oxide, whether crystallised or amorphous, is very difficult to fuse, and not at all volatile. It is not attacked by acids, even in the concentrated state. According to Rose, it forms, when heated with the strongest *sulphuric acid*, a syrupy liquid, which deposits the whole of the stannic oxide on dilution with water. When fused with *acid sulphate of potassium*, it dissolves, but separates completely from the fused mass on addition of water. It is not dissolved by fusion with alkaline carbonates, but is rendered soluble by fusion with *caustic alkali*. When fused with *sulphur*, it yields sulphide of tin and sulphurous anhydride; by ignition in *chlorine-gas*, it is converted into stannic chloride; even natural tinstone is decomposed in this manner. It is reduced to the metallic state by ignition with *hydrogen*, *charcoal*, *carbonic oxide*, and *carburetted hydrogen-gas*; also by heating with *potassium* and *sodium*.

Stannic oxide is much used in the preparation of enamel, to render the glass opaque, and in the manufacture of opaque glasses in general.

Stannic Hydrates and Salts.

Stannic oxide forms two hydrates, differing from one another in composition and properties—both however being acids, and capable of forming salts by exchanging their hydrogen for metals. These hydrates or acids are **stannic acid**, $SnO^2.H^2O$ =

$H^2Sn^{iv}O^3$, and **metastannic acid**, $Sn^5O^{10}.5H^2O = H^{10}Sn^5O^{15}$, the former being capable of exchanging the whole of its hydrogen for metal, and forming the stannates which contain M^2SnO^3, whereas the latter exchanges only one-fifth of its hydrogen for metals, forming the metastannates, $M^2H^8Sn^5O^{15}$. Berzelius, who first observed the differences between these two acids, supposed them to contain different modifications of stannic oxide; but the polymerism of the two hydrates, and the diversities of composition of their corresponding salts, is quite sufficient to account for their differences of character without the aid of any such hypothesis (Frémy, Ann. Ch Phys. [3], xii. 462; xxiii. 393). According to R. Weber, however (Pogg. Ann. cxxii. 358; Jahresb. 1864, p. 243), stannic and metastannic acids exhibit no essential differences in their behaviour towards bases. He finds, indeed, that normal stannate of potassium can take up a large quantity of stannic hydrate, forming a clear solution, which, when evaporated over oil of vitriol, leaves a hydrated salt containing 1 at. K^2O to 5 at. SnO^2; and that metastannic acid dissolved to saturation in potash-ley, and evaporated in like manner, yields a salt containing 1 at. K^2O to 6 or 7 at. SnO^2. Hence Weber concludes that the relations of stannic and metastannic acids to bases are not essentially different, and that their supposed polymerism has no existence; but his results require confirmation.

STANNIC ACID.—This hydrate is precipitated by acids from solutions of alkaline stannates, also from the solution of stannic chloride by a carbonate of barium or calcium, not in excess; alkaline carbonates throw down an acid stannate. When dried in a vacuum, it has the composition $SnO^2.H^2O = SnH^2O^3$; after drying in a stream of dry air, it contains 22·5 per cent. water, corresponding with the formula $3SnO^2.7H^2O$, or $3SnH^2O^3.4H^2O$; and at 140° it gives off 5 at. water, leaving the hydrate $3SnO^2.2H^2O$, which has the same composition as metastannic acid dried at the same temperature (p. 820).

Stannic acid, when recently precipitated, is gelatinous; after drying in the air, it forms hard translucent lumps, like gum-arabic, which redden litmus. According to Weber, stannic acid dried in the air at ordinary temperatures contains $SnO^2.2H^2O$, and has therefore the same percentage composition as air-dried metastannic acid.

Stannic hydrate dissolves in the stronger acids, forming the **stannic salts**. These salts are also formed by exposing solutions of stannous salts containing excess of acid to the air, or by treating them with chlorine, or with a small quantity of nitric acid. The solution of stannic hydrate in hydrochloric acid is identical with aqueous stannic chloride. The stannic salts of oxygen-acids are very unstable. The general reactions of the stannic salts have been already described (p. 810). The individual salts are described under the respective acids.

Stannates.—Stannic hydrate exhibits acid much more decidedly than basic properties. It forms easily soluble salts with the alkali-metals, and from these the insoluble stannates of the earth-metals and heavy metals are obtained by double decomposition. The stannates are decomposed by acids, yielding gelatinous stannic acid. The general formula of the normal stannates is $M^2Sn^{iv}O^3 = M^2O.SnO^2$. They have been examined chiefly by Frémy (*loc. cit.*) and Moberg. (J. pr. Chem. xxviii. 230.)

Stannate of Ammonium.—An acid salt, $(NH^4)^2SnO^3.SnO^2.xH^2O$, remains as a yellowish jelly on evaporating an ammoniacal solution of stannic acid over oil of vitriol (Moberg). A stannate of ammonium is also precipitated, on mixing a solution of potassic stannate with sal-ammoniac, as a gelatinous mass, which dissolves in pure water, but is reprecipitated by ammonia. (Berzelius.)

Stannate of Potassium, $K^2SnO^3 = K^2O.SnO^2$, is prepared by dissolving stannic acid in potash-ley, or by fusing metastannic acid or anhydrous stannic oxide with hydrate of potassium, till a sample mixed with nitric acid gives a precipitate which redissolves in excess of nitric acid. The solution, evaporated over oil of vitriol, yields transparent rhombic prisms, containing $K^2SnO^3.4H^2O$, according to Frémy; $K^2SnO^3.3H^2O$, according to Moberg (*loc. cit.*), Marignac (Ann. Min. [3], xv. 277), and Ordway (Sill. Am. J. [2], xl. 473). Marignac prepares the salt by gradually adding 30 pts. metastannic acid to 80 pts. fused hydrate of potassium till the mixture boils up. The mass, if it has not been too strongly heated, dissolves almost wholly in water; and on evaporating the liquid, the salt is obtained in crystals, which are rhombohedral combinations, often forming twins, and always with curved faces.

Ordway prepares pure stannate of potassium by mixing the solution of the crude commercial salt (obtained by igniting tin with hydrate and nitrate of potassium) with an equal volume of strong alcohol, repeatedly treating the syrupy layer which separates, with alcohol, pressing the pasty mass ultimately obtained (which still contains free alkali), then dissolving it in water, and washing with alcohol. The concentrated solution [illegible] in a vacuum yields the salt in hard, transparent, monoclinic crystals, of [illegible] 3·197.

Stannate of potassium gives off its water at a red heat. It has an alkaline reaction, dissolves easily in water, but is insoluble in alcohol. According to Ordway, 100 pts. water, at 10°, dissolve 106·6 pts. of the salt, forming a solution of specific gravity 1·618; and at 20°, the same quantity of water dissolves 110·5 pts. of the salt, forming a solution of specific gravity 1·627. The aqueous solution is precipitated by chloride of ammonium, but not by chloride of potassium or sodium. Dilute acids do not form a permanent precipitate till three-fourths of the alkali are neutralised. A solution, neutralised up to this point, yields, with alcohol, a white flocculent precipitate of potassic metastannate. (Ordway.)

Stannate of potassium is used in calico-printing for the same purposes as stannate of sodium, and is prepared, on the large scale, by similar processes (*infra*).

Stannate of Sodium, $Na^2SnO^3 = Na^2O.SnO^2$, is formed in the same manner as the potassium-salt, and separates from the alkaline liquid, on heating, in the crystalline form; by solution in water, it is obtained in fine hexagonal plates, containing $Na^2SnO^3.3H^2O$ (Moberg; Rammelsberg; Ordway). Marignac, by proceeding in the same way as for the preparation of the potassium-salt, obtains stannate of sodium in rhombohedral crystals, with curved faces. Ordway obtains pure stannate of sodium as a crystalline precipitate, by adding acetate of barium to the aqueous solution of the commercial salt, and mixing the filtered liquid with about an equal volume of alcohol. If only so much alcohol be added as not to produce permanent turbidity, the salt separates in transparent crystals. H. Jonas (Chem. Centr. 1865, p. 607), by recrystallising the commercial salt, obtained pure sodic stannate, in oblique rhombic prisms containing $Na^2SnO^3.9H^2O$.

Stannate of sodium is less soluble in warm than in cold water, and consequently separates on heating a solution prepared in the cold. According to Ordway, 100 pts. water dissolve 67·4 pts. of it at 0°, and 61·3 pts. at 20°. According to Haeffely (Dingl. pol. J. cxliv. 66), a solution of sodic stannate, of specific gravity 1·3, deposits, when heated, crystals of the composition above given; on cooling, however, these crystals redissolve, so that the solution acquires a specific gravity of 1·35; it then gradually deposits crystals containing $Na^2SnO^3.8H^2O$, the aqueous solution of which yields immediately when heated, and in the course of some weeks at ordinary temperatures, crystalline metastannate of sodium.

A solution of stannate of sodium is used in calico-printing as a "preparing salt," or mordant, chiefly for fabrics composed of wool and cotton together; it serves to render the cotton-fibre more susceptible of taking the dye, so that the whole fabric, when taken out of the dye-bath, or the steam-chamber, may exhibit a uniform depth of colour. The dilute solution, when brought in contact with the fibre, deposits stannic hydrate upon it, which binds the colouring-matter, the action being assisted by boiling, by the influence of atmospheric carbonic acid, or by the addition of a little sulphuric acid or sal-ammoniac to the bath.

Stannate of sodium is prepared, on the large scale, for these purposes by fusing tinstone with hydrate, nitrate, chloride, or sulphide of sodium; by boiling the tin-ore with caustic soda-ley; by fusing metallic tin with a mixture of carbonate and nitrate of sodium, or heating it with soda-ley mixed with nitrate and chloride of sodium, and evaporating the solution in an iron pot till it becomes heated to the melting-point of tin. Haeffely prepares it by heating soda-ley with tin and litharge; stannate of sodium is then formed, and metallic lead separated in the form of a sponge, which quickly reoxidises when heated in contact with the air. In this process, tin containing lead, or the cuttings of tinplate (tinned iron), may be used instead of pure tin. [For details of the several manufacturing processes, see Richardson and Watts's *Chemical Technology*, vol. i. pt. iv. p. 35, and pt. v. p. 342.]

An *arsenio-stannate of sodium*, $Na^2O.6SnO^2.2As^2O^5 + 5aq.$, is sometimes used in English dyehouses and printworks. It is prepared by adding nitric acid in excess to a boiling solution of stannate and arsenate of sodium containing an excess of the latter, and treating the resulting gelatinous precipitate, $2SnO^2.As^2O^5.10H^2O$, with excess of soda. The arsenio-stannate then separates in shining needles, while ordinary stannate of sodium remains in solution. This arsenical salt is said to be more economical in use than the ordinary stannate; but it does not produce brighter colours than the latter, and is likely to be prejudicial to the health of the workmen. (Haeffely, Dingl. pol. J. cxl. 290.)

The *stannates of barium, calcium*, and *strontium* may be prepared by boiling a solution of the potassium- or sodium-salt with the hydrates or carbonates of the alkaline earth-metals, or by calcining a mixture of tin-ore with lime, baryta, or strontia, or with the corresponding nitrates at a high degree of heat in a reverberatory furnace. These earthy stannates, when decomposed by hydrochloric acid, yield pure stannic acid, which may be used for the preparation of the alkaline stannates. (James Young's patent, 1848, No. 12,359, and 1849, No. 12,744.)

Stannates of Copper.—The *cupric salt*, which is used as a non-arsenical green pigment, may be prepared by adding a solution of 1 at. tin (118 pts.) in nitromuriatic acid, to a solution of 1 at. cupric sulphate (250 pts.), then adding caustic soda in excess, and washing and drying the resulting precipitate; or by igniting 100 pts. nitrate of sodium with 59 pts. tin, dissolving the mass in water, and using the solution to precipitate cupric sulphate (Gentele).—The *cuprous salt*, which has not yet been obtained pure, is formed, together with other products, in the action of stannous hydrate on cupric oxide, both in alkaline solution (p. 816).

Metastannic Acid, $Sn^5H^{10}O^{15} = Sn^5O^{10}.5H^2O$.—Produced by the action of nitric acid upon tin. Tin treated with strong nitric acid is completely transformed into a white powder, which, when dried in the air at ordinary temperatures, contains $Sn^5O^{10}.10H^2O = Sn^5H^{10}O^{15}.5H^2O$, or $5SnO^2.10H^2O$; but when heated for some time to 100°, it gives off 5 at. water, and is reduced to $Sn^5H^{10}O^{15}$, or $5SnO^2.5H^2O$. At 140° it gives off more water, leaving the hydrate $3SnO^2.2H^2O$ (or $5SnO^2.4H^2O$, according to Frémy's later statements); at 160° it is converted into $5SnO^2.3H^2O$, and at a red heat, into anhydrous stannic oxide.

According to Weber, nitric acid of specific gravity 1·2 converts tin, at ordinary temperatures, into stannous nitrate, stannic acid, and metastannic acid, which is coloured yellow by admixed stannous metastannate. With nitric acid of specific gravity 1·35, the products, if the liquid is well cooled, are metastannic acid [? stannic] and stannic nitrate; by dilution and heating, the stannic acid is converted into insoluble metastannic acid, which indeed is always produced under the influence of heat.

Metastannic acid is white, crystalline, insoluble in water, and in nitric acid. It takes up hydrochloric or sulphuric acid without dissolving in it.

The sulphuric compound is decomposed by water, which removes the whole of the sulphuric acid. The compound with hydrochloric acid dissolves in pure water, but is precipitated from the solution by strong hydrochloric acid. On distilling the solution, hydrochloric acid is given off, with only traces of stannic chloride, and metastannic acid remains. According to Weber, the solution, evaporated over oil of vitriol, leaves a residue consisting of $SnCl^4.3SnO^2.5H^2O$. The same solution becomes turbid on boiling, and by prolonged ebullition with fresh quantities of water, the whole of the metastannic acid is separated, the more quickly as the solution is more dilute (Frémy). (For the reactions of the hydrochloric acid solutions with acids, alkalis, &c., see p. 811). A dilute solution of ordinary stannic acid in hydrochloric acid undergoes a gradual change, and, after some time, exhibits the characters of a solution of metastannic acid. The transformation is quicker as the solution is more dilute, and in very concentrated solutions it does not take place at all; in a dilute solution also, the change may be prevented by addition of tartaric acid. The gradual transformation of stannic into metastannic acid may be recognised by the reaction of the solution with sulphuric acid, stannous chloride, ammonia, tartaric acid, and ferrocyanide of potassium (p. 811).

On the other hand, metastannic acid is converted into normal stannic chloride by prolonged digestion with strong hydrochloric acid, especially at the boiling heat. When heated in dry hydrochloric acid gas, it yields a distillate of stannic chloride, from which ordinary stannic acid may be obtained. By fusion with excess of a caustic alkali, metastannic acid is completely converted into ordinary stannic acid.

Metastannates.—These salts may for the most part be represented by the formula $M^2H^8Sn^5O^{15}$, or $M^2O.4H^2O.5SnO^2$. They exist only in the hydrated state, being decomposed when deprived of their basic water. Löwenthal supposes that pure metastannic acid does not unite directly with alkalis, but that the so-called metastannates are mixtures of ordinary stannates with metastannic acid, the quantity of this acid contained in them being less in proportion as the acid used in their preparation had been more completely converted into ordinary stannic acid: hence the variations which have been observed in the composition of some of these salts.

Metastannic acid dissolves slowly in alkalis, and is gradually deposited in its original state, as the solution absorbs carbonic acid from the air. From solutions of the alkaline metastannates, acids throw down metastannic acid, insoluble in nitric acid, but soluble in ammonia, whereas the original metastannic acid formed by the action of nitric acid upon tin is insoluble in ammonia.

The metastannates of potassium and sodium, heated with excess of base, are transformed into stannates. They are soluble in water. The other metastannates are insoluble, and are obtained by double decomposition.

Metastannate of Potassium, $K^2H^8Sn^5O^{15}$, is prepared by dissolving metastannic acid in cold potash; it may be precipitated in the solid state by adding pieces of potash to the liquid. It is gummy, uncrystallisable, and strongly alkaline. At a red heat, it gives off its water, and is decomposed; the calcined mass, digested in water, yields up all its alkali, and leaves nearly pure stannic oxide (Frémy).—Another metastannate of potassium, containing, according to Weber, $K^2H^6Sn^7O^{18}$ or $K^2O.3H^2O.7SnO^2$, was prepared by Rose, by adding caustic potash-ley to the solution of metastannic acid in hydrochloric acid, till the precipitate at first formed was redissolved, and then precipitating with alcohol. This salt is soluble in water; the solution, when heated, does not become turbid, but gelatinises after a while; it is precipitated by potash and by many salts, and leaves a gummy residue when evaporated.

Metastannate of Sodium, $Na^2H^8Sn^5O^{15}$, is obtained like the potassium-salt, is white, crystallo-granular, and dissolves slowly but completely in water. The aqueous solution decomposes when gently heated, and on boiling, deposits the whole of the metastannic acid (Frémy). Haeffely describes another sodium-salt, $Na^2H^8Sn^5O^{15}.4H^2O$, which was deposited from a solution of the ordinary stannates, slowly at ordinary temperatures, more quickly when heated.

Stannous Metastannate, $(Sn''H^8)\overset{iv}{Sn^5}O^{15} = SnO.5SnO^2.4H^2O$.—Frémy formerly assigned to this compound the formula $SnO.3H^2O.3SnO^2$; according to Schiff (Ann. Ch. Pharm. cxx. 47), it is $SnO.6SnO^2.4H^2O$; according to Tschermak (Chem. Centr. 1862, p. 305), $SnO.6SnO.9H^2O$. It is formed by placing metastannic acid in contact with stannous chloride. It is yellow, and insoluble in water; at 140° it gives off water, and becomes brown-black, or, if dried in a stream of carbonic anhydride, cinnamon-brown (Schiff); dark-brown (Tschermak). When treated with nitric acid, or heated in contact with the air, it takes up oxygen, and is converted into metastannic acid. It dissolves in potash, and the solution, when boiled, deposits tin like other stannous salts. Hydrochloric acid dissolves it, forming a solution of stannous chloride and hydrochlorate of metastannic acid.

When a solution of hydrochlorate of metastannic acid is mixed with dissolved stannous chloride, a yellowish precipitate is formed, perhaps identical with the body just described. A similar yellow body, containing, according to Schiff, $(Sn''H^{10})\overset{iv}{Sn^6}O^{18}$ or $SnO.6SnO^2.5H^2O$, is formed by the action of stannous chloride on ordinary stannic acid.

When stannic oxide is heated in an atmosphere of carbonic anhydride or ammonia, a brown oxide is formed, containing Sn^8O^{15}, either $SnO.7SnO^2$ or $Sn^2O^3.6SnO^2$. (Tschermak.)

Stannous chloride does not act upon normal stannic chloride; but with anhydrous stannic oxide it forms a chocolate-brown powder, containing $Sn^{21}O^{41}$ or $SnO.20SnO^2$. This substance does not turn yellow when boiled with water; it is less easily attacked by acids than the hydrated yellow compound; but when fused with alkalis it is easily converted into alkaline stannate.

TIN, OXYCHLORIDE OF. See p. 807.

TIN, OXYFLUORIDE OF. See p. 813.

TIN, OXYIODIDE OF. See p. 814.

TIN, PHOSPHIDE OF.—*a*. Formed by throwing phosphorus upon melted tin, or by fusing together equal parts of tin and glacial phosphoric acid, whereby stannic or stannous phosphate is likewise formed (Pelletier, Landgrebe, Schw. J. lv. 106). The compound may also be formed by heating in a blast-furnace for an hour, 6 pts. of tin-filings or 8 of stannic oxide with 1 charcoal, 10 bone-ash, 5 pounded quartz, and 5 boracic acid (Berthier, Ann. Ch. Phys. [2] xxxiii. 180). It is silver-white (lead-coloured, according to Berthier); it may be cut with the knife; extends under the hammer, but at the same time splits into laminæ. Contains from 13 to 14 per cent. of phosphorus, which burns away on the application of heat (Pelletier).—*β*. When the compound of stannic chloride with phosphoretted hydrogen is decomposed by water, the phosphoretted hydrogen, as it escapes, reduces the stannic chloride to the state of stannous chloride, and at the same time precipitates phosphide of tin in the form of a yellow powder, which remains for a long time suspended in the liquid, and oxidises readily in the air. When washed and dried out of contact of air, it exhibits the phosphorus-flame before the blowpipe. When ignited in hydrogen-gas, it gives up its phosphorus, amounting to 55·43—56·88 per cent., and is converted into metallic tin. (H. Rose, Pogg. Ann. xxiv. 326.)

TIN, SELENIDES OF. The *protoselenide*, SnSe, is produced, with incandescence, when tin is heated with selenium (Berzelius); according to Uelsmann (Ann. Ch. Pharm. cxvi. 124), it is also formed even when tin is heated with excess of selenium. It is light-grey with metallic lustre, coarsely laminar with crystalline fracture, and easily cleavable. It does not melt in a glass tube, or decompose when heated in hydrogen-gas; but when heated in contact with the air, it burns without melting, giving off selenium, and forming stannic oxide. The protoselenide is also formed, when selenhydric acid gas is passed into protochloride of tin, as a dark-brown precipitate, which dries up to a nearly black powder, soluble in caustic alkalis and in sulphides of alkali-metals.

The *diselenide*, or *Stannic selenide*, $SnSe^2$, is formed by precipitating aqueous stannic chloride with selenhydric acid. It is a glittering, dark, yellowish-red precipitate, becoming light red-brown when dry. When heated in hydrogen-gas, it gives off half its selenium; it dissolves in caustic alkalis and alkaline sulphides, the solution quickly depositing sulphur when exposed to the air.

According to Little (Ann. Ch. Pharm. cxii. 213), stannic selenide is also formed by heating tin in selenium-vapour, and is then a tin-white, metallically lustrous mass, having a conchoïdal fracture, and a density of 5·133: it is easily fusible, is not attacked by hydrochloric acid, but is easily decomposed by nitric acid; dissolved by nitromuriatic acid.

TIN, SULPHIDES OF. There are three sulphides of tin corresponding to the oxides; the sesquisulphide, however, is perhaps a compound of the other two.

The *protosulphide*, or *Stannous sulphide*, SnS, is formed, with vivid incandescence, when finely-divided tin, such as tinfoil, is heated with sulphur. The resulting mass generally contains metallic tin, and must therefore be pulverised, and repeatedly heated with sulphur in a close vessel. Stannous sulphide thus prepared is a dark, lead-grey, lamino-crystalline mass, of specific gravity 4·8 (Karsten); 5·2 (Boullay), somewhat tough, difficult to pulverise, and less fusible than tin. Becquerel has obtained it by electrolytic action, in white metallically lustrous cubes.

The same compound is obtained, as a brown-black amorphous precipitate, by passing sulphydric acid gas into the solution of a stannous salt. This amorphous sulphide may, however, be rendered crystalline by adding it by small portions, after washing and drying, to anhydrous stannous chloride in the melted state, as long as it is taken up thereby; then leaving the dark-brown liquid to cool, dissolving out the stannous chloride by dilute hydrochloric acid, and removing an admixed dark-brown powder by levigation; stannous sulphide then remains in small, thin, lead-grey, metallically lustrous laminæ, greasy to the touch, and having a specific gravity of 4·973. (Schneider, Pogg. Ann. xcv. 169.)

Stannous sulphide dissolves in boiling *hydrochloric acid*, giving off sulphydric acid, and yielding a solution of stannous chloride. It dissolves but slightly in *monosulphide of ammonium*, even when freshly precipitated, but easily in solutions of *alkaline polysulphides*, or of the monosulphides mixed with sulphur, the protosulphide of tin in either case being converted into disulphide. It is slowly oxidised by heating with *nitric acid*.—*Chlorine-gas*, at ordinary temperatures, converts it into liquid stannic chloride, and a crystalline compound of that substance with tetrachloride of sulphur (H. Rose):

$$2SnS + 8Cl^2 = SnCl^4 + SnCl^4.2SCl^4.$$

When heated in *hydrogen-gas*, it is slowly reduced to the metallic state.—By fusion with *cyanide of potassium*, it yields sulphocyanate of potassium and metallic tin.

Sesquisulphide of Tin, Sn^2S^3, is produced by gently igniting an intimate mixture of 3 pts. stannous sulphide and 1 pt. sulphur in a retort. 100 pts. of stannous sulphide thus treated, take up 10·5 pts. of sulphur. It is greyish-yellow, with metallic lustre. When strongly ignited in a close vessel, it gives off one-third of its sulphur. —With *potash-ley* it yields a solution of potassic stannate and sulphostannate, and a residue of stannous sulphide. Concentrated *hydrochloric acid* converts it into disulphide of tin, leaving half the tin in the form of protoxide. The same compound separates, in the form of a liver-coloured powder, on digesting a saturated solution of a sulphostannate with disulphide of tin. By digestion with caustic potash, it is converted into the black protosulphide. (Berzelius.)

Disulphide of Tin, or *Stannic Sulphide*, SnS^2. *Sulphostannic acid*.—This compound may be produced either in the dry or in the wet way. It cannot, however, be obtained by simply heating tin with sulphur, because the union of tin and sulphur is always attended with great development of heat, sufficient to resolve the disulphide, if formed, into protosulphide and free sulphur. This decomposition may, however, be prevented by adding to the mixture certain volatile substances, such as mercury or sal-ammoniac, which, in passing into vapour, will render latent a certain portion of the heat evolved, and thus keep down the temperature. According to L. Gmelin, however, sal-ammoniac, when present, takes a direct part in the reaction, which then consists of two stages; first, the formation of ammonio-stannous chloride, with evolution of hydrogen and ammonia:

$$Sn + 4NH^4Cl = 2NH^4Cl.SnCl^2 + H^2 + 2NH^3;$$

and, secondly, the formation of stannic sulphide and ammonio-stannic chloride, by the action of the sulphur on the ammonio-stannous chloride:

$$2(2NH^4Cl.SnCl^2) + S^2 = SnS^2 + 2NH^4Cl.SnCl^4 + 2NH^4Cl.$$

The following are some of the mixtures used:

a. Protochloride of tin and sulphur (Proust).—*b*. Equal parts of sifted tin-filings, sulphur, and sal-ammoniac (Pelletier).—*c*. 4 pts. of tin-filings, 3 pts. sulphur, 2 pts. sal-ammoniac (Woulfe).—*d*. A pulverised amalgam of 2 pts. tin and 2 pts. mercury, with 1⅓ pt. sulphur and 1 pt. sal-ammoniac (Thénard).—*e*. A pulverised amalgam of 12 pts. tin and 6 pts. mercury, with 7 pts. sulphur and 6 pts. sal-ammoniac (whereby 1⅓ pt. of volatile liver of sulphur, 13¼ pts. sublimed matter, and 16 pts. of fine, and for the most part sublimed, mosaic gold are obtained) (Woulfe).—*f*. A pulverised amalgam of 12 pts. tin and 3 pts. mercury, with 7 pts. sulphur and 3 pts. sal-ammoniac.—*g*. 2 pts. stannous oxide and 1 pt. sulphur.—*h*. 8 pts stannic oxide, 7 pts. sulphur, and 4 pts. sal-ammoniac (Woulfe).—*i*. 10 pts. stannous sulphide, 5 pts. sulphur, and 4 pts. sal-ammoniac (Woulfe).—*k*. 5 pts. stannous sulphide, 1 pt. stannous chloride, and 2 pts. sulphur.—*l*. 5 pts. stannous sulphide and 8 pts. mercuric chloride; this mixture yields a very beautiful preparation. (Woulfe.)

Either of these mixtures is slowly heated to redness in a glass retort or a loosely covered flask, immersed in a sand-bath. Vapours of mercury, sal-ammoniac, &c. are then given off, afterwards the excess of sulphur; while the stannic sulphide partly remains at the bottom of the vessel, and partly collects in the upper portion, as a sublimate consisting of soft golden-yellow or brownish-yellow laminæ, unctuous to the touch, having a metallic lustre, and a specific gravity of 4·60, according to Karsten—4·4, according to Boullay. This crystalline stannic sulphide is commonly called mosaic gold, *Aurum mosaicum*, s. *musivum*, and as such was known to the alchemists. Stannic sulphide is likewise obtained in gold-coloured spangles, by passing the mixed vapours of stannic chloride and hydric sulphide through a porcelain tube heated to dull redness.

Mosaic gold is sometimes used, in place of the amalgam of tin and zinc, for coating the rubbers of electrical machines; it produces powerful excitation, requires no grease, and does not stick to the glass.

Stannic sulphide is obtained in the amorphous state by passing sulphydric acid into a solution of stannic chloride, or of a stannic salt acidulated with hydrochloric acid. The resulting light-yellow precipitate, after drying, is yellowish-brown and somewhat translucent, still contains a certain quantity of water, and decrepitates when heated.

Stannic sulphide, ignited in a close vessel, is resolved into sulphur and stannous sulphide, a portion, however, subliming without decomposition; in contact with the air, it yields sulphurous anhydride and stannic oxide. In *chlorine-gas* it deliquesces even at ordinary temperatures, forming a brown liquid, which afterwards solidifies to yellow crystals of the compound $SnCl^4.2SCl^4$ (p. 808). Heated with *iodine* in a stream of carbonic anhydride, it yields the compound $SnSI^2.SI^2$, as a brown, crystalline, fusible mass, or a dark-yellow sublimate. This iodosulphide dissolves without decomposition in chloroform and in carbonic disulphide, and separates from the latter solution in rhombic crystals of the colour of potassic dichromate. It is decomposed by water into sulphur, stannic sulphide, and hydriodic acid, similarly by aqueous alkalis; *alcohol* decomposes it, with separation of sulphur; *hydrochloric* and *nitric acids* separate sulphur from it. (Schneider, J. pr. Chem. lxxix. 419.)

A boiling alcoholic solution of *iodine* does not attack crystalline mosaic gold, but slowly dissolves amorphous stannic sulphide; and the solution yields crystals identical with those of the compound $SnSI^2.SI^2$, deposited from solution in carbonic disulphide. (Schneider.)

Crystalline stannic sulphide is not decomposed by *hydrochloric acid*; the amorphous sulphide boiled with concentrated hydrochloric acid is slowly dissolved, with evolution of sulphydric acid. Hot *nitric acid* oxidises only the amorphous sulphide: boiling *nitromuriatic acid* likewise oxidises mosaic gold, forming sulphuric acid and stannic oxide. Stannic sulphide fused with *litharge* yields, either by partial mutual decomposition, a mixture of the sulphides and oxides of tin and lead; or, if the litharge is in excess, it yields metallic lead, sulphurous anhydride, and a yellow glass.

Sulphostannates.—Stannic sulphide reacts as a sulphur-acid or sulphanhydride, forming sulphur-salts with the more basic metallic sulphides. The sulphostannates of the alkali-metals are produced by fusing tin with the polysulphides of the alkali-metals, or by dissolving stannic sulphide in the aqueous sulphides or hydrates of the same metals; in the latter case, an oxygen-salt is produced simultaneously with the sulphur-salt.

The sulphostannates of the alkali-metals are soluble in water; those of all other metals are insoluble, and are obtained by precipitation, the precipitates being sometimes yellowish, but mostly brown or black. (Kühn, Ann. Ch. Pharm. lxxxiv. 110.)

Hydric Sulphostannate, Stannic Sulphydrate, or *Sulphostannic Acid,* $H^2Sn^{iv}S^3 = H^2S.SnS^2$, is obtained, by treating the solution of an alkaline sulphostannate with a dilute acid, as a yellow precipitate, which becomes dark-coloured on exposure to the air. (Kühn.)

Sulphostannate of Ammonium is obtained by dissolving stannic sulphide in monosulphide of ammonium, or stannous sulphide, stannous oxide, or stannous hydrate in polysulphide of ammonium.—The *potassium-salt* is obtained in like manner; on mixing its aqueous solution with alcohol, a dark-brown, heavy, oily liquid separates, having nearly the composition $K^2SnS^3.10H^2O$; this compound gives off all its water at 100°.—The *sodium-salt*, $Na^2SnS^3.2H^2O$, forms yellow glassy crystals, whose dominant faces belong to the regular octahedron. A solution of stannous sulphide and sulphur in monosulphide of sodium, deposits colourless monoclinic crystals, resembling gypsum, and containing $Na^2S.Na^2SnS^3.12H^2O$. Höring obtained a similarly crystallised salt containing $Na^2SnS^3.7H^2O$.—The *sulphostannates of barium, calcium,* and *strontium,* obtained by precipitation, are sparingly soluble in water.

TIN, SULPHOCHLORIDE and **SULPHO-IODIDE OF.** (See pp. 809, 814.)

TINCAL. Crude borax, as it is imported from Asia, in yellow greasy crystals. (See BORATES, i. 646.)

TIN-ORE. Native stannic oxide (p. 816).

TINPLATE, or *Tinned Iron-plate.*—An alloy of 2 pts. iron and 1 pt. tin, obtained by heating the two metals together to redness. (See IRON, iii. 370; also *Ure's Dictionary of Arts,* &c. iii. 897.)

TIN-PYRITES. *Stannine. Bell-metal ore. Sulphuret of Tin. Étain sulfuré. Zinnkies.*—A cuproso-ferrous sulphostannate, sometimes also containing zinc, occurring in Cornwall, and at Zinnwald in Bohemia, in cubical forms, but rarely in distinct crystals, mostly massive, and imbedded in crystallo-granular aggregations, with traces of cleavage of the cube and rhombic dodecahedron, and with uneven to small conchoïdal fracture. Hardness = 4·0. Specific gravity = 4·3 to 4·5. It is opaque, with metallic lustre, yellowish-steel-grey colour inclining to brass-yellow, and black streak. Before the blowpipe, on charcoal, it melts to a grey brittle bead, containing copper and iron, and surrounded by a white deposit of stannic oxide. The bead gives, with sodic carbonate and borax, a pale, not perfectly malleable button of copper; when heated in a tube, it gives off sulphurous anhydride, together with a white fume. Nitric acid decomposes it easily, forming a blue solution, with separation of sulphur and stannic oxide.

Analyses:—*a.* From Whealrock, Cornwall (Klaproth, *Beiträge,* v. 298).—*b.* From the same (Kudernatsch, Pogg. Ann. xxxix. 146).—*c.* From St. Michael's Mount, Cornwall (Johnston, Rep. Geol. Cornwall, &c., 1839).—*d.* From the same (Mallet, Sill. Am. J. [2], xvi. 33).—*e.* From Zinnwald (Rammelsberg, Pogg. Ann. lxxxviii. 607):

	a.	*b.*	*c.*	*d.*	*e.*
Sulphur	30·5	29·64	29·93	29·46	29·05
Tin	26·5	25·55	31·62	26·85	25·65
Copper	30·0	29·39	23·55	29·18	29·38
Iron	12·0	12·44	4·79	6·73	6·24
Zinc	. .	1·77	10·11	7·26	9·66
Gangue	. .	1·02	. .	0·16	
	99·0	99·81	100·00	99·64	99·98

These analyses lead to the formula $Cu^2M''Sn^{iv}S^4 = \left.\begin{matrix}Cu^2S\\M''S\end{matrix}\right\}SnS^2$, or $(2Cu^2S.SnS^2).(2M''S.SnS^2)$, where M'' denotes Fe and Zn.

TIN-RADICLES, ORGANIC. The general properties and relations of these bodies have been described in the article ORGANO-METALLIC BODIES (iv. 219, 227). It is there explained that organo-tin compounds may be divided into three groups, analogous in composition to the oxides of tin, and represented by the following formulæ, in which R denotes a monatomic alcohol-radicle:

$$Sn''R^2. \qquad 2Sn'''R^3. \qquad Sn^{iv}R^4.$$

Moreover, one atom of alcohol-radicle in compounds of the second group, and one or two atoms in those of the third group, may be replaced by negative radicles, such as chlorine. Hence arise the following series of organo-tin compounds (R+ denoting an alcohol-radicle, and R− a negative radicle like chlorine):

$$\underset{\text{Stannous compounds.}}{\overset{\text{First Series.}}{Sn''\left\{\begin{matrix}R+\\R+\end{matrix}\right.}} \qquad \underbrace{\overset{\text{Second Series.}}{2Sn'''\left\{\begin{matrix}R+\\R+\\R+\end{matrix}\right.} \qquad \overset{\text{Third Series.}}{2Sn'''\left\{\begin{matrix}R+\\R+\\R-\end{matrix}\right.}}_{\text{Stannoso-stannic compounds.}}$$

$$\underbrace{\overset{\text{Fourth series.}}{\mathrm{Sn^{iv}}\begin{cases}\mathrm{R}+\\ \mathrm{R}+\\ \mathrm{R}+\\ \mathrm{R}+\end{cases}}\qquad\qquad \overset{\text{Fifth series.}}{\mathrm{Sn^{iv}}\begin{cases}\mathrm{R}+\\ \mathrm{R}+\\ \mathrm{R}+\\ \mathrm{R}-\end{cases}}\qquad\qquad \overset{\text{Sixth series.}}{\mathrm{Sn^{iv}}\begin{cases}\mathrm{R}+\\ \mathrm{R}+\\ \mathrm{R}-\\ \mathrm{R}-\end{cases}}}_{\text{Stannic compounds.}}$$

In the stannic compounds the atomicity of the tin is fully satisfied: hence these bodies cannot take up any other radicle (such as oxygen, chlorine, &c.) by direct combination, but only by substitution for one or more atoms of alcohol-radicles; in other words, they do not themselves act as radicles. In the stannous compounds, on the contrary, there are two units of atomicity still unsatisfied, and in the stannoso-stannic compounds one such unit: hence these bodies are capable of acting as radicles, taking up chlorine, oxygen, &c. directly, and being thereby converted into stannic compounds. The stannoso-stannic compounds are evidently monatomic; the stannous compounds are always diatomic, uniting with 2 at. chlorine, iodine, &c., or 1 at. oxygen, sulphur, &c., to form stannic compounds; there is no known instance of an organo-stannous compound taking up only 1 at. of a monatomic radicle, to form a stannoso-stannic compound (iv. 227).

Organo-tin compounds have been obtained, containing methyl, ethyl, and amyl. The ethyl-compounds have been most completely studied, and will be most conveniently described first.

a. ETHYL-COMPOUNDS: STANNETHYLS.[*]

Three compounds are known, containing only tin and ethyl, viz.:

Stannous ethide, or Stannodiethyl, $\mathrm{Sn''(C^2H^5)^2}$.

Stannoso-stannic ethide, or Stannotriethyl, $\mathrm{\overset{\prime\prime\prime}{Sn}{}^2(C^2H^5)^6}$.
Stannic ethide, or Stannotetrethyl, $\mathrm{Sn^{iv}(C^2H^5)^4}$.

The first and second of these compounds, as already observed, act as organic radicles, taking up oxygen, chlorine, &c., and forming compounds which may be regarded either as salts of these same radicles, or as stannic compounds containing ethyl and negative radicles:—

$$\mathrm{Sn''(C^2H^5)^2]''.I^2]} \quad = \quad \mathrm{Sn^{iv}}\begin{cases}\mathrm{(C^2H^5)^2}\\ \mathrm{I^2}\end{cases}$$

Stannodiethyl-iodide. Stannic di-iododiethide.

$$\mathrm{[Sn''(C^2H^5)^2]''.O} \quad = \quad \mathrm{Sn^{iv}}\begin{cases}\mathrm{(C^2H^5)^2}\\ \mathrm{O}\end{cases}$$

Stannodiethyl-oxide. Stannic oxydiethide.

$$\mathrm{[Sn''(C^2H^5)^2]''.SO^4} \quad = \quad \mathrm{Sn^{iv}}\begin{cases}\mathrm{(C^2H^5)^2}\\ \mathrm{(SO^4)''}\end{cases}$$

Stannodiethyl-sulphate. Stannic sulphatodiethide.

$$\mathrm{[Sn'''(C^2H^5)^3.I} \quad = \quad \mathrm{Sn^{iv}}\begin{cases}\mathrm{(C^2H^5)^3}\\ \mathrm{I}\end{cases}$$

Stannotriethyl-iodide. Stannic iodotriethide.

$$\mathrm{[\overset{\prime\prime\prime}{Sn}{}^2(C^2H^5)^6]''.S} \quad = \quad \mathrm{\overset{iv}{Sn}{}^2}\begin{cases}\mathrm{(C^2H^5)^6}\\ \mathrm{S''}\end{cases}$$
